Heuristic methods were developed by well-experienced engineers and researchers. The first attempt to develop a systematic heuristic approach for the synthesis of multicomponent separation sequences was made by Siirola and Rudd.[11] Common example is hierarchical heuristic approach.[12] Heuristic rules are applied at five design levels to generate and evaluate the alternatives using economic criteria. The hierarchical heuristic method emphasizes the strategy of decomposition and screening. It allows for a quick location of flowsheet structures that are often ''near''

optimal solutions. The major limitation of this method, because of its sequential nature, is the impossibility to manage interactions between different design levels. The same reason causes problems in the systematic handling of multiobjective issues within the hierarchical design. The hierarchical heuristic method offers no guarantee of finding the best possible design. The heuristic approach has been used in many applications, e.g., synthesis of separation systems,[13] waste minimization,[14] and metallurgical process design.[15]

A different approach to process synthesis is offered by means–ends method.[16] It is based on the observation that the purpose of material processing is to apply various operations in such a sequence that the differences in properties between the raw materials and the products are systematically eliminated. As a result, the raw materials are transformed into the desired products. The means–ends method starts with an initial state and successively applies transformation operators to produce intermediate states with fewer differences until the goal state is reached. The hierarchy for the reduction of property differences is as follows: identity, amount, concentration, temperature, pressure, and finally form. This property changing method has its limitations, as it ignores the influences and the impacts on other properties. Moreover, the search method takes an opportunistic approach, which cannot guarantee the generation of a feasible flowsheet. The means–ends analysis approach has been used as a systematic process synthesis method for overall process flowsheet synthesis, as well as for the more detailed case of a separation system to resolve the concentration differences in nonideal systems that include azeotropes.

The phenomena-driven method for the process synthesis analyzes not the processing units, the so-called building blocks, but the phenomena that occur in those blocks. This method is based on opportunistic task identification and integration. It was applied to separation process synthesis, based on thermodynamic phenomena.[17] It explored the relationship between the physicochemical properties, separation techniques, and conditions of operation. The number of alternatives for each separation task is reduced by systematically analyzing these relationships. Then, possible flowsheets are produced with a list of alternatives for the separation tasks.

The conflict-based method for process synthesis applies TRIZ approach.[18] TRIZ is a method for the identification of the system's conflicts and contradictions for the generation of innovative designs. The conflict-based approach decomposes a design problem into subproblems instead of applying hierarchical design. It is an efficient method for modifying the solution space and screening alternatives at an early stage. The design problem is represented by the conflicts between the inter-related design objectives or the characteristics of the process flowsheet. It overcomes the difficulties of considering the interconnection of the hierarchical design levels as well as the limitations of insufficient problem representation. CBA has been developed and used for the preliminary design of distillation and reactor/separator systems, as well as for waste management.[18,19]

The next method for process synthesis is case-based reasoning (CBR). CBR reuses solutions that were applied in the past to similar problems. It is composed of several steps combined into a cyclic procedure. In the first step, retrieval, a new problem is matched against problems of previous cases by calculating the value of the similarity functions to find the most similar problem and its solution. If the proposed solution does not meet the necessary requirements of the new problem, the adaptation phase is applied. The returned solution and a new problem together form a new case that is incorporated into the case base during the learning step. The main disadvantage of CBR is the very strong influence of old design cases and the lack of sufficient adaptation methods to support innovative design. CBR has been used for the synthesis of separation systems.[20]

The emerging approach to process synthesis is based on the principle of equipartition of the driving forces.[21] According to this principle, design could be considerably improved by the equal distribution of the driving forces throughout the process by assuming that the rates of entropy production are proportional to the square of the driving forces. Although the fundamentals of this principle are the subject of discussion, the potential importance of the method is hard to overestimate. The example of application of this method has been presented for the design chemical reactor.[22]

Chemical Product Design

A new and very active field of research is chemical product design.[23–25] The activity of CAPE in product design concentrates on the analysis of the relations of material function, its properties, and composition.

There are three main classes of methods applicable to product design: experimental design, knowledge-based methods, and computer-aided molecular design.

There are two formulations of the problem of product design (Fig. 2).

The first is forward problem and occurs when the design starts from the given structure of a molecule or composition of the material, and aims at the determination of the properties of this material. The second approach, reverse problem, starts with the given properties of material and finds the molecular composition fulfilling the requirements. The experimental methods

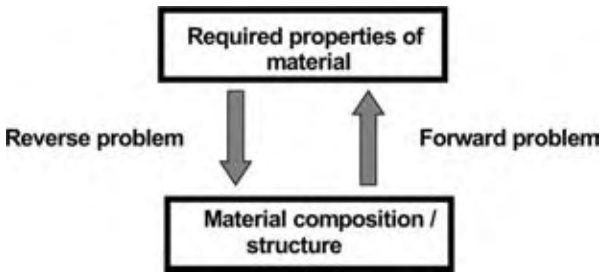

Fig. 2 Forward and reverse formulation of chemical product design problem.

are an example of the forward problem formulation. The knowledge-based as well as computer-aided molecular design methods could be used in forward or reverse problem formulation.

Experimental methods of product design

Historically, the oldest method is experimental product design, which evolved into sophisticated statistical methods, capable of handling very complicated mixing and processing problems. The CAPE activities concentrate on the statistical analysis of the processes that can lead to the identification of new products.

There are two major types of experimental design: planned experiments and high-throughput experiments (HTE). Recently, the second type has been attracting the interest of CAPE practitioners.

HTE is used to tackle problems where the parameter space is too large to be handled efficiently using conventional approaches. HTE consists in the use of miniaturized laboratory equipment, robots, screening apparatus, and computers. The main field of HTE application is in the determination of drug composition, multifunctional materials, coatings, and catalysts, as well as that of their formulation. The fundamental problems related to the application of CAPE to HTE consist in handling the complexity related to the amount of data and highly complicated phenomena under consideration. As a consequence, research is now on the design of databases, data mining, integration, and representation; conversion of data to knowledge; experimental control systems; and decision supporting system to facilitate ''hit-to-lead'' process that aims at maximizing the number of successful designs.

The following are examples of CAPE applications in HTE.

The catalyst has been designed as given in Ref.[26] The proposed process of ''knowledge extraction'' consists in planning HTE experiments in a way allowing for the discrimination of the models of catalytic reactions, determination of the kinetic constants, and relating them to the catalyst microstructure. The proposed forward modeling is realized by the application of the rules capturing human expertise, neural networks (NN), and genetic algorithms (GA).

An example of CAPE tool application to HTE in pharmaceutical design is the use of CBR for identifying the required conditions for protein crystallization.[27] The application of HTE and CAPE to drug development in the context of knowledge discovery is presented in Ref.[28]

Knowledge-based methods of product design

The use of CAPE knowledge-based methods is aimed mainly at limiting the cost and time of new product development. They are especially useful because of the existence of a huge amount of data and information stored by the companies. The common feature of these methods is the use of historical data, and information and generation, on this basis, of a new knowledge applicable to the actual product design problems. The proposed methods are rule-based reasoning, CBR, NN, GA, and data mining.

The CBR has been used in various applications, e.g., formulation of tablets, plastics, rubber, and agrochemicals. There are several works dealing with tablet formulation, e.g., Ref.[29] The CBR–rule-based hybrid system is aimed at retrieval as well as adaptation. The potentially interesting formulation is adapted by the application of the rule-based system. It allows to determine the most appropriate ingredients by the elimination of various conflicts and constraints related to the simultaneous presence of some of these in a tablet. The adaptation is realized using the voting mechanism, which selects the most frequently used ingredients among the retrieved cases. Another new application of CBR in chemical product design is presented in Ref.[30] The problem consists in the determination of the recipe for tire tread manufacturing (elastomers, silica, carbon black, accelerants, etc.) as well as determination of the conditions for compound mixing and vulcanization. The design of lubricating oils applying CBR has been introduced in Ref.[31] The main problem tackled is design of the additive formula that should be combined with the oil to create a lubricating agent.

The application of NN in product design concentrates on a few classes of materials. The fuel additives[32] have been used as combustion modifiers, antioxidants, inhibitors of corrosion, deposit controllers, etc. The authors have proposed a hybrid approach combining modeling and NN. The results obtained from modeling have been introduced into the net and compared with the experimental results. Such an approach enabled the tuning of the model allowing for the prediction of the build-up of the deposit as a function of the composition of the additives.

In Ref.[33] the author has proposed application of NN for the formulation of a rubber mixture. The net was used for the purpose of direct (what are the properties of the mixture when the composition is given) and indirect modeling (what should be the composition to ensure the required properties of the mixture). There have been adaptive usage of NN in learning how to map the relations between the inputs and outputs.

In Ref.[34] the authors have applied NN to predict the molecular surface of the acid, reactive and direct dyes. The mapping of the three-dimensional molecular surfaces into Kohonen network enabling the prediction of substantivity is an example of the direct formulation of the product design problem.

There are several applications of NN in drug design, especially in tablet formulation. They concentrate on finding the relation between the composition of the tablet and the required release time, prediction of the physicochemical properties of the substances based on their molecular composition, and formulation of the special-purpose tablets (e.g., fast disintegrating). An example of application of NN to the direct and reverse problems of chemical product design is given in Ref.[35] In the first case, the objective was to determine the optimal composition ensuring the required release of the active substance from the tablet. The second dealt with the determination of the optimal composition of the mixture of ketoprofen hydrogels composed of two gel bases, two penetration enhancers, and two solvents. The objective function was the required rate of penetration of active substance and skin irritation.

NN have also been used in the design of refrigerants. In Ref.[36] the authors have studied the prediction of the specific volume of refrigerant–absorbent couple in the function of system composition, pressure, and temperature using NN. The objective was to determine the properties of the couple such as ensuring zero ozone depletion, thermal resistance, high evaporation heat at low pressure, low specific volume of vapor, low solidification, and high critical temperatures.

The application of NN to the formulation of the polymer composites has been reviewed in Ref.[37] The authors presented a comprehensive overview of NN application in the estimation of fatigue life, design of unidirectional and laminate composites, assessment of wear of composites, and optimization of the processing.

GA are gaining a lot of attention in CAPE. This very promising tool of artificial intelligence has been used to design polymers[38] and catalysts.[39] Very often GA are combined with first-principles modeling and other artificial intelligence methods.

Nowadays the ''classical'' rule-based systems are relatively seldom encountered as a tool for the support of the product design. However, there are several examples of hybrid systems in the design of cosmetics (rule-based and first principles)[40] and pharmaceuticals (rule-based and NN).[41]

Data mining is a term used for a group of techniques used in finding useful patterns in the datasets. This approach consists in the analysis of huge data depositories in search of useful correlations between material properties and their composition. A simple example of data mining application in rubber design is given in Ref.[42]

CONCLUSIONS

CAPE is a multidisciplinary branch of process engineering spreading very rapidly into new fields outside the processing industries. The emerging fields for CAPE applications are proteomics, financial engineering, and material sciences, to name a few.[43–45]

In the near future, the main concerns of CAPE will probably focus on issues related to product design (molecular modeling for solving function–property–composition problems), supply chain management (cost reduction of raw materials, effective use of energy and its new sources), and life cycle assessment (mitigation of climate change, process sustainability).

The problems likely to be handled by CAPE methods and tools that to respond to the above-mentioned challenges are multiscale modeling, designing of metabolic processes, solving of quantitative and qualitative models, reuse of the designs, development of creativity-supporting methods for promotion of innovative design, uncertainty handling, effective methods for solving large-scale dynamic problems, and management of information overload.

Conductive Polymers

Ronald W. Gumbs
Gumbs Associates Ltd., East Brunswick, New Jersey, U.S.A.

INTRODUCTION

Organic polymers that possess the electronic, magnetic, and optical properties of metals are known as conductive polymers (CPs). Because of their conjugated π electron backbones, they can be oxidized or reduced more easily and more reversibly than conventional polymers with charge-transfer agents, also commonly called dopants, a term borrowed from condensed matter physics. While retaining some of the mechanical properties of polymers, they do not melt or dissolve in common organic solvents, a major impediment to their widespread commercialization in the same manner as traditional plastics. The same electronic structure that confers electrical conductivity to these polymers also contributes to their intractability and instability.

Conductive Polymers is a new field in materials science utilizing the unique electronic properties of a class of easily synthesized polymers with the predominant property of high and controllable conductivity. Written from the perspective of an industrial polymer chemist, this entry reviews the search for processible CPs and covers the synthesis, properties emanating from their conductivity, and applications with emphasis on the processing of these polymers for various commercial applications.

OVERVIEW

Ranby[1] has appropriately classified polymers into four generations that are available as commercial products and summarized in Table 1.

According to Ranby,[1] the fourth generation of polymers started with the discovery[2] that polyacetylene (PA) could be rendered electrically conductive by doping; the chemistry of its doping is described elsewhere.[3] Curiously enough, some of the major CPs were first prepared in the 19th century before the general concept of polymers was well understood. According to Naarmann,[4] the term PA was used in 1866 and a high molecular weight copper acetylene was formed when acetylene was passed over copper powder below 250°C. Thiophene and pyrrole were polymerized in 1883 and 1888, respectively. Polyaniline (PANi) was synthesized in 1891 and initial attempts to prepare polyphenylene (PP) were made as far back as 1842.

The Concept of Doping

Conjugated polymers are either electrical insulators or semiconductors, and those that can have their conductivity increased by several orders of magnitude above that of semiconductors are commonly referred to as electronic polymers. Indeed, the conductivity attainable by an electronic polymer has been increased infinitely by the discovery[5] of superconductivity in regio-regular poly(3-hexylthiophene) at 2°K.

The concept of doping[3,6] is what distinguishes CPs from most organic polymers. During doping, an organic polymer, either an insulator or semiconductor possessing a low conductivity, typically in the range from 10^{-10} to 10^{-5} S/cm, is transformed into a synthetic metal (ca. 1–10^4 S/cm). In essence, the controlled addition of small concentrations of chemical species results in dramatic changes in the properties of the polymer. Doping can be reversed to produce the original pristine polymer with minor or no degradation of the polymer backbone.

Synthetic metals are prepared by oxidation or reduction in which some of the π electrons are removed (*p*-doping) or external electrons added (*n*-doping). Simultaneously, there is an insertion of counterions near the charged sites, resulting from the reduction or oxidation of the dopants. These counterions stabilize the doped state, and both doping and undoping can be carried out chemically or electrochemically.

The backbone of the CP in its doped state primarily consists of a delocalized π-system, but in its undoped state, the polymer may have a conjugated backbone such as in *trans*-PA or it may have a nonconjugated backbone as in the leucoemeraldine and emeraldine base forms of PANi.

There are many reviews of the vast literature on CPs, including: 15 books;[6–21] compilations in various encyclopedias;[4,22–28] and an excellent overview by Kanatzidis.[29] They cover all aspects of the theory, energy band structure, chain structure, morphology, comparison of conductivities with metals, semiconductors and insulators, doping, synthesis and characterization, electrochemistry, processing, and potential

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007714

Table 1 Evolutionary development of synthetic polymers

Generation	Period introduced	Examples	Distinguishing features
First	1930–1950	Vinyls, polystyrenes, acrylics, epoxies, phenolics	Low density and ease of processing for applications in packaging, paints, coatings, laminates, and adhesives
Second	1950–1965	High-density polyethylene, isotactic polypropylene, polycarbonate, polysulfones, linear polyesters, synthetic rubbers	Improved mechanical strength
Third	1965	PPS, polyimides, aromatic polyesters, aromatic polyamides, fluoropolymers, thermoplastic elastomers	High mechanical strength, very high melting point, superior chemical resistance
Fourth	1977	Intrinsically CPs	Electrical conductivity

commercial applications of the fourth generation of polymers.

CPs AS SEMICONDUCTORS

The electrical property of a material is determined by its electronic structure, and the relevant theory that explains the electronic structure in the solid state is band theory. This theory, however, does not fully explain conductivity in polymers. It is noteworthy that the energy spacing between the highest occupied and lowest unoccupied bands is called the bandgap; the highest occupied band is called the valence band and the lowest unoccupied band is called the conduction band. The bandgaps of insulators and semiconductors are wide and narrow, respectively; there are no bandgaps in metals.

According to band theory, the electrical properties of a solid depend on how the bands are filled. There is no conduction when the bands are filled or empty. If the material has a narrow bandgap, thermal excitations of electrons from the valence band to the conduction band occur, giving rise to conductivity in classical semiconductors.

Because CPs conduct current without having a partially empty or partially filled band, concepts from solid state physics are used to explain the electronic phenomenon in these polymers. Thus, chemists refer to solitons, polarons, and bipolarons when they discuss the fundamentals of CPs. And, Fig. 1 shows the energy level diagram for an undoped, slightly doped, and heavily doped polymer to further illustrate the concept of doping.

The semiconductor band structure of CPs enables electronic excitations or electron transfer, e.g., from the valence to the conduction band, leading to most of the properties that are of interest. Excitation of electrons from the valence band to the conduction, e.g., by photons, typically yields excited state properties such as photoluminescence and nonlinear optical (NLO) properties.

Oxidation of the CP, i.e., essentially a removal of electrons from the valence band leads to the presence of charges on the CP. These charges are strongly delocalized over several monomeric units in the CP. They also cause a relaxation or structural distortion of the geometry of the CP to a more energetically favored conformation. In addition, a charge may also be donated to the conduction band of the CP, causing reduction of the CP.

SYNTHESIS OF CPs

Many of the procedures used to prepare neutral CP precursors are commonly employed in the polymer industry. Hence, the polymerization methods of Ziegler-Natta, Friedel-Crafts, and nucleophilic displacements yield PA, PP, and polyphenylene sulfide (PPS), respectively. Other methods include: Dields-Alder elimination, Wittig, and electrochemical coupling. The procedures used to prepare CPs in this vast arsenal are generally divided into two main categories: chemical and electrochemical.

Chemical Methods

There are two general routes to the synthesis of conjugated polymers: addition polymerization of unsaturated monomers and condensation polymerization or stepwise coupling of monomers with difunctional groups.

Addition polymerization

An alkyne, such as acetylene or any of its derivatives, undergoes addition polymerization to yield PAs. A typical procedure involves adding acetylene under 80 kPa (600 mm Hg) of acetylene to a solution of $Al(C_2H_5)_3 : Ti(OC_4H_9)_4$ (4 : 1) in toluene (0.1–0.2 molar

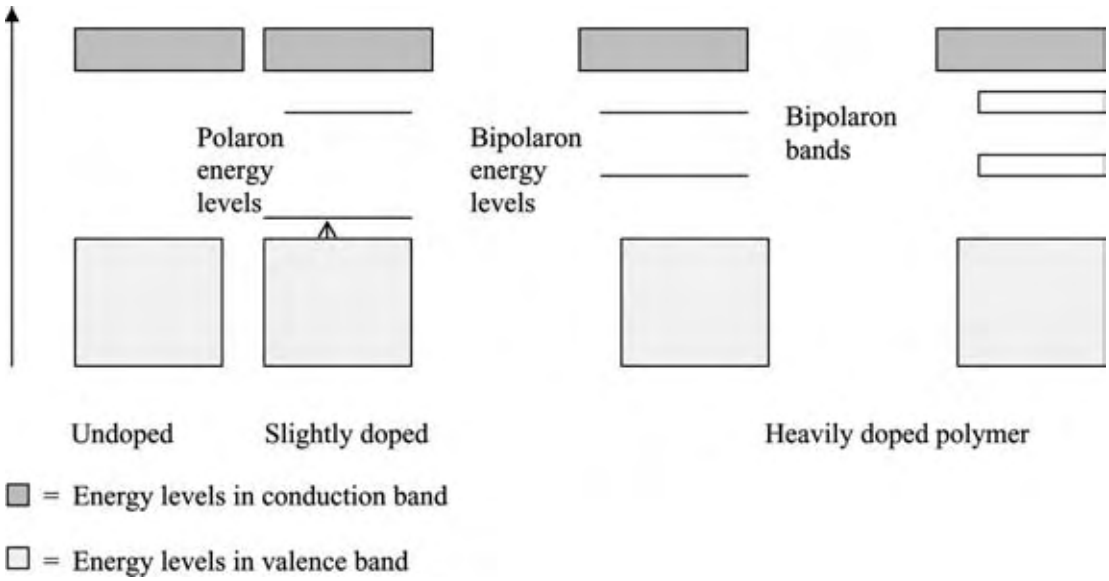

Fig. 1 Band structure of a CP. *(View this art in color at www.dekker.com.)*

in Ti) at –78°C and 80 kPa (600 mm Hg) for 20 min. Polyacetylene is also prepared by ring-opening metathesis polymerization of cyclo-octatetraene. A summary of the methods used to prepare PA and its derivatives is included in reviews.[13,21]

$$n\mathrm{HC}{\equiv}\mathrm{CH} \longrightarrow -(-\mathrm{CH}{=}\mathrm{CH}-)_n-$$

Condensation polymerization

This method has been used successfully to prepare polyarylenes and poly(arylene vinylenes) but not in the synthesis of PA and its derivatives. It is a straightforward extension of well-established aryl coupling reactions, which have been comprehensively reviewed.[13,21] Essentially, stepwise coupling of monomers with difunctional groups is carried out in a more controlled fashion than during addition polymerization, but conversion rates are low and purification of monomers is necessary. It includes: Wurtz–Wittig coupling of dichlorides with sodium or potassium; Ullman coupling of the di-iodide with copper; Grignard coupling of the dibromide with magnesium in ether and a complex of nickel chloride; diazonium coupling; oxidative coupling; and elimination reactions.[4]

Oxidative coupling of monomers, such as pyrrole, thiophene, aniline, aromatic, and other heteroaromatic systems is the most widely used method. In brief, it involves the use of an oxidant that reacts with the monomer to generate a radical cation and a radical anion. The former combines with another radical cation to form a dimer, which undergoes further oxidation to propagate the polymerization.

There are, of course, numerous examples of elimination reactions involving the loss of water, hydrogen halides, oxygen, nitrogen, and other small molecules with the formation of a double bond. Both direct and indirect methods are employed, including processes with soluble precursor polymers. It is interesting to note that polymerization of phenyl vinyl sulfoxide and subsequent elimination of benzenesulfonic acid lead to the formation of PA.

Electrochemical Methods

Electrochemical oxidation of resonance stabilized aromatic molecules is a common and singular method used to prepare CPs. It involves the oxidative coupling of monomers and is an ideal method to prepare conductive films that show reversible redox reaction. The polymerization can be monitored by in situ combination of the electrolysis system and appropriate spectroscopic or electro-analytical techniques; the electrochemistry of CPs is the subject of a recent review[13] with 748 references.

Polymerization of monomer is initiated by species, typically radical cations, formed in an electrode reaction during electrolysis. For each electron transferred through solution, a corresponding chemical reaction must occur on the potential of the electrode together with the discharge potential of the various species present. The system consists of an electrolysis cell with electrodes, electrolytes, monomer, and solvent. Important steps in the process are: initiation takes place at the surface of the electrode and propagation is either homogeneous or heterogeneous; the growth of the polymer may occur on the electrode surface or in the

bulk of the electrolysis solutions, which is similar to reaction in chemically initiated polymerization; chain transfer and termination are also generally similar to the corresponding steps in the chemical method.

SOLUBILITY OF CPs

The discovery[22] in 1986 that AsF_5-doped CPs are soluble in AsF_3 created much surprise and skepticism among workers in the field. It generated a search for less exotic solvents and, as a result, the literature contains many reports of soluble CPs. On closer examination, however, many of these materials in their doped states do not form genuine solutions. Evidently, the authors of these reports were unaware that light scattering or ultracentrifugation of mixtures of solvents and polymers can in fact determine whether the mixture is a solution or dispersion.

For purposes of clarity, it is perhaps instructive to describe the distinction between a solution and dispersion. The term ''solution'' refers to a complete solvent shell around an atom, molecule, or a single polymeric chain on the molecular scale. It refers to a single phase and a homogeneous solution. The term ''dispersion'' means that particles larger than 1 nm are surrounded by and embedded in a medium. Thus, dispersions are not homogeneous, but consist of at least two phases. This heterogeneous system contains a pure solvent phase with no dissolved molecules and the pure dispersed phase. Both phases approach each other at the interfaces.

Solution in Corrosive Solvents

There are reports[22] that doped CPs are soluble in unusual solvents, which are difficult to handle for many reasons. Polyaniline dissolves in concentrated acids such as sulfuric acid, methane, and trifluoromethane sulfonic acids; concentrations as high as 20% by weight are possible. After precipitation of the polymer in methyl alcohol, the polymer retains its conductivity and exhibits some crystallinity. And recently, MacDiarmid and others have spun fibers from concentrated H_2SO_4 solutions.

PPS doped with AsF_5 dissolves readily in AsF_3,[22] but cast films are no longer soluble. Frommer has suggested that the solubilization mechanism involves solvation of both reactive radical intermediates and dopant counterions.[22] In addition, dialkyl esters of phosphoric acid dope PANi and render it soluble in certain solvents such as decalin. The resulting solutions can be mixed with conventional polymers and used to prepare films and fibers.

On the other hand, Wessling insists that these mixtures ''look like solutions (clear green), but they are dispersions.'' In comprehensive fashion, he shows that there is a decrease in viscosity and absorbance over time, which is accompanied with flocculation. He also presents convincing evidence to support his dispersion theory. He does concede, however, that the AsF_5/AsF_3 system is a genuine solvent for CPs based on the evidence.

Solution in Water

The sodium salts and the acids of poly-3(2-ethanesulfonate) thiophene and poly-3-(4-butanesulfonate) thiophene are the first known examples of water soluble CPs;[21] many other examples of water-soluble, self-doped CPs are given in recent reviews.[20] Indeed, it is well known that the incorporation of highly soluble sulfonate groups on the CP backbone is a common method of achieving water solubility in a doped CP. The two most popular routes are the use of sulfonated polymeric dopants and the polymerization of sulfonated monomers.

Substituted Derivatives

Polymers formed from the electropolymerization of 3-thiophenecarboxylic acid, 3-cyanothiophene, and 3-nitrothiophene are soluble in acetonitrile. In addition, substitution of alkyl groups with more than six carbon atoms at the 3-position of the thiophene molecule and subsequent polymerization renders the reduced form of the polymer soluble. Indeed, solubility increases with chain length of the alkyl group and the de-doped or reduced forms are truly soluble in solvents such as toluene, THF, and methylene chloride.[17]

PROCESSING OF CPs

In view of the chemical nature of CPs, many clever schemes have been devised to achieve processibility while maintaining electrical conductivity. Most reports of solubility and processibility involve many schemes, such as the use of corrosive solvents, e.g., concentrated H_2SO_4 and AsF_3, processing of the de-doped polymers followed by re-doping, dispersion of the CPs as colloids, thermoforming of blends with thermoplastics, incorporation of solubilizing groups, the use of soluble precursor polymers, substitution of long-chain alkyl groups, copolymerization, and in situ polymerization.

Solution Processing

The processibility of CPs is of course related to their solubility, and many applications involve processing of solutions.

Processing of Neutral Form Followed by Doping

The most popular method of processing is based on limited evidence that the reduced or de-doped form is soluble. It is widely applied to PANi based on extensive experimental studies by MacDiarmid and his group. In brief, a solution of the de-doped and neutral form of the CP (the emeraldine base) in an organic solvent is used to coat a substrate and the cast film is chemically doped after drying.

There are, however, some problems with this method. First, high molecular weight fractions are not soluble in the strongest solvent, *N*-methyl pyrrolidone, for emeraldine base. Second, Wessling has shown by membrane filtration and photon correlation spectroscopy that these transparent, clear blue liquids are in fact dispersions and not solutions.

Based on the PANi model, it is generally assumed that this method is applicable to all CPs as a means of processing. It is known that some CPs exhibit some solubility in organic solvents in their de-doped states, but the fractions with the highest molecular weight do not dissolve and cast films frequently do not re-dissolve.

Counterion-Induced Processibility

Cao and coworkers reported that problems in processing of doped PANi could be solved by the use of functionalized protonic acids. Indeed, solutions of camphor–sulfonic acid doped with PANi in *m*-cresol show liquid crystallinity and high electrical conductivity, according to Smith and his coworkers. This prompted additional work with this and other polymers. Unfortunately, the conductivity of cast films of solutions of polypyrrole (PPy) doped with dodecyl benzene sulfonic acid in *m*-cresol is low (ca. 10^{-3} S/cm).

Copolymerization

Since conventional polymers are very miscible with organic solvents and melt-processible, it was thought that a true copolymer with conjugated and nonconjugated segments might lead to processibility. Consequently, many attempts have been made during the past 20 yr to prepare electrically conductive vinyl copolymers that are processible. And while conductive random, alternating, block, and graft copolymers have been prepared, the processibility of conventional polymers has not been achieved.

In the most recent attempt,[30] an inverted emulsion process was used to synthesize conducting copolymers of aniline and acrylonitrile using benzoyl peroxide as the oxidizing agent. The solubility of the copolymers in dimethyl sulfoxide was confirmed by electronic absorption spectroscopy, and the conductivity of the copolymers ranged from 0.01 to 0.04 S/cm. It is interesting to observe that MacDiarmid and others are skeptical of any finding that aniline is capable of copolymerizing with vinyl monomers.

Processing via In Situ Polymerization

Many commercial applications of CPs involve coatings on various substrates and the most important method for processing CPs as coatings is the in situ polymerization of monomers on the surfaces of substrates. It is commonly used to coat fabrics and to fabricate Langmuir–Blodgett films.[27]

Dispersibility of CPs

Spinks and coworkers[26] have reviewed the preparation of sterically stabilized PA, PP, and PANi colloids. There is a large body of significant work on the CP coated particles, CP-silica nanocomposites, and the other CP colloids.

Colloidal Dispersions

Techniques using colloidal dispersions of CPs are widely used to process CPs as solutions, i.e., sols and gels.[26] The initial challenge, however, is to prepare dispersions that are stable and to this end additives such as surfactants and soluble polymers are employed. The most commonly used method of preparing stable dispersions is to polymerize the monomer, e.g., pyrrole in an aqueous solution of a water soluble polymer such as methylcellulose and subsequently washing the CP with water at 70°C where gelation occurs in order to remove the unreacted monomer, oxidant ($FeCl_3$), and $FeCl_2$. Other water soluble polymers are used, including the following: poly(vinyl alcohol), poly(acrylamide), and poly(vinyl pyrrolidone). The problem is that the washing in hot water is not as effective as with the cellulose ether.

Alloying and Blending of CPs with Conventional Thermoplastics

In order to disperse low concentrations of CPs in thermoplastics[28] and elastomers,[25] it is necessary to prepare highly structured fine aggregates to permit percolation in the polymer blend. With better polymerization techniques and new blending methods, the percolation threshold decreases. Indeed, a critical concentration as low as 1.5 vol% and a saturation

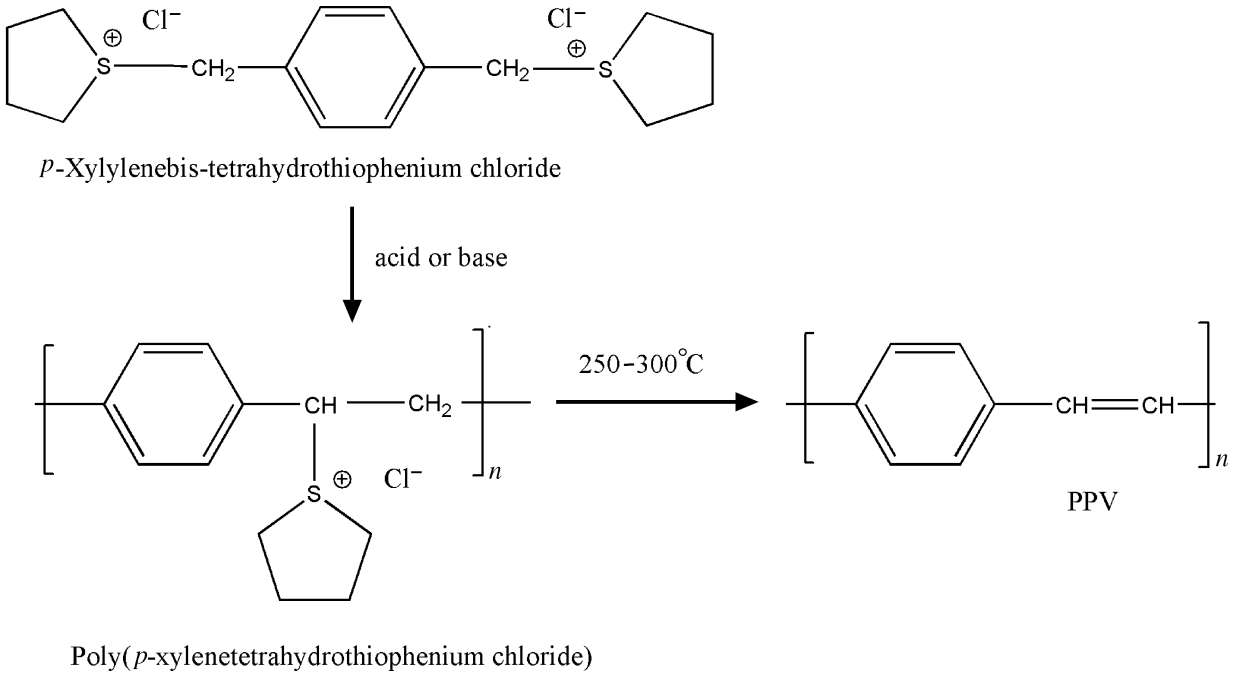

Fig. 2 Preparation of PPV via a precursor route.

concentration of 25 vol% are possible with PANi in PMMA.

Alloying and Blending of CPs with Conventional Thermosets

It is a much more formidable problem to disperse a CP, such as PANi, in a thermosetting polymer system, such as a polyurethane or an epoxy resin. As thermosets are reactive, they react with active hydrogens of the CP, resulting in de-doping and loss of conductivity. The di-isocyanate groups react with secondary amine groups and with residual water in PANi. Encapsulation of the CP leads to a serious decrease in conductivity of the fully cured blend. But some clever ruses have been devised to prepare conductive epoxy resins by using di-anhydride curing agents with emeraldine base. Apparently, the di-anhydride is an effective doping agent, whereas amine curing agents are de-doping agents.

Precursor Routes

Processing through a precursor route involves the use of an intermediate, processible polymer that can be later converted into the fully conjugated material. It is most often used with poly(*para*-phenylene vinylene (PPV), a relatively stable and insoluble polymer that can be manipulated as soluble precursor polymers to form films and fibers. There are many different precursor routes to PPV, including the sulfonium and alkoxy derivatives as described in a recent review.[13] Fig. 2 shows a typical chemical reaction commonly used to prepare films of PPV. In fact, a 2.5% solution of the precursor in water is commercially available. In addition, nine monomeric precursors for PPV derivatives are available to produce red, orange, and green emitters for light-emitting diodes (LED) devices.

GENERAL CLASSES AND APPLICATIONS OF CPs

Table 2 contains idealized structures of some CPs with typical dopants and values for the conductivities of thin films. The exact structures of PPy and polythiophene (PT) are unknown. Polyacetylene is the most crystalline and PANi can exist in several oxidation states with electrical conductivities varying from 10^{-1} S/cm to the values reported in Table 2. In its undoped state, PPS is an engineering thermoplastic with a conductivity of less than 10^{-16} S/cm. Upon doping with AsF_5, conductivities as high as 200 S/cm have been obtained after casting a film from a solution of AsF_3.[22]

Classes of CPs

Among the many conjugated polymers, PA, PANi, PPy, PT, PPS, and PPV have received the most

Table 2 Structure and conductivity of some common CPs

Polymer	Structure	Dopants	Approximate conductivity (S/cm)
PPy		BF_4^-, $C1^-$	100–500
PT		BF_4^-, $C1O_4^-$, $FeC1_4^-$	1,000
Poly(3-alkylthiophene)		BF_4^-, $C1O_4^-$, $FeC1_4^-$	1,000
PPV		AsF_5	1,000
PP		AsF_5, Li, K	1,000
PPS		AsF_5	200
PANi		HCl	5–100
PA		I_2, Br_2, Li, Na, AsF_5	1,000

attention. A list of the general classes of CPs with references is shown in Table 3.

Applications of CPs

All books, reviews, and entries on CPs describe the potential applications. Chandrasekhar[21] and others[11–20] have reviewed in comprehensive fashion the applications of CPs, including: batteries; sensors; electro-optic and optical devices; microwave- and conductivity-based technologies; electrochromic devices; electrochemomechanical and chemomechanical devices; corrosion protection; semiconductor, lithography, and electrically related applications—photovoltaics, heterojunction, and photoelectrochemical cells; capacitors; electrolytic and electroless metal plating; CP-based ''molecular electronic devices;'' catalysis and delivery of drugs and chemicals; membranes; and LEDs.

Conductive polymers have been studied for a variety of applications in batteries, primarily for secondary or rechargeable batteries. They have been investigated as the anode as well as cathode materials, with cathode materials in Li secondary batteries being the major focus. Suggested uses have included CP (anode/cathode) batteries, lead-acid batteries, and Zn batteries. Polyaniline and polypyrrole have been the primary focus, but other common CPs have been investigated. To be sure, the advantages of CPs as battery electrodes are light weight, low cost, processibility into odd shapes and sizes, less corrosive nature, and compatibility with both organic liquid and solid electrolytes.

Conductive polymers are attractive materials for application as LEDs because they require low voltage, of the order of 2–5 V, and they are processible in their undoped state to yield films and odd shapes/sizes. In addition, they are inexpensive, and exhibit increasingly higher quantum efficiencies. Their emission colors are tunable by tailoring the CP backbone, i.e., copolymerization, layering or combining multiple CPs, or several other techniques, from the visible region to the near IR. Whether they can displace liquid crystals in displays is an open question as of this writing.

Conductive polymers have been investigated for applications as sensors, with sensing accomplished through the following modes:

Conductometric, using change in conductivity.

Potentiometric, monitoring the change of open circuit potential at a CP electrode.

Amperometric, monitoring the current at a CP electrode.

Voltammetric, monitoring the change in current while varying the applied potential at a CP electrode.

Gravimetric, entailing the effect of a weight change in a CP.

Optical, typically involving the effect of doping or analyte binding on the optical properties of a CP.

pH-Based, using the effect of change in pH in the sensor environment.

The electro-optic and optical devices based on CPs can be classified into three categories: those based on second order NLO properties; those based on third order NLO properties; those based on properties other than NLO; CP-based lasers. The driving forces behind the development of these devices are discussed elsewhere.[12]

The military applications of CPs have been extensively investigated during the past 25 yr with dramatic results in the following areas: electromagnetic impulse (EMI) shielding; conductive coatings and composites for electrostatic discharge dissipation (ESD) or

antistatic applications; passive absorbers for microwave-region radiation for radar cross section (RCS) reduction; dynamic (switchable) microwave absorption and RCS control; microwave smoke camouflage; and several other applications that are classified.

Another application of CPs with equal significance to the military is in the area of electrochromic devices, which may be of two types:

Mode of function: Reflectance-, transmittance-, and cumulative-mode devices.

Spectral region of response: Near-UV-visible, near-UV-visible-NIR, IR, visible-NIR-IR, micro/millimeter-wave, and wide spectral.

Because of the demonstrated success achieved with electrochromism in CPs, there is an ongoing search for a CP-based device capable of modulating the entire spectrum from the visible through the IR to the microwave region.

The reversible reaction between the doped and undoped CP is significant in terms of military applications. When combined with the physical, chemical, optical, and electronic properties of both forms, it is easy to comprehend why CPs are truly the fourth generation of polymers in modem warfare. In the area of stealth, PANi is used in the smart skins of radar-evading aircraft. But, as the microwave absorption is converted to thermal energy, these aircraft can be observed by their heat signature. And, because there is a significant difference between the IR specular reflectance of doped and undoped CPs, devices based on CPs can be used to track, camouflage, and evade incoming heat seeking missiles. In the visible and near IR regions of the spectrum, electrochromic devices with exceptional contrast are available.

Polyaniline has been successfully exploited because of its relatively low cost, acceptable environmental stability, and ease of processing. And even though PPy is inherently more difficult to process, it has been used as a coating on fabrics for several applications—EMI shielding and camouflage applications—because of its higher conductivity.[13]

The electrochromic properties of PANi from the visible to the microwave region can be improved by copolymerization of aniline with other aromatic amines such as diphenyl amine and *N*,*N*′-diphenylbenzidine. Devices with solid electrolytes, rapid switching, high contrast, and acceptable cycling stability have been discovered and successfully exploited by Chandrasekhar.[21]

One of the more fascinating applications is the electromechanical actuation with CPs, leading to artificial muscles, wings, and propellers. The basis behind such actuation is that CPs swell on doping, with an increase in volume of about 35%. Thus, if a bilayer of a CP and a flexible material that does not swell or contract is created, electrochemical or chemical redox of the CP will result in bending of the bilayer.

Corrosion of metals is a serious problem which has been successfully addressed with CPs, and consequently anticorrosion coatings represent the largest market for CPs. The driving forces behind this development are: the issue of cracks and pinholes in conventional protective coatings, as well as slow diffusion of the corroding species to the metal surface; environmental issues, such as the unacceptability of chromates; cost; and ease of application. The principles underlying the use of CPs for this application are based on the fact that metal corrosion is primarily an oxidative process, involving the loss of electrons from the metal to an oxidizing species in the environment. Hence, the fundamental nature of corrosion is electrochemical, and a CP is capable of serving as an in situ oxidant or anodic protective material. In other words, it oxidizes the surface of the metal with which it is in contact, thereby being itself reduced.

COMMERCIAL PRODUCTION

Very few CPs are produced in bulk quantities. Polyphenylene sulfide, a member of the third generation of polymers, was produced in bulk quantities many years before CPs were established and its dopability was elucidated. Polyethylenedioxythiophene is commercially available as a water-based colloidal dispersion (Baytron P water dispersion), and presumably as dispersible powders. The powders with a conductivity of 5–10 S/cm can be dispersed in thermoplastic polymers and in organic solvents such as xylene. Polyaniline doped with dodecylbenzene sulfonic acid and complexed with zinc dodecylbenzene sulfonate is commercially available as a powder, which can be dispersed in polyolefins. The same polymer doped with *p*-toluenesulfonic acid is also available as a dispersible powder, Ormecon, and in a predispersed form for solution processing in polar and nonpolar media. Based on Ormecon PANi, there are many commercial products marketed for many different applications.

Other CPs are produced in large quantities inhouse by many companies for marketing as products for specific applications. Milliken Research Corporation, for example, supplies PPy-coated textiles for microwave absorption, ESD, and other uses.[13] Ashwin-Ushas Corporation markets several different electrochromic devices for the visible, IR, and microwave regions. Sigma-Aldrich, Inc. offers a wide range of CPs from the main polymer classes and a complete complement of monomer precursors.

For the bulk production of CPs, the chemical method is used. It is essentially a scaleup of the procedures used in the laboratory. In the case of PANi, benzidine is a byproduct formed during oxidation of aniline and is a carcinogen. Consequently, it must be removed by extraction or copolymerization during oxidation. In addition, the aqueous waste must be either treated before release into the environment or recycled.

Electrochemical methods involving the continuous production in a flow-through cell and the partially immersed cylindrical horizontally revolving electrode are being used to produce CPs inhouse. For instance, flexible films of PPy with excellent mechanical properties and chemical stability have been produced continuously by electrochemical polymerization. The films with an average thickness of 80 μm are commercially available.

CONCLUSIONS

The main characteristic of a CP is a conjugated backbone that can be subjected to oxidation or reduction, resulting in what is frequently termed *p*-type of *n*-type doping, respectively. Doping leads to a dramatic increase in electrical conductivity, but also to a decrease in stability, solubility, and fusibility. A vast arsenal of synthetic methods is available to prepare CPs, which can be dispersed in conventional polymers to form processible blends or alloys. To be sure, polymers have numerous technological applications because of their low cost and density combined with flexibility. But the ultimate goal of preparing a pure polymer—a synthetic metal—with the physical properties of a metal remains as elusive as that of the alchemist's dream of converting lead into gold.

Contact Angles, Surface Tension, and Capillarity

C

Peter R. Pujadó
UOP LLC, Des Plaines, Illinois, U.S.A.

INTRODUCTION

Contact angles are an external manifestation of surface tensions or interfacial tensions and, as such, can be used to determine the value of such surface tensions.

Surface tensions arise from the unbalance of molecular attractive (and repulsive) forces that result at an interface from the different nature of the materials that come in contact. Surface tensions are more readily observed in liquids—between immiscible liquids or between a liquid and a gas. Surface tensions are also present on the surface of solids, but the rigidity of the solid structure prevents their manifestation in an observable way, except in combination with the surface of a liquid in contact with the solid surface. Thus, while the surface tension and the surface free energy in a liquid are the same, this is not the case on solid surfaces.

The balance of forces between surface tensions at the contact line results either in the Neumann triangle for a liquid/liquid/liquid or liquid/liquid/gas system or in the Young–Dupré equation on a liquid/liquid/solid or a liquid/gas/solid system (Fig. 1). While the Neumann triangle represents a true balance of forces, the Young–Dupré equation is little more than a definition of the $(\sigma_{AS} - \sigma_{BS})$ term, a difference between the respective solid/fluid surface free energies and not truly solid/fluid interfacial tensions.

BACKGROUND INFORMATION

As a rule, any system in equilibrium will tend to adopt a configuration that minimizes its energy state within the constraints or degrees of freedom that the system faces. When liquid interfaces are present, in addition to gravitational, electrostatic, and other forms of energy, we must include the energy of the surfaces. In the absence of other energy manifestations, liquids will adopt configurations that minimize their surface energy—in effect, their surface area. Thus, in the absence of gravity, a liquid droplet will be spherical because a sphere encompasses the smallest possible surface area around a fixed given volume. In the presence of gravity, a droplet sitting on a flat solid surface will adopt a ''sessile'' configuration; if suspended from the bottom of a flat surface, it will adopt a ''pendent'' configuration. Axisymmetric sessile drops are particularly useful in determining the contact angle at the contact line between the liquid and the solid. Similar measurements can be taken at the contact line between immiscible liquids, particularly at the contact line of an axisymmetric lens (a sessile lens) of an immiscible liquid floating on the surface of another liquid.

The equations that govern the shape of sessile and pendent configurations are very simple but nonlinear and cannot be solved analytically except for some very simple configurations or in limiting cases. Fortunately, numerical solutions are readily available such that, given the physical dimensions of a particular, say, sessile drop configuration, the interfacial forces can be readily calculated.

The effects of surface tension on sessile and pendent drops or lenses are but a simple manifestation of capillary hydrostatics. The field of capillarity can be far more extensive, principally when coupled with electromagnetic forces and also for liquid interfaces in motion, or in the motion in liquid interfaces that may result from local variations in surface tension as may be caused, for example, by local variations in temperature, or by the localized introduction of surfactants (interfacial tension modifiers), or by localized space-delimited chemical reactions. Wicking flows (as in ''heat pipes'') and flows in porous media (as in petroleum reservoir displacement) are a few of many other examples in which interfacial forces play a predominant role.[1]

Although often disregarded and not strikingly apparent in everyday life, capillary phenomena are everywhere and frequently can be found playing an important role in physical systems. Capillary phenomena occur wherever there is an interface between gas and liquid or between two liquids. The importance of capillarity depends on the ratio between the area of the region in which surface effects are dominant and the volume of the bulk phases.

In classical natural philosophy capillarity was regarded as a branch of hydrostatics and its study was focused on two fundamental areas: 1) nature of capillary forces and interpretation of their origin and 2) external manifestations of capillary forces. It is not known who first became aware of the existence of surface phenomena but the discovery of capillarity has been attributed to Leonardo da Vinci. Maxwell in his famous contribution to the ninth edition of

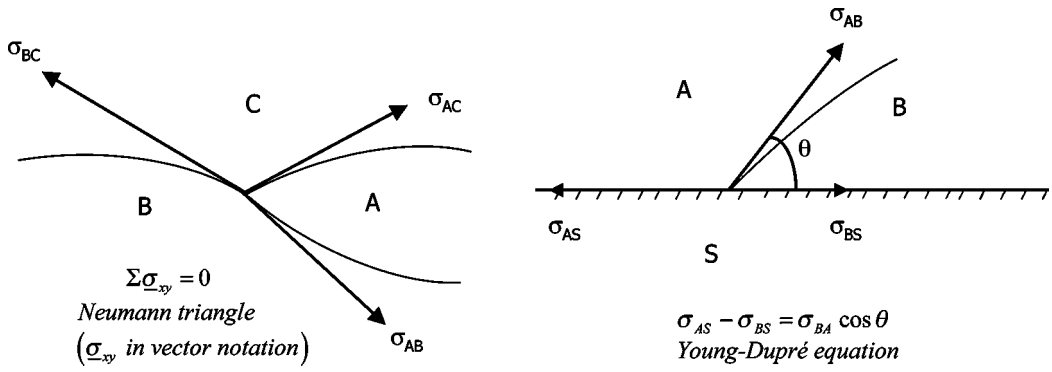

Fig. 1 Balance of forces between surface tensions at the contact line: Neumann triangle and Young–Dupré equation. *(View this art in color at www.dekker.com.)*

The Encyclopaedia Britannica outlined the history of the subject. Additions were made by Lord Rayleigh when he revised Maxwell's article for the 11th edition.[2] An annotated historical bibliography can be found in Young's *Lectures*.[3] Capillary forces as such were first studied by Laplace.[4] Gauss subsequently inaugurated an alternative mathematical approach.[5] The subject was later taken up by Lord Rayleigh, van der Waals, von Neumann, Bakker, and many others.[6–10] In recent years statistical mechanics has provided new insights into the theory of capillary forces.[11,12] First appearing in 1954, Lifshitz's theory of collective intermolecular forces in condensed media seems to represent a breakthrough that has led to a better understanding of the nature of capillary forces.[13–15]

THE EQUATION OF CAPILLARITY

The configuration of a capillary meniscus is governed by a balance of fluid pressures and surface tension and is correctly described by the Young–Laplace equation:[1,16,17]

$$\Delta p = 2H\sigma_{AB} \tag{1}$$

subject to the appropriate boundary conditions. In this equation, H is the local mean curvature of the meniscus while σ_{AB} represents the value of the surface tension between two fluids A and B, assumed to be uniform throughout each individual liquid/liquid or liquid/gas interface. If the principal radii of curvature at any given point of a surface are r_1 and r_2, $2H = 1/r_1 + 1/r_2$. At every ordinary point of a surface there is a direction for which the radius of normal curvature is a maximum and a direction for which it is a minimum, and they are at right angles to each other.[18] These maximum and minimum radii, r_1 and r_2, are the principal radii of curvature at that point. Except for a plane or a sphere, $r_1 \neq r_2$. In the case of a sphere with uniform radius, r, $2H = 2/r$.

More sophisticated analyses add higher-order terms to the Young–Laplace equation, but such refinements are neither apparent nor necessary because the basic equation accurately represents even the most complex systems.

An easily verifiable manifestation of capillarity and the contact angle can be observed by dipping a thin glass tube in a liquid such that the radius r of the tube is small enough for the shape of the liquid meniscus to be approximately spherical so that $2H = 2\cos\theta/r$, where θ is the contact angle between the liquid and the glass and $r/\cos\Delta z$ is the radius of curvature of the meniscus. If the liquid wets the glass, the liquid will climb a certain height, Δz, inside the tube.[19] We can then write the equation of capillarity as:

$$\frac{2\sigma\cos\theta}{r} = g\Delta z(\rho_B - \rho_A) \tag{2}$$

If the liquid wets the glass, θ is either zero or close to zero and not easily observable. Contact angles are more easily observable if the liquid does not wet the glass, $\theta > 90°$, so that instead of the liquid climbing inside the tube, the liquid is depressed to a lower level relative to the free liquid surface. This is the case, for example, if the glass tube is immersed in mercury or if the glass tube is coated with paraffin wax internally and is submerged in water.

Another way to see the contact angle is by depositing a droplet of liquid on a flat horizontal surface. By using appropriate combinations of liquids and solid surfaces we can obtain contact angles that may range from $\theta = 0°$ (totally wetting and spreading liquid) to $\theta = 180°$ (totally nonwetting liquid), as may be obtained, for example, by depositing a droplet of water on a smooth horizontal surface coated with a perfluoroethylene polymer (e.g., Teflon^{TM}).

Provided that the droplet is very small the effects of gravity can be neglected and the droplet may be assumed to be spherical with radius r. If so, the Young–Laplace equation becomes

$$\Delta p = 2H\sigma = 2\sigma/r \tag{3}$$

It follows from this simple relationship that the vapor pressure over a convex surface is greater than over a plane.[20] Various interesting consequences arise from this fact. One, for example, is that water vapor will not condense in a totally dust-free environment for lack of nucleating centers. Another is that when mercury is spilled and the drops break down into very small microdroplets, the increased vapor pressure greatly augments the risks of toxic exposure to mercury.

In the general form of the Young–Laplace equation, $\Delta p = p_A - p_B$ (A above and B below), and the local mean curvature is positive for a meniscus that is concave upward. The Young–Laplace equation is more often formulated in terms of the hydrostatic pressures developed in a uniform body force field, such as that of gravity near the earth's surface:

$$2(H - H^o)\sigma = g(\rho_B - \rho_A)(z - z^o) \tag{4}$$

where g is the local acceleration of gravity, ρ_B and ρ_A the densities of the fluids below and above the interface, respectively, and H^o the mean curvature of the interface at a datum elevation z^o. Owing to the way in which mean curvature depends on the first and second derivatives of elevation on the interface, this equation is strongly nonlinear. Solutions in closed form are available only for well-known cases of interfaces with translational symmetry, which have the shape of elasticas or lintearіae, and a few limiting cases of interfaces with rotational symmetry when $g \to 0$ or $\Delta p \to 0$, such as spheres, nodoids, cylinders, unduloids, and catenoids.[21] In general, the Young–Laplace equation has to be solved numerically and, even so, practically all the numerical solutions are limited to rotationally symmetric (axisymmetric) systems, except for a few ''three-dimensional'' interfaces studied by Petrov and Chernous'ko, Concus and Finn, Larkin, and others.[22–27] While, in principle, the nonaxisymmetric problem is not too difficult to tackle numerically, fitting the boundary conditions often becomes an impossible task.

The first solutions of the differential equation for rotationally symmetric menisci were computed geometrically, or graphically, by Thomas Young himself.[28] Young's method was employed by John Perry beginning in 1874, on instructions from Sir William Thomson, who later was to become Lord Kelvin and who wrote that between 1854 and 1859 he had worked out the method with what may be a slightly more general starting procedure than Young's.[29] The first numerical solutions of note were those for sessile and pendent drops developed by J. C. Adams, probably around 1855, and applied by Bashforth soon thereafter.[30] Subsequent developments have been reviewed by Bakker, from the van der Waals's school, and Padday, a British surface chemist and industrial scientist.[31–33] Padday's own computations are by far the most comprehensive that have appeared to date. A different and more efficient method was developed by Chun Huh and further expanded by Pujadó.[34,35] This method can be adapted to determine configurations of interfaces acted on by normal viscous stress as well as pressure. In fact, this is the boundary condition that should be used for the solution of the Navier–Stokes flow equation in a domain bounded by a free surface, the location and configuration of which is unknown a priori.

PARAMETRIZATION OF THE EQUATIONS

The explicit gravity-dependent Young–Laplace equation can be rewritten in dimensionless form as follows:[35]

$$2Ha = \frac{1}{x}\frac{d}{dx}\left[\frac{x\,y'}{\left(1 + (y')^2\right)^{1/2}}\right] = \varepsilon y \tag{5}$$

where $x = r/a$ [a is a capillary constant defined by $a^2 = \varepsilon\sigma/(g(\rho_B - \rho_A))$, with $\varepsilon = +1$ when $\rho_B - \rho_A > 0$, a sessile profile, and $\varepsilon = -1$ when $\rho_B - \rho_A < 0$, a pendent profile] and $y = (z - z^o)/a + y^o$, where y^o is the dimensionless ordinate of the datum point (usually the apical point) and is given by $y^o = \varepsilon 2H^o a$.

Then, by introducing $y' = dy/dx = \tan\varphi$, the above dimensionless equation can be decomposed into a system of first-order nonlinear differential equations:[6,24,34]

$$\begin{aligned}\frac{dx}{d\phi} &= \frac{x\cos\phi}{\varepsilon xy - \sin\phi}\\ \frac{dy}{d\phi} &= \frac{x\sin\phi}{\varepsilon xy - \sin\phi}\end{aligned} \tag{6}$$

which is a convenient form for numerical integration in terms of the independent variable φ and can be used with no difficulty for the entire range $0 \le \varphi < \infty$ in the sessile case ($\varepsilon = +1$) and up to the first inflexion point $0 \le \phi < \phi_{in}^1$ in pendent configurations ($\varepsilon = -1$).

To overcome the difficulty encountered at the inflexion points, we need a system of equations in terms of an independent variable that increases or decreases monotonically with arc length regardless of the profile of the meniscus. For this the natural choice is the dimensionless arc length, s, itself. It is defined as

$$ds = [(dx)^2 + (dy)^2]^{1/2} \tag{7}$$

The Young–Laplace equation can now be written as a system of three first-order nonlinear differential equations:

$$\begin{aligned} \frac{dx}{ds} &= \cos\phi \\ \frac{dy}{ds} &= \sin\phi \\ \frac{d\phi}{ds} &= \varepsilon y - \frac{\sin\phi}{x} \end{aligned} \tag{8}$$

Both sessile and pendent profiles form continuous families either of which can be generated by using these equations regardless of the value of ε. The choice of ε, given a convention for the changes of s and φ, affects only the sessile or pendent character of the starting point and its neighborhood. The initial value chosen for y for any given abscissa, x_0, sets the curvature at that point and fully determines the profile. The initial value chosen for s is irrelevant; the integration depends only on the step size, Δs, and its sign.

The actual configuration of a meniscus is given by that member of the family of solutions of the Young–Laplace equation that satisfies a given set of boundary conditions. By using this method we effectively change a tedious two-point boundary-value problem into a much simpler initial-value problem and the final solution is obtained by interpolating or iterating over a sequence of profiles. Larkin used a similar initial-value artifice to integrate the two-dimensional partial differential equation of Young and Laplace over a domain lacking rotational symmetry.[25] It should be noted though that the Young–Laplace equation is elliptic and its solution over a domain subject to a given set of boundary conditions has to be carried out by solving a system of algebraic equations defined over the mesh points of a finite-difference lattice.

BOUNDARY CONDITIONS AND INTEGRATION START-UP FOR POINTS OF ZERO SLOPE

Starting the integration of the Young–Laplace equation at a point of zero slope is exceedingly convenient whenever possible, the reason being that the solution in the vicinity of such a point behaves as a Bessel function or a modified Bessel function of zero order. Several types of profiles, real or hypothetical, can be considered. For the purposes of this article, only sessile drops and bubbles will be analyzed.

Sessile capillary menisci in the vicinity of a point with zero slope are described by the modified Bessel equation

$$y'' + (1/x)y' - y = 0 \tag{9}$$

which can be obtained by expanding $(1 + (y')^2)^n$, $n = 1/2$, $3/2$, etc. about $y' = 0$, and neglecting all terms $(y')^n$ with $n \geq 2$.

When the point of zero slope lies on the axis of rotational symmetry, as is the case with axisymmetric drops and bubbles, the solution for points in the immediate vicinity of the axis is

$$y(x) = \tan\phi^+ \frac{I_0(x)}{I_1(x^+)} \quad 0 \leq x \leq x^+ \tag{10}$$

where x^+ is an abscissa for which the above approximation still holds within a given tolerance. Normally, this is the abscissa corresponding to a φ^+ of up to 0.5°; values of φ^+equal to 0.1° or smaller can be chosen for safety.

This method automatically gives us the coordinates of the starting point of the curve at (x^+, y^+)

$$y^+ \equiv y(x^+) = \tan\phi^+ \frac{I_0(x^+)}{I_1(x^+)} \tag{11}$$

and the dimensionless apical curvature, i.e., the curvature at the point $x = 0$

$$y_0 \equiv y(0) = 2H^o a = \tan\phi^+ \frac{1}{I_1(x^+)} \tag{12}$$

The choice of a sign for φ^+ determines whether we obtain a sessile bowl ($\varphi^+ > 0$) or a sessile dome ($\varphi^+ < 0$) according to our convention for curvature signs.

Using the Bessel approximation as a start-up artifice always gives us a two-parameter family of solutions (or a one-parameter family for each initial abscissa x_0) as is always the case with a second-order differential equation. The parameter x^+ is directly related to the curvature y_0 or y^+ of a given profile. However, to singularize a profile that passes through a point (x^o, y^o) three parameters are necessary (x^o, y^o, φ^o), although solutions may not exist for some combination of parametric values (for example, if $x^o = 0$, no profiles with finite nonzero slope at x^o exist). In all cases, once x^+ and y^+ have been determined, we may proceed

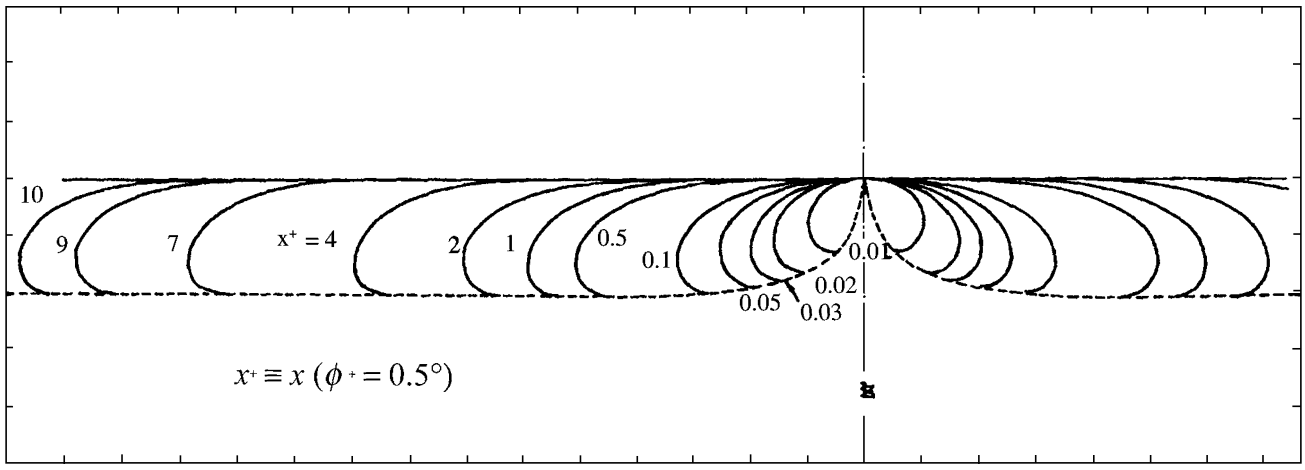

Fig. 2 Axisymmetric sessile drops.

with the integration of the equations by making use of some standard Runge–Kutta subroutine or an equivalent method.

REPRESENTATIVE ROTATIONALLY SYMMETRIC MENISCI

Figs. 2 and 3 show a family of bounded axisymmetric sessile configurations integrated all the way from $\varphi^+ = 0°$ (or $\varphi = \varphi^+$) to $\varphi = 180°$.

For any given angle, $\varphi > 0$, the thickness of the meniscus increases rapidly with increasing radius, passes through a maximum, and decreases slightly as it tends to an asymptotic limit as the radius tends to infinity. The limit is given by the two-dimensional solution of a translationally symmetric configuration—the separating elastica. If the integration is continued beyond $\varphi = \pi$, the profile is found to coil over itself indefinitely, as indicated in Fig. 4, where the first few loops are shown. If the integration is extended it will be noticed that the "centers" of the loops fall close to a straight line—the generatrix of a conical surface—which passes through the origin ($x = 0$, $y = 0$) (Fig. 5).

This is characteristic of all solutions of the Young–Laplace equation that have a nodoidal (i.e., coil-like) character and appears also in many other representative cases. The curves in the figures have been drawn for sessile drops with the denser liquid—shaded area—below. Sessile bubbles have identical configurations except that they are turned upside down, yet have the heavier fluid still on the lower side. All of these curves are parametrized with respect to their curvature at the origin, y_0, which is equivalent to parametrization by the value of their starting x^+.

The family of so-called "bounded" sessile configurations, that is, sessile drops and bubbles centered at the axis, belongs to the one-parameter subfamily

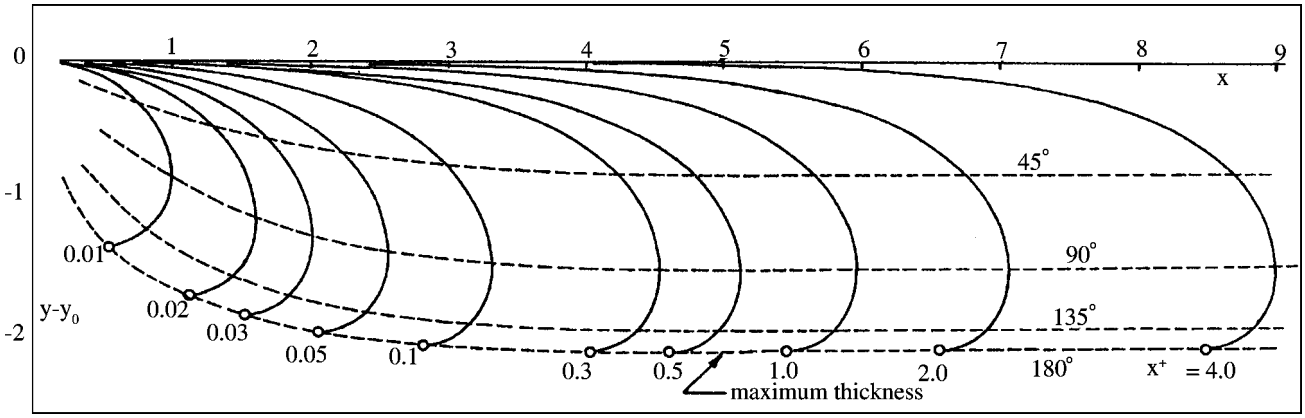

Fig. 3 Axisymmetric sessile drops. Locus of various contact angles: 45°, 90°, 135°, 180°.

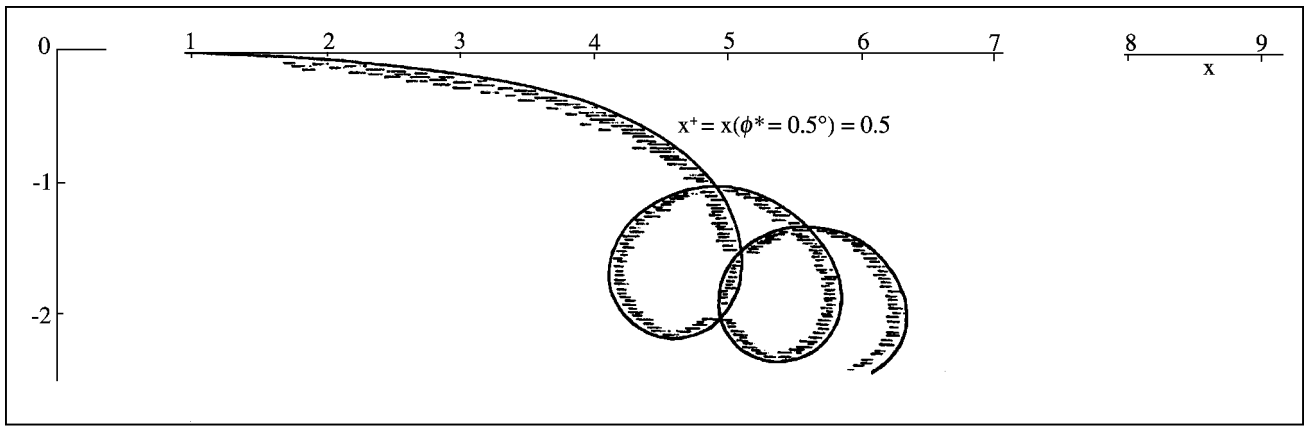

Fig. 4 Axisymmetric sessile profile integrated beyond 180°.

of solutions mentioned above. So does the family of bounded pendent configurations, that is, pendent drops and bubbles centered at the axis. Figs. 6 and 7 show equilibrium configurations of pendent drops with increasing curvature (decreasing x^+).

Similar calculations can be done for families of unbounded sessile profiles. An unbounded sessile profile can be visualized physically as the configuration of an axisymmetric dry patch, or that of a meniscus around a cylindrical rod with its axis perpendicular

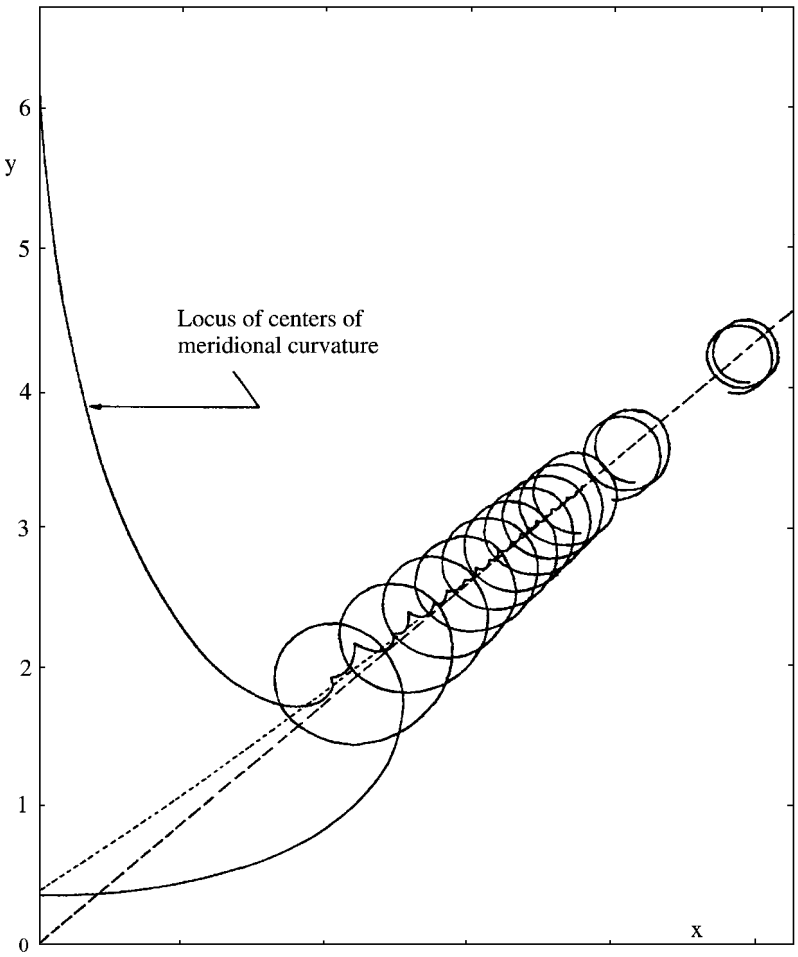

Fig. 5 Axisymmetric sessile profile with extended integration.

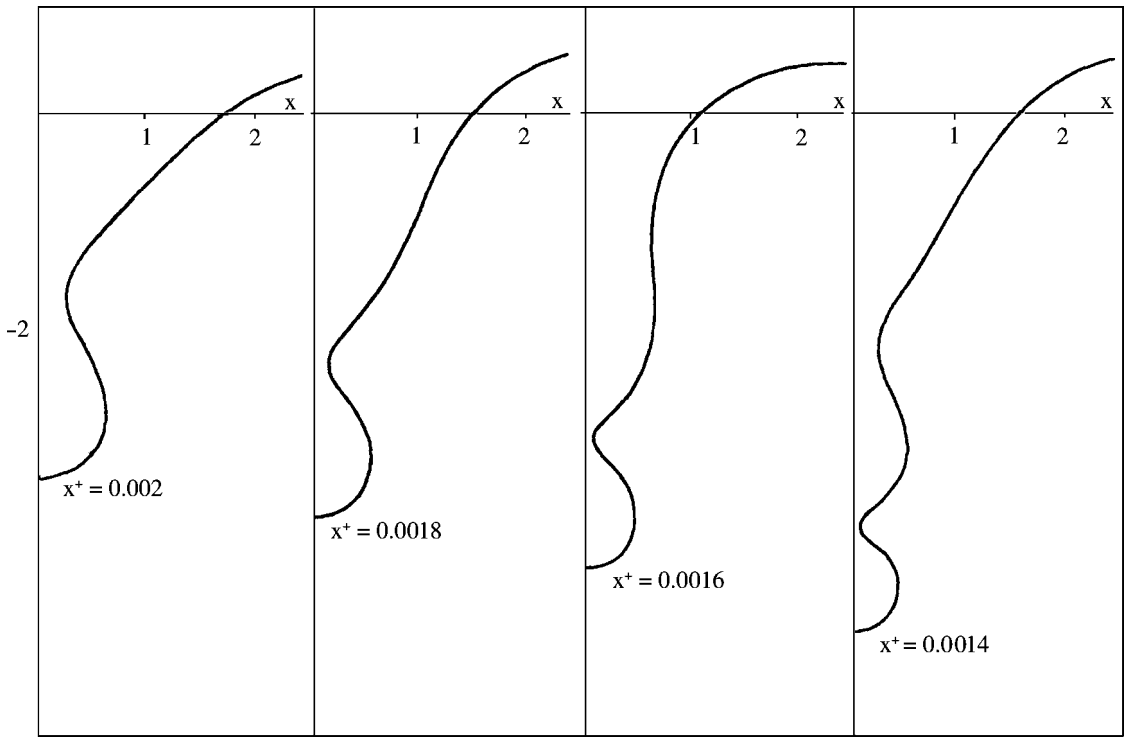

Fig. 6 Axisymmetric pendent drop assumed to be in static equilibrium (for $x^+ = 0.002,\ 0.0018,\ 0.0016$, and 0.0014).

to the free liquid interface, or the external meniscus around the ring of a de Noüy tensiometer. In this case, the boundary condition is

$$y'(x) \rightarrow 0 \quad \text{as } x \rightarrow \infty \tag{13}$$

and the solution of the Bessel approximation becomes:

$$y(x) = \tan \phi^+ \frac{K_0(x)}{K_1(x^+)} \quad x^+ \leq x \tag{14}$$

Likewise, the same treatment can be applied to the calculation of the shapes of pendent drops and bubbles. The behavior of pendent profiles about the apical point of zero slope, $y'(x_0) = 0$ at $x_0 = 0$, is given by the Bessel equation:

$$y'' + (1/x)y' + y = 0 \tag{15}$$

of which, the solution is

$$y(x) = \tan \phi^+ \frac{J_0(x)}{J_1(x^+)} \quad 0 \leq x \leq x^+ \tag{16}$$

where again the starting point for numerical integration is located at

$$y^+ \equiv y(x^+) = \tan \phi^+ \frac{J_0(x^+)}{J_1(x^+)} \tag{17}$$

such that the apical curvature is $y^o \equiv y(0) = a2H^o = \tan \varphi^+(1/J_1(x^+))$.

Not discussed here, but also equally feasible is the calculation of the equilibrium profiles of sessile and pendent lenticular configurations—for example, drops of an immiscible liquid floating on an interface (like oil on water) form a sessile lens as illustrated in Fig. 8.[36]

AXISYMMETRIC MENISCI AND THE DETERMINATION OF CONTACT ANGLES

It may be observed in Figs. 2 and 3 that the dimensionless profiles provide a unique correlation between the diameter of the meniscus (or the diameter of the meniscus at the contact line) and the elevation of the apical point with respect to the plane on which the meniscus rests. Therefore, once we have established the apical curvature of the meniscus that corresponds to that profile, it is a fairly straightforward task

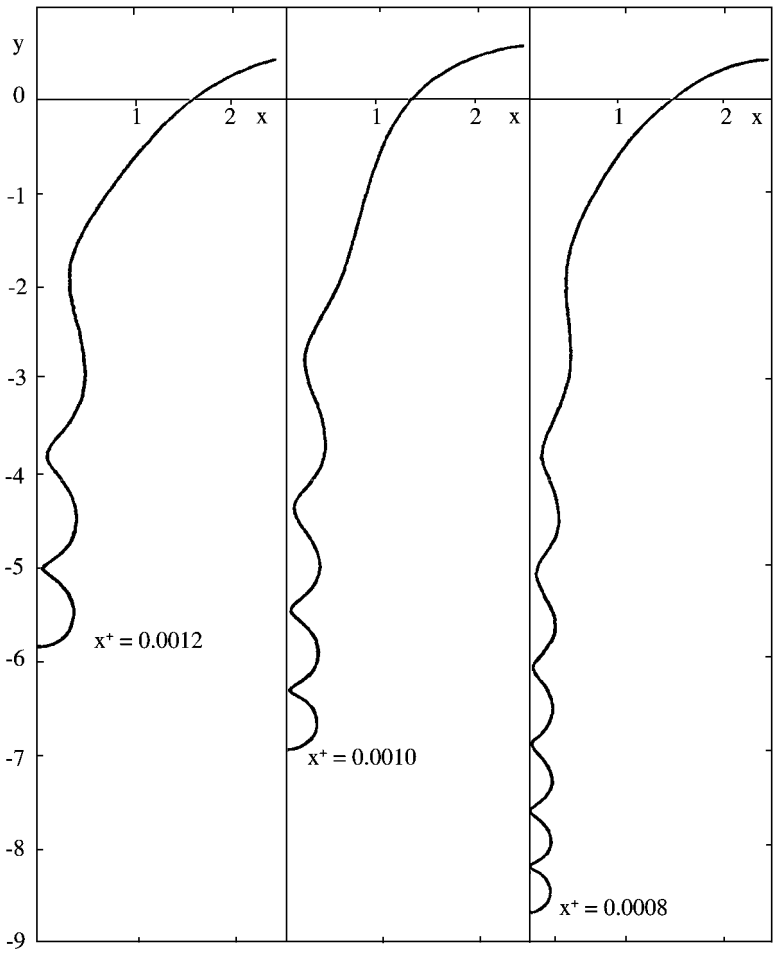

Fig. 7 Axisymmetric pendent drop assumed to be in static equilibrium (for $x^+ = 0.0012$, 0.0010, and 0.0008).

to determine the values of the capillary constant, a^2, and the surface tension, σ. The dimensions of the meniscus should be established by taking precise microscopic measurements.[37–44]

Alternatively, equivalent correlations can be derived for other menisci or capillary phenomena that will lead to similar determinations of the surface tension σ. These could depend on the relative elevations of the menisci inside thin capillary tubes or in between plates, or in more accurate measurements using ring tensiometers or other commercially available devices.

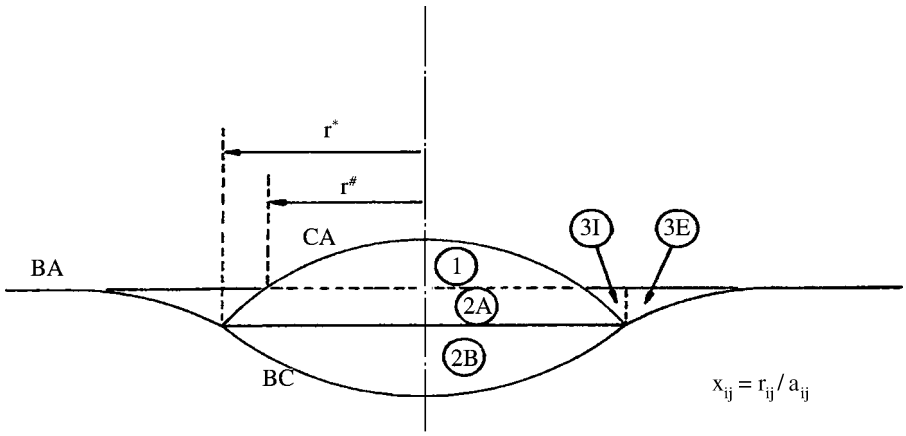

Fig. 8 Sessile lenticular configuration.

CONCLUSIONS

Capillarity phenomena are everyday occurrences that result from the existence of surface tension or interfacial tensions. In addition to the static phenomena discussed herein, surface tension and capillarity are also responsible for numerous dynamic phenomena that may result from localized gradients in temperatures or in compositions; the study of dynamic capillary phenomena (e.g., Marangoni flows, Bénard cells) is the subject of much literature coverage and is beyond the scope of this survey.

Static capillary phenomena lead to precisely determined geometrical shapes like sessile menisci, pendent menisci, minimal surfaces, which can be used for the physical determination and measurement of the surface tension or the interfacial tensions between fluids. In addition to the simple forms considered herein, more complex forms (e.g., sessile lenticular drops) can be studied.[35,36] Mathematical resolution of these shapes is a combination of the (numerical) solution of the highly nonlinear Young–Laplace equation together with an appropriate set of boundary conditions. For practical purposes, only axisymmetric forms are readily amenable to mathematical analysis.

Corrosion in the Process Industries

J. A. Richardson
Anticorrosion Consulting, Durham, U.K.

R. A. Cottis
School of Materials, Corrosion and Protection Centre, University of Manchester, Manchester, U.K.

INTRODUCTION

Corrosion makes a large impact on the economics of chemical processing. A recent U.K. government study estimated that corrosion expenditure amounts to ~4.5% of the turnover of the U.K. chemical/petrochemical industry. Much of this total expenditure represents investment in materials and protection practices to manage corrosion in new equipment. However, a significant proportion arises from the failure to identify and mitigate well-known corrosion risks at the design stage, and the U.K. study estimated that 15% of the total estimated cost may be saved by the application of existing corrosion prevention technology.

This entry provides an introduction to the management of corrosion in the process industries. It is necessarily rather general in character, and it should not be relied on for decision making; rather it provides a background for nonspecialists to help them to appreciate the decisions and advice of specialists.

MATERIALS FOR PROCESS EQUIPMENT

Process equipment has to operate over wide ranges of temperature, pressure, and fluid composition. Volatile hydrocarbons are stored at temperatures well below –100°C, and furnace tubes may be required to operate at temperatures above 1000°C. Crude oil distillation equipment operates commonly under vacuum, whereas supercritical processes operate at pressures of several hundred atmospheres. Aqueous solutions of mineral acids, alkalis, and salts can be extremely corrosive toward metallic materials, whereas plastic materials are much more vulnerable to organic solvents. The wide diversity of commercial chemical process conditions dictates that all classes of engineering materials find use in chemical process equipment.

The safe design and operation of pressurized equipment demands levels of strength and toughness that are generally achievable only in metallic materials. Consequently, the great majority of process equipment is of metallic construction. Economics dictates carbon and low alloy steels as preferred first option materials, but they lack useful strength above ~600°C, have relatively poor toughness below 0°C, and have poor corrosion resistance. Stainless steels and nickel alloys have strength and toughness capabilities across much wider temperature ranges, and wide ranging corrosion resistance, depending on the alloy. Copper, aluminum, and lead alloys have limited temperature capabilities, but find niche applications based on their specific corrosion resistances. Titanium, zirconium, and tantalum alloys are amongst the most corrosion-resistant metals available, though at a price, and are commonly used as lining materials on cheaper, steel substrates. Cobalt alloys are used principally for their wear resistances in the handling of solids, slurries, etc.

Plastic materials have limited strength and temperature capabilities, but provide cost-effective corrosion resistances toward many fluids that are highly corrosive to metallic materials. Thermoplastic materials such as polyethylene, polypropylene, polyvinyl chloride) and the fluoropolymers (PVDF, FEP, PTFE), and thermosetting polyester, epoxy and furane resins reinforced with glass or carbon fibers (FRPs), find uses in relatively small, low-pressure vessels and piping systems, and in valves and pumps. Elastomeric materials, ranging from natural rubbers to relatively expensive, synthetic fluoroelastomers, are widely used as joint sealing materials. All the polymeric materials find uses as corrosion-resistant lining materials for steels.

Ceramic materials have excellent temperature capabilities and good corrosion resistances, but are brittle, and thus unsuitable for pressure containment. In volume terms, their major use is as refractories for the thermal protection of steels. At lower temperatures, chemical stoneware; acid-resistant bricks; and specific oxide, carbide, and nitride ceramics have niche applications as corrosion-resistant linings and surfacings, in valves and pumps, and in seals and bearings. Silicon carbide and impervious graphite find use as heat exchange materials for particularly corrosive duties. Solid borosilicate glass is used for relatively small vessels and piping systems operating at low pressures, and

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007716

proprietary glass formulations are used as corrosion-resistant linings for steels.

CORROSION CHEMISTRY

Corrosion is fundamentally a chemical reaction between a metal and its environment.[a] As such it is a heterogeneous reaction between a fluid and a solid. At higher temperatures (when the environment is a gas rather than a liquid), the reaction is typically a direct reaction between oxygen and the metal to form the metal oxide. The oxide will form as a solid on the metal surface,[b] and oxidation will be controlled by the transport of oxygen and metal ions through the corrosion product.

In fluids that allow conduction of ionic charge, such as solutions of salts in water or molten salts, the corrosion reactions may split into two parts (which may occur in different places): the anodic reaction that results in the conversion of metal to metal cations and produces surplus electrons in the metal, and the cathodic reaction that consumes electrons and hence balances the anodic reaction:

Anodic reaction :

$$Fe \rightarrow Fe^{2+} + 2e^{-} \quad \text{iron corrosion}$$

Cathodic reaction :

$$2H^{+} + 2e^{-} \rightarrow H_2 \quad \text{hydrogen evolution}$$

Cathodic reaction :

$$O_2 + 2H_2O + 4e^{-} \rightarrow 4OH^{-} \quad \text{oxygen reduction}$$

Note that the two cathodic reactions are given—the first tends to be more important in acids and for reactive metals such as aluminum, while the second tends to be more important in neutral solutions and for less-reactive metals such as steel and copper alloys.

An important aspect of corrosion in liquids is the nature of the corrosion product. If this takes the form of a soluble salt, then the metal will remain in contact with the liquid, and rapid corrosion can be expected (this is known as active corrosion). If the corrosion product is solid (often an oxide or hydroxide), then it will tend to form a barrier between the metal and the solution, and this will tend to stifle the corrosion process (in this situation the metal is described as being passive, and the protective corrosion product is called a passive film).

CORROSION ENVIRONMENTS

There are an essentially infinite number of corrosion environments, but there are a number of key classes in the process industries:

Atmospheric: Atmospheric corrosion due to the combined effects of rain and the deposition of salt and other pollutants will affect most equipment. Corrosion occurs while the metal surface is wet, and is strongly influenced by the composition of deposits (such as sulfates from industrial atmospheres and chlorides from marine atmospheres). External corrosion of steel and stainless steel process equipment beneath thermal insulation and fireproofing is of particular concern.

Gases: While most corrosion is electrochemical, corrosion in noncondensing gases is chemical, because there is no possibility for the transport of ionic charge in the environment, or of dissolution of the corrosion product. This leads to a rather different character for corrosion in gases, which will consist of the growth of scales of corrosion product. This requires the transport of oxygen and metal ions through the scale, and this generally requires a high temperature to occur at a significant rate.

Waters: Water plays an important part in corrosion at lower temperatures. It acts as a solvent for salts that modify the corrosion process; it ionizes these salts, and thereby allows the passage of ionic charge; it may dissolve the corrosion products; it can dissolve a moderate amount of oxygen; and it can act as an oxidant itself with the evolution of hydrogen. The content of soluble salts, and hence the ionic conductivity, is important. Fresh water (e.g., unpolluted river water and tap water) has a low salt content, and in consequence, it is relatively noncorrosive toward carbon steel. This is especially true at moderate temperatures when oxygen is excluded from the water; many heating and cooling systems (including most domestic central heating systems) rely on deaeration of tap water (often by reaction with the steel in a closed system) to control corrosion. Similarly, the major water treatment for lower pressure boiler waters is concerned with the maintenance of a low salt content and the removal of oxygen. Even in the presence of oxygen, clean river water gives an acceptable corrosion rate of carbon steel (many steel-hulled boats for use only in freshwater are used without any corrosion protection). As the salt content increases, the water becomes more corrosive, especially in the presence of oxygen, and seawater is very corrosive to many metals.

[a]The term ''corrosion'' may also be applied to nonmetals, and these are touched on in this article, but the chemistry in this case will be different, and the wide variety of nonmetallic materials precludes detailed coverage here.

[b]At higher temperatures and in the presence of salt deposits, the corrosion product may be liquid, in which case the behavior may be more like that of aqueous corrosion. At very high temperatures, the oxide may be volatile, in which case very rapid corrosion can occur.

Acids: Acids tend to produce high corrosion rates, both because protective oxides become soluble in acids and the reduction of hydrogen ions becomes an effective cathodic reaction. There is a major distinction between oxidizing acids (notably nitric acid), which provide an alternative cathodic (oxidation) reaction and can corrode even noble metals such as copper and silver, and so-called reducing acids (such as hydrochloric and sulfuric, though the term ''nonoxidizing acids'' might be more accurate), which require an alternative reactant (such as dissolved oxygen) to corrode the noble metals, but which can corrode steels and more reactive alloys with hydrogen evolution. Note that oxidizing acids can cause passivation of iron and steels; so iron will corrode rapidly in concentrated hydrochloric acid, but it will passivate in concentrated nitric acid.

Alkalis: Most metals are protected by a passive oxide in mildly alkaline solutions, but the protective oxide will redissolve in strong alkali to form oxy-anions of the metal, allowing corrosion to occur. For carbon steels, the region of corrosion in alkali is very limited, but it can lead to the serious problem of caustic stress corrosion cracking (SCC).

Salts: In general, the nature of the anion present in dissolved salts is important for corrosion, largely as a result of the interaction of the anion with protective passive films. An important property of the anion present in salts is the pKa of the corresponding acid, as many localized corrosion processes involve the production of local acidic conditions at anodic regions; anions of weak acids will act as buffers and limit the drop in pH. Halides tend to be particularly aggressive, both because they have a low pKa and support the formation of strong acids, and because metal halides tend to be soluble. In contrast, carbonates and phosphates have a high pKa, and therefore restrict any drop in pH and tend to inhibit corrosion. The cation present in the salt can also affect corrosion, most commonly because of the precipitation of hydroxides at local cathodic regions (which tend to become more alkaline than the bulk solution). Thus, calcium and zinc cations tend to act as cathodic inhibitors for iron and steels in neutral solutions.

TYPES OF CORROSION

Corrosion can produce a range of morphologies, some of which can be particularly damaging for a given amount of metal loss. Thus uniform corrosion, in which the metal loss is distributed over the entire metal surface, usually causes relatively slow, manageable loss in section thickness of components, whereas some localized forms of corrosion can lead to failure of components in a matter of months, weeks, or even days.

Uniform or General Corrosion

Uniform corrosion usually occurs in fairly aggressive environments that attack the whole surface. Examples include carbon steel in seawater or acids, or aluminum alloys in strong alkali. The rate of metal loss is usually rather high, but, because it is distributed over the whole surface, the performance can usually be predicted, and managed with corrosion allowances, in most situations. Thus, sheet steel piling is often used in seawater without any corrosion protection, the corrosion rate of around 0.1 mm/yr,[c] coupled with the relatively thick steel sections, giving an acceptable life.

Galvanic Corrosion

When two dissimilar metals are electrically connected together, such that electrons can flow from one metal to the other, it is probable that the anodic, metal dissolution reaction will concentrate on one metal, while the cathodic reaction occurs on both. This accelerates the corrosion of the anodic component. The acceleration will be particularly severe if the area of the cathodic metal is much larger than that of the anodic metal (Fig. 1). While the anodic metal will corrode more, the cathodic metal will normally corrode less, and one form of galvanic corrosion provides a method of corrosion control (know as cathodic protection), in which the anodic, corroding metal is provided deliberately in order to restrict the corrosion of the cathodic metal.

Dealloying or Selective Attack

Dealloying occurs when one component of an alloy is lost preferentially. Thus, brass is an alloy of zinc (a rather active metal) and copper (a rather noble metal). Consequently, the zinc tends to be lost in preference to the copper. Often the copper will form a ''seal'' over the surface, preventing further corrosion, but if conditions do not allow this, then the corrosion can penetrate into the component, removing most of the zinc. The result is a porous copper component, which has little mechanical strength, and the problem is often discovered when the component fractures. Similarly, one component of a two-phase alloy can

[c]The corrosion rate quoted is a typical average value. The rate varies according to depth, and a number of other factors, with the region around high tide normally having the highest corrosion rate. Recently, the phenomenon of accelerated low water corrosion has been identified, with corrosion rates of 1 mm/yr or more, and corrosion protection should be considered for all new structures.

Fig. 1 Galvanic corrosion of a steel blank flange around a threaded brass coupling from a liquid fertilizer storage tank. *(View this art in color at www.dekker.com.)*

corrode preferentially, when the process is better called selective attack (Fig. 2).

Differential Aeration Corrosion

When there is a difference in oxygen content between two parts of a component, the part with the higher concentration will tend to become more alkaline (and may passivate), while the part with the lower concentration will tend to become more acidic (and will corrode more readily). The acceleration in corrosion rate due to differential aeration is relatively limited, because there must be a relatively large anodic area compared to the cathodic area in order to produce enough alkalinity to passivate the steel.

Crevice Corrosion and Pitting Corrosion

These forms of corrosion are similar to differential aeration corrosion, in that an oxygen-free region becomes acidic by virtue of the net anodic reaction and consequently corrodes rapidly when coupled to a region in aerated solution. However, a key difference is that these forms of corrosion occur on alloys that are initially passive;[d] so there is no limit to the area of the passive, cathodic region. Thus, the severity of the attack may be much greater (Fig. 3). Crevice corrosion occurs when there is a narrow gap between two pieces of metal or a piece of metal and an insulator. The oxygen is consumed by the slow passive corrosion in the crevice, causing the crevice to become sufficiently acidic that the passivity breaks down and active corrosion starts. This then produces stronger acidification and reinforces the process. Pitting corrosion occurs on a free surface, often initiated by a local defect in the passive oxide, such as a surface sulfide inclusion (though in service, it is often initiated by a local crevice under a particle of dirt or similar). Once the pit has initiated, it is stabilized in essentially the same way as crevice corrosion. While they also occur in other passive alloys, crevice corrosion and pitting corrosion are particular problems with stainless steels, particularly in chloride-containing solutions. The main approach to control of these problems is in alloy composition, where increasing chromium, molybdenum, and nitrogen contents improve the resistance to pitting and crevice corrosion.

Flow Effects

Solution flow typically enhances corrosion rates, by increasing the transport of dissolved oxygen to the metal surface, by increasing the rate of removal of protective corrosion products, and, in extreme cases, by physically removing the corrosion products or even metal (in the case of erosion by suspended particles or cavitation) (Fig. 4). In a few situations flow can be beneficial; thus for stainless steels in chloride solutions, flow can prevent the development of the acidification that is necessary for pitting and crevice corrosion.

Stress Corrosion Cracking

The term SCC can be defined as ''the initiation and propagation of cracks in a metallic component as a result of the combined influence of a mechanical stress and a specific corrosive environment''. The stresses involved may be externally applied working stresses or internal residual stresses (often produced by deformation

[d]It can be argued that any form of corrosion that occurs in a crevice is crevice corrosion, and any form of corrosion that leads to small local penetration is pitting corrosion.

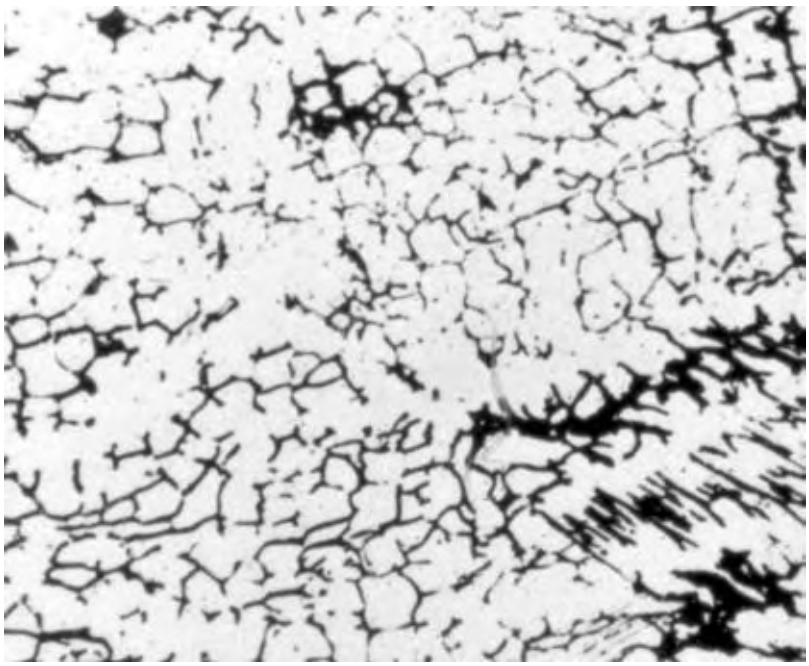

Fig. 2 Selective attack of the black ferrite phase in a stainless steel weld bead. *(View this art in color at www.dekker.com.)*

or welding during fabrication). Most alloys will suffer from SCC in some environments, usually ones that give a relatively low rate of general corrosion. Crack growth rates vary over a wide range, with typical times to failure ranging from hours to years (Fig. 5).

Corrosion Fatigue

Metal fatigue is the process of crack initiation and growth due to the action of a fluctuating mechanical stress. Corrosion fatigue is simply metal fatigue that

Fig. 3 Crevice and pitting corrosion of a stainless steel autoclave head. Note the crevice corrosion underneath the bolts (now removed) and in the gap between the two parts that are still assembled, and the pitting corrosion on the free surface. This corrosion was probably caused by chloride derived from thermal insulation. *(View this art in color at www.dekker.com.)*

Fig. 4 Flow-induced corrosion of a pump impeller. *(View this art in color at www.dekker.com.)*

is accelerated by the action of a corrosive environment (Fig. 6). The typical effect of corrosion is to reduce the time to failure compared to testing in air, especially at lower stresses and cyclic load frequencies, and to reduce or eliminate the fatigue limit.

Hydrogen Effects

Hydrogen embrittlement

Hydrogen will dissolve easily in metals, and, once in solution, it can cause brittle fracture. In general, body-centered cubic metals, such as ferritic steels, are most susceptible to hydrogen embrittlement, while face-centered cubic metals, such as austenitic stainless steels, are much less susceptible. Additionally, the susceptibility increases as the strength of the material increases (Fig. 7).

Hydrogen-induced cracking (HIC) and stress-oriented HIC

These processes involve crack formation by the precipitation of dissolved hydrogen onto lamellar nonmetallic inclusions. They are a particular problem

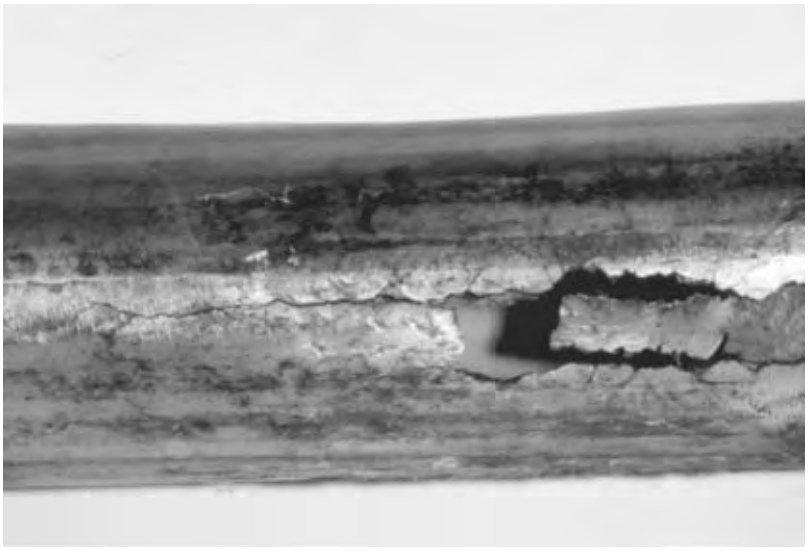

Fig. 5 External SCC of a stainless steel pipe after contact with wet, chloride-containing, thermal insulation.

Fig. 6 Environmentally assisted cracking of a weld in a deaerator, caused by a combination of static residual and cyclic operating stresses, and revealed by magnetic particle inspection.

in equipment handling 'sour' hydrocarbon fluids that contain hydrogen sulfide (Fig. 8).

Hydrogen attack

This is a high temperature process relevant to equipment in petroleum refineries and petrochemical plants containing hydrogen. It is associated with the formation of methane by the reaction of hydrogen and carbon inside the steel. This results in decarburization, and the methane precipitates at the nonmetallic inclusions to produce cracking in a similar way to HIC.

Fretting Corrosion

Fretting corrosion occurs when two metal surfaces are rubbed together, usually in a relatively noncorrosive environment, such as moist air. The rubbing removes the protective oxide, allowing further oxidation to occur, and the oxide produced acts as an abrasive to accelerate this process.

Microbial Corrosion

Corrosion of steels and stainless steels may be induced by the metabolic products of microbial growth and

Fig. 7 Cracks in a high strength steel relief valve spring. The cracks have been revealed using a dye that penetrates into the crack then seeps back out into a porous white coating. The cracks were caused by hydrogen embrittlement of the excessively hard steel, coupled with tensile residual stresses and the storage environment on a chemical plant (with an occasional trace of H_2S). *(View this art in color at www.dekker.com.)*

Fig. 8 Hydrogen-induced cracking—note the internal split produced by the precipitation of hydrogen gas onto flattened sulfide inclusions.

reproduction. The classic case is the corrosion of steel by sulfate reducing bacteria under anaerobic conditions in soils, or under deposits and tubercles in waters. Stainless steels are also vulnerable to pitting in waters containing iron and iron manganese bacteria, in the event that hydrotest or cleaning waters are retained in equipment for long periods prior to recommissioning.

MANAGEMENT OF CORROSION IN NEW EQUIPMENT

Management of Corrosion by Design

The corrosion of an alloy in an environment is influenced by chemistry, temperature, stress, geometry, and galvanic effects, which are exacerbated in process equipment by heat transfer and fluid flow. All these factors can be varied by design, and it follows that the propensity of process equipment to corrosion can be influenced strongly by design detail.

Chemistry definition

The commonest cause of unpredicted corrosion problems is the failure to define, accurately, the chemistry of process streams, including startup, shutdown, and transient conditions, or to anticipate changes in chemistry at specific locations in equipment. The corrosivity of a process stream is often determined by its minor components, e.g., the presence of 10s–100s ppm chlorides can promote localized corrosion of stainless steels and other passive alloys. It is important that minor components are defined, quantified, and evaluated at the design stage, including their possible local concentration such as in distillation and separation equipment.

Heat transfer is a particular promoter of the development of local chemistries that are very different from the bulk fluid chemistry, in particular, where phase changes occur. Early condensates from acid gas/vapor streams can be very concentrated and corrosive relative to bulk condensates as in the cases of carbonic acid from steam, sulfuric acid from flue gases, and hydrochloric acid from refinery overhead streams. Initially, benign condensates or cooling fluids can concentrate due to intermittent contact with surfaces hot enough to promote concentration or dryout, as in the chloride-induced, external SCC of austenitic stainless steels under thermal insulation. Extremely high concentration factors are possible under boiling heat transfer in crevices or under deposits, or under film boiling conditions at high heat flux regions, as in water side, on-load corrosion in process and utility boilers. There are practical design measures, which mitigate the risks of developing corrosive microenvironments in heat transfer equipment, e.g., preferring tubeside water and horizontal orientation, or venting of top tubesheets in vertical, stainless steel water coolers, and the attenuation of heat fluxes in highly rated boilers by tube inlet ferrules.

Temperature definition

Although normally straightforward for bulk process streams, it is important to select materials for skin rather than bulk temperatures in heat transfer equipment, and to evaluate the effects of mixing exotherms on local bulk fluid temperatures, such as that may occur in acid addition/dilution equipment.

Control of stress and stress concentration

Design codes for process equipment specify maximum allowable stresses for materials, the basis for which varies, depending on the type of equipment and the class of material. Corrosion allowances are specified commonly in design to ensure that pressurized components remain thick enough throughout their service lives to maintain membrane stresses below the design maximum allowable levels.

In practice, process equipment commonly contains regions with substantially higher stresses. The codes sometimes allow higher stresses in local regions of the equipment, design stresses can be concentrated by defects in materials, and fabrication processes such as cold working and welding introduce ''residual'' stresses of the order of the yield stress.

Environmentally assisted cracking (EAC) problems such as SCC and corrosion fatigue commonly initiate at such high stress regions. Clearly, locally high stresses permitted by the design code are ''given'', and if they present a risk of EAC to a specific material, then an alternative must be specified. However, stress concentration effects arising from defects can be mitigated in design

by specifying detail such as transitional radii at changes in cross section, machining/grinding of weld toes, quality of surface finish, etc. Residual stresses can be reduced in design by specifying processes such as thermal stress relief, temper bead welding, peening, etc.

Control of geometry

The major effects of geometry relate to vulnerability of process equipment to crevice corrosion and erosion–corrosion.

Crevice corrosion in process equipment is associated most commonly with flanged joints with gaskets, heat exchanger joints, and weld defects. Screwed and socket welding flanges present crevices to the fluid, whereas slip-on welding and welding-neck flanges avoid crevices. Care is needed in the specification and sizing of gaskets to avoid crevices. The ubiquitous tube/tubeplate joint in tubular heat exchangers is inevitably at potential risk of crevice corrosion, particularly where high heat transfer rates into the crevice can superheat the crevice relative to the bulk fluid.

Consideration might be given in design to locating fluids that might promote crevice corrosion on the tubeside of the exchanger, and/or to procedures for closing off crevices such as tubeplate back face bore welding. Plate and other compact heat exchangers, with very large areas of compression or welded joints, can be particularly vulnerable to crevice corrosion, and consideration might be given to upgrading the material to mitigate risks. Crevice corrosion can occur at welds where lack of sidewall fusion or root penetration creates a crevice, and appropriate fabrication and inspection procedures must be implemented to prevent such defects.

Erosion–corrosion is avoided in design through the use of limiting velocities for fluids that have been established by testing and/or experience. Beyond that, it is important to design and fabricate fluid systems to minimize flow disturbance, by using where appropriate long radius bends/elbows and gradual changes in cross section, ensuring that flanges are aligned correctly, avoiding excessive weld root protrusion in fabrication, etc. It is also important to select, size, and locate components that disturb flows, such as probes, valves, and orifice plates, to minimize local and downstream turbulence. Thus, it is a good design practice to locate control valves and orifice plates away from bends, etc.

Control of galvanic effects

Inevitably, process systems are constructed in a variety of materials, and the potential for galvanic interaction needs to be addressed in the design. Although the risk of galvanic corrosion is confined mostly to mixed metal systems, carbon/graphite (widely used in heat exchange and jointing systems) and silicon carbide (mostly a heat exchanger material) are sufficiently electrically conducting for their potential contributions to galvanic corrosion to require evaluation.

Available galvanic series of materials have been obtained in specific environments, mostly seawater, and are of limited use in galvanic corrosion risks in chemical process fluids that may have very different conductivities, tendencies to promote passivity on specific materials, etc. However, as a general rule, it is a good design practice to avoid material combinations that are widely separated in such series, and in particular, to avoid unfavorable area ratios involving small areas of ''active,'' anodic metal coupled to large areas of ''noble,'' cathodic material, e.g., more active fasteners and weld filler metals. Galvanic effects may be mitigated through coatings. Preferably, both couple members are coated, but if only one can be coated, it should be the noble, cathodic member. Equipment items judged to be vulnerable can, in principle, be isolated electrically using insulated flange joints, but in practice this may be frustrated by remote earthing via steel supports, pipe hangers, etc. Galvanic effects at material breaks in piping systems can be mitigated by physical separation of couple members using insulated spool pieces made from FRP, or coated, more noble couple member. Galvanic effects can be overridden by applying cathodic protection to the couple, as in the protection of the water boxes of seawater coolers by sacrificial anodes.

Management of Corrosion by Materials Selection

Materials selection for corrosion resistance is as reliable as the information upon which it is based. Corrosion information derives from two sources—experience or test results.

Experience is sometimes codified in the form of industry guides that address generic, industry-wide corrosion problems. More commonly, experience takes the form of corporate experience of materials performance in specific applications, obtained from the operation and inspection of existing equipment. This information may be accessible across corporate boundaries through informal industry networks, depending on its commercial significance, and electronic networks, such as CORROS-L (see www.jiscmail.ac.uk) and the NACE Corrosion Network (see www.nace.org), which are increasingly important.

In the absence of relevant experience, materials selection decisions have to be based on the results of corrosion tests, which range from relatively simple,

laboratory procedures, through semitechnical/pilot plant tests, to operating plant tests and trials. Corrosion test results are widely available in the public domain, usually as tabulated corrosion rate data for specific environments, from materials suppliers and professional corrosion organisations. Alternatively, new corrosion tests can be undertaken to inform materials selection decisions for applications where no relevant experience or test data is available.

Corrosion tests have inevitable limitations in their capacities to mimic actual service conditions of equipment. Standard, ambient pressure, immersion test procedures, with intermittent fluid refreshment, are available for both metallic and nonmetallic materials, but are limited to the ambient pressure boiling point of the fluid, and provide limited scope to simulate the effects of stress, geometry, heat transfer, and fluid flow. Such test procedures can be conducted at plant pressures and temperatures in autoclaves, and can be upgraded to focus on specific factors such as fluid flow and heat transfer. Even so a laboratory test, however elaborate, is a poor substitute for a test in the plant itself.

The key advantage of plant testing is direct exposure to the service fluid, thereby avoiding the risks of missing undefined, significant fluid constituents, or time-dependent chemistry changes, in unrefreshed laboratory liquors. Test coupons can be installed in plants in racks, or bolted directly onto trays, baffles, flanges, slip rings, etc, or onto retractable coupon holders. Care is needed to locate test coupons in the right places, particularly where phase and/or chemistry changes occur such as in separation and distillation equipment. Test plant components such as spool pieces, impellers, heat exchanger tubes, agitator paddles, column internals, etc., provide perfect simulation of all potential contributory factors to corrosion, as long as the attendant risks of premature failure can be accommodated.

It is not uncommon for new processes to encounter significant corrosion problems during the early stages of commercial operation, reflecting the poor reliability of the information used to select materials. Public domain corrosion tables are useful guides to corrosion performance but, not least because of the common absence of test details, are relatively unreliable information sources. Laboratory and/or plant coupon testing are more reliable, but the most reliable information derives from field performance data from operating plant inspections and/or long-term plant component tests. It is also important that materials selection is an integral part of process design from the earliest, chemistry definition stages through process design iterations, and that any laboratory, semitechnical, pilot plant, and sidestream activities are used to evaluate candidate materials as an integral part of process development.

Management of Corrosion by Inhibition

Although its scientific basis is beyond the scope of this contribution, corrosion control by the addition of corrosion inhibiting chemicals is important in several areas of chemical processing. The major application is in the management of corrosion, principally of steel, in cooling water and steam raising systems. Well-established practices are available commercially, and the great majority of corrosion problems in process industry water systems arise from the failure to specify at the design stage, and/or manage in service, appropriate water treatment practices. Inhibition is practised in several other areas of chemical processing, including the control of overheads corrosion of steel and other alloy heat exchangers by condensing hydrochloric acid in oil refining, and the control of wet carbon dioxide corrosion of steel vessels and pipelines in oil/gas recovery and acid gas stripping.

Management of Corrosion by Coatings and Linings

A wide variety of coatings and lings are available for the protection of steel in chemical process equipment, and they often provide cost-effective alternatives to more expensive, corrosion-resistant alloys.

Chemical plant atmospheres can promote particularly rapid atmospheric corrosion. For structural steelwork, galvanized zinc and/or paint coatings are usually specified. As alternatives to galvanizing, a variety of zinc- or zinc phosphate-containing primers are specified routinely, overcoated with compatible paint systems, including micaceous iron oxide epoxy, acrylic polyurethanes, silicones, etc. Paint coatings are also used for the prevention of atmospheric corrosion of process equipment, although care is needed in the use of metallic zinc, because of concerns about polarity reversal on warm/hot surfaces. A particular concern is the control of external corrosion beneath thermal insulation and fireproofing, for which relatively high-quality paint systems are required for the protection of steel, while thin aluminum foil is an alternative to paint coatings for reducing the risk of external SCC of stainless steel surfaces.

High performance paint coatings can be used for the internal corrosion protection of steel process equipment such as storage tanks, pipelines, vessels, and even heat exchangers, although a detailed account of the options is beyond the scope of this contribution. In environments where the corrosion rate of steel would be $>\sim 0.5$ mm/yr if exposed, thicker linings are preferred to relatively thin paint coatings. A wide range of thermoplastic, FRP, rubber, and glass linings are available, depending on the application.

Corrosion-resistant metals and alloys, including stainless steels, nickel alloys, titanium, zirconium, and tantalum can be applied as linings or claddings to cheaper steel substrates. Most (>90%) are applied by roll bonding, but weld overlaying and explosive bonding are also used, as appropriate. Particularly expensive metals, such as tantalum, can be used as very thin (~0.5 mm) loose linings.

Management of Corrosion by Electrochemical Intervention

Wet corrosion of metals being an electrochemical process, it can be controlled, in principle, by electrochemical intervention, and commercial practices are available for specific applications. The most widely used technique is the cathodic protection of steel in soils and waters, which involves lowering the potential of steel to levels at which the rate of corrosion is negligible using distributed sacrificial anodes of zinc, magnesium or aluminum alloys, or inert impressed current anodes driven by an external power supply. Cathodic protection is used commonly in association with coatings, to confine current demand to defect sites in an otherwise protective coating. It is used in the process industries for the external protection of buried/immersed pipelines and infrastructure, and occasionally the internal control of corrosion, including galvanic corrosion, in tubular water coolers.

Anodic protection involves the promotion of passivity on steel or stainless steel equipment by raising and controlling the potential into the passive range in the process fluid, using auxiliary cathodes, or coupling to more noble materials, or by the addition of oxidizing species to the fluid (a special case of inhibition). Anodic protection is used mostly to extend the useful range of stainless steels in reducing sulfuric and phosphoric acids, where it finds practical usage in heat exchangers and storage tanks. It is used, not merely to control corrosion at acceptable rates, but also to prevent unacceptable contamination of process fluids with corrosion products.

MANAGEMENT OF CORROSION IN OPERATING EQUIPMENT

The corrosion performance of equipment in service is determined largely by decisions taken at the design stage. However, design decisions often anticipate appropriate management and maintenance processes in service, and if these are not delivered, then problems may ensue. For example, if the plant is operated, knowingly or otherwise, outside the design envelope, the risk of corrosion will increase, and it can only be mitigated by appropriate review of the original materials of construction under the revised process conditions, and upgrading if required. If corrosion is to be controlled by corrosion inhibition, or electrochemical intervention, then corrosion risks in service will be determined by the extent to which these processes are managed and maintained according to the design intent.

In modern practice, corrosion risks in operating chemical process equipment are managed within the broader context of loss-of-containment risk mitigation, based mainly on risk-based inspection (RBI). The principles of RBI are beyond the scope of this contribution, but are based essentially on risk mitigation by optimizing inspection frequency and coverage, using appropriate tools, techniques, procedures, and practices. The results of these activities define whether the design intent is being realized in practice, or whether further risk mitigation is required in the forms of equipment replacement or repair, or equipment modification and redesign (increased corrosion allowances, changes in materials, addition of coatings/linings, addition of corrosion inhibitors, etc). They also define the need for additional monitoring of corrosion rates through appropriate inspection and/or monitoring techniques.

The inspection of process equipment to detect and size corrosion damage is beyond the scope of this contribution, and the following summary is confined to techniques that can be used for on-line corrosion monitoring. Techniques such as radiography and ultrasonics can be used externally to track corrosion distribution, wall thickness, and defect size through periodic measurements, but there are limitations relating to sensitivity and conditions of measurement. Periodic or continuous fluid analysis for the presence/concentrations of corrosion products can provide useful information, but the locations and distributions of the corrosion from which the products arise can only be inferred. Otherwise, the available techniques for corrosion monitoring fall into three broad categories.

Firstly, there are techniques that provide information on accumulated metal loss, from which average corrosion rates can be obtained by periodic measurements. The simplest approach involves the use of coupons, which can be retrieved at intervals from critical locations on the plant to provide average corrosion rates from weight or dimensional change. Alternatively, probes with elements comprising strips, wires, or thin-walled tubes of the test material can be inserted at critical locations, and the changes in their dimensions monitored by changes in their electrical resistance, which can be measured readily and intermittently online, the latest commercial technology being sensitive to nanometer changes in dimension. In a third technique, hydrogen that has been generated during

corrosion of the internal surface permeates the wall of a pipe or vessel and is collected in a chamber on the external surface, where the change of pressure can be related to metal loss on the internal surface.

A second category of techniques based on electrochemistry, provide instantaneous measurements of corrosion rate/state. Linear polarisation resistance and electrochemical noise measurements require the introduction of probes with varying numbers of elements of test material. Measurements are made across individual pairs of elements, involving the detection of small changes in potential or current, which are generated spontaneously, or in response to the application of small potential or current perturbations. Corrosion rates, and information on the propensity to localized corrosion, can be generated from the measurements, the principles behind which are beyond the scope of this contribution. The corrosion potentials of plant components can be measured online, and although they contain no information as to corrosion rate, they can provide useful information as to whether components are passive or not, or close to potential ranges where there may be a vulnerability to localized corrosion. Finally, in an electrochemical variation to the technique referred to earlier, hydrogen that permeates through a pipe or vessel wall can be oxidized electrochemically in a cell strapped onto the pipe exterior, thereby providing an indirect measurement of corrosion rate on the interior surface.

The final two techniques allow remote, direct monitoring of metal loss from plant components. Thin layer activation (TLA) uses isotopes created in a surface layer of the component by proton irradiation. Corrosion is monitored through periodic measurements of the loss in activity as the surface corrodes, which can be made outside the pressure envelope. The electric field signature method (FSM) measures changes in the electric field pattern in a metallic structure induced by corrosion, from voltage measurements amongst pairs of an array of pins distributed on the external surface. TLA and FSM are sensitive to around 1% of layer depth and wall thickness, respectively. They are relatively expensive techniques, but find use in the diagnosis and control of critical and expensive corrosion problems on operating plant.

CONCLUSIONS

Corrosion will always remain a significant challenge to the process industries. Process technologies will continue to develop into areas where there is no relevant experience of materials performance. There are inevitable risks in the use of corrosion testing to predict materials performance. With the exception of a relatively few generic problems in the nuclear and oil/gas processing fields, corrosion models do not allow reliable prediction of materials performance. However, for the majority of process equipment, corrosion prevention is a relatively mature technology, based on major progress in the understanding of the mechanisms and control of corrosion phenomena over the last 40–50 yr. Much of this progress has been made through industry initiatives, and the accumulated knowledge and experience can be sourced in the activities and publications of bodies such as the National Association of Corrosion Engineers (NACE, http://www.nace.org), American Petroleum Institute (API, http://www.api.org), and the Materials Technology Institute (MTI, http://www.mti-link.org) in the USA, and the European Federation of Corrosion (EFC, http://www.efcweb.org) and DECHEMA (http://www.dechema.de) in Europe. Of particular relevance are the NACE Special Technical Groups (STGs) on Water Treatment (STG11), Petroleum Refining and Gas Processing (STG34), Process Industry (STG36–39) and Energy Generation (STG41), and the EFC Working Parties (WPs) on Corrosion and Scale Inhibition (WP1), Corrosion by Hot Gases and Corrosion Products (WP3), Nuclear Corrosion (WP4) and Corrosion in the Refinery Industry (WP15). Most process/chemical chemical engineers receive little or no training in corrosion and its management in their graduate education and early formative years. When corrosion issues arise in the design or the operation of process equipment, it is advisable to consult corrosion specialists on all but very routine matters, and the earlier the involvement of the specialist, the better.

Critical Phase Behavior

J. Richard Elliott, Jr.
Department of Chemical Engineering, University of Akron, Akron, Ohio, U.S.A.

INTRODUCTION

The critical pressure is defined as the pressure above which no vapor can exist. The critical temperature is defined as the temperature above which no liquid can exist. The supercritical fluid (SCF) region is, therefore, the region above both the critical temperature and the critical pressure. The subject of critical phase behavior can be perplexing to the uninitiated and painfully obvious to the fully indoctrinated. This entry is directed primarily at the former, especially those who have an appreciation for general thermodynamics and chemical processing but lack exposure to the nuances of the critical region. We also include a broad survey of patents and technology that impact chemical processing and relate to critical phase behavior.

BACKGROUND

For pure fluids, the critical region is complicated by behavior that cannot be easily correlated. The most obvious instance is the curvature of the temperature–density coexistence curve. Classical equations tend to overestimate the critical point when fit to data outside the critical region. In other words, the true curvature is flatter than the curvature of a classical equation. Mathematically, $(\rho^L - \rho^V) \sim (T_c - T)^{0.325}$ instead of the classical curvature given by $(\rho^L - \rho^V) \sim (T_c - T)^{0.5}$. Remedies for this problem generally take the form of either scaling crossover equations[1] or multiparameter equations.[2] Extensions to mixtures further complicate the issue. Critical scaling tends to be a specialized subject with no single approach being recognized as a conventional standard. Fortunately, the qualitative behavior from classical equations is generally correct once allowance is made for deviations very near the critical point. Because most applications of critical phase behavior are related to mixtures, the focus is on mixtures in this entry.

The critical region becomes very interesting when one considers the behavior of mixtures. At its most basic level, the critical point is the point at which the vapor and the liquid become indistinguishable at fixed overall composition. The path to the critical point follows an indirect route when the composition is rich in a supercritical component like CO_2 and leans in a heavy component like hexadecane. Above the critical temperature, one may easily find a dew point at low pressure, and an increasing fraction of liquid as one raises the pressure from that point. But increasing the pressure at fixed temperature may result in the fraction of liquid decreasing before one reachs the bubble point. How can this be possible? Raising the pressure at fixed temperature makes the vapor phase denser, making it a better ''solvent.'' The vapor phase then dissolves more of the heavy component. Ultimately, one reachs a point where all but one drop is vapor.

With this preparation, the reader can appreciate the key elements of a subject that can be challenging. The critical region is a space where phases are barely distinguishable; hence subtle changes make large differences. The focus in this entry is on critical phase behavior as it pertains to extraction and separation. We omit coverage of supercritical reactions because the phase behavior is qualitatively similar with or without reaction. Reactions merely alter the compositions. The impact on reactions of high compressibility in the critical region is of special interest, however, and initial study can be facilitated through the compilation of Noyori.[3]

BASICS OF CRITICAL PHASE BEHAVIOR

Fig. 1 provides the most logical starting point for any introduction to critical phase behavior. The solid curve represents the distinct boundary between the vapor and the liquid phases along the vapor pressure curve. The dashed lines, on the other hand, represent regions of the phase diagram that have been defined by convention for purposes of general reference. Physical properties like density, viscosity, and diffusivity vary continuously across these imaginary boundaries, but are generally similar within the designated regions. We focus especially on the properties near the critical point and in the SCF region because the properties in that region are sensitive to variables within the engineer's control, not just temperature and pressure, but also composition. This sensitivity can provide engineers with the ability to tune the phase behavior. If one includes liquid–liquid and micellar critical behavior within the scope of this subject, advanced topics like nanoscale morphology can be contemplated as well as more conventional topics like extraction.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007719

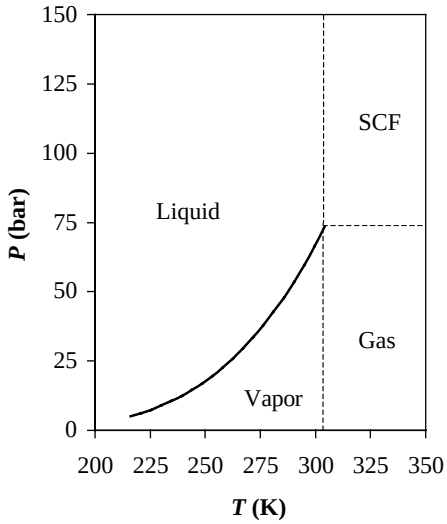

Fig. 1 Phase diagram for pure CO_2.

The key is to recognize the engineering possibilities when the thermodynamics are indefinite. Thermodynamics can be difficult and critical phase thermodynamics excruciating, but opportunities abound and much can be accomplished with a simple, general understanding of what is occurring.

Phase Diagrams and Classifications of Phase Behavior

Despite the many opportunities in the critical region, there are also constraints. Some of the most striking are the discontinuities that occur in the critical loci of mixtures. At first glance, one might assume that the critical points of mixtures should vary continuously from one pure component to the other as the composition varies. That does happen occasionally, but rarely in applications of interest.

In mixtures like CO_2 and polystyrene, the CO_2 phase can hold only a limited amount of polymer before polymer-rich phase begins to precipitate. One might suggest increasing the pressure to increase the density and the carrying power of the CO_2. But then a second liquid phase is more likely to form than a truly SCF phase. Or, at temperatures around 50–80°C, vapor–solid equilibrium may predominate. At the polymer-rich end of the critical locus, the critical temperature is extremely high. A small amount of CO_2 can be dissolved under these conditions, but the upper critical locus diverges toward very high pressures instead of approaching the critical point of CO_2 as the temperature is reduced. Such problems with polymers may seem relatively obvious in retrospect, but similar problems occur with lower molecular weight components like vegetable oil. Hydrogenation of vegetable oil is a common application, but one should consider the difference in critical temperatures between hydrogen (33 K) and vegetable oil (>600 K).

Clearly, we must carefully consider the constraints that arise when we combine components in the critical region. Fortunately, van Konynenburg and Scott[4] have analyzed these constraints in a very general manner and organized the analysis into a classification scheme like Aristotle's genus and species. Their approach was remarkably simple but effective. They studied the van der Waals equation of state for mixtures with a range of choices for the parameters a and b appearing in the equation. Qualitatively, these parameters are capable of describing the critical phase behavior of nearly all binary mixtures. Illustrations of the phase diagram types are given in Fig. 2.[5] Note that type VI behavior is not mentioned by van Konynenburg and Scott. However, type VI behavior can be exhibited by the van der Waals equation.[6] This behavior appears to be exclusive to aqueous systems.[7] Other type variations have been suggested over the years,[8,9] but the current consensus holds that these six types are sufficient.

Types II and III are the most commonly encountered in SCF applications. Classes I and V represent mixtures for which $H^E < 0$, where H^E is the excess heat of mixing. Generally, $H^E < 0$ when solvation interactions occur in the absence of association, as in the acetone + chloroform system. Strongly solvating mixtures like these are relatively uncommon.

These diagrams illustrate the trends of the critical loci as the composition changes. Critical loci roughly correspond to the upper limit of temperature and pressure for a phase envelope at fixed composition. Fig. 3 illustrates in three dimensions the compositions leading to each critical point. Above the critical locus, we would expect to see only a single phase. The slashes along the critical locus indicate the side on which the phase envelopes open up into two phases. In types III–V, the critical locus is interrupted by a vapor–liquid critical end point (VLCEP). At the VLCEP, the liquid phase splits into two liquid phases. An upper critical end point (UCEP) is similar, but the vapor merges with one of the liquid phases. In types IV and V, the lower critical end point (LCEP) also plays a significant role. The LCEP is a condition at which a liquid phase merges with a vapor phase. The resulting liquid–liquid (LL) condition gradually evolves along the critical locus into a vapor–liquid (VL) condition as the two tangent points on the Gibbs energy curve shift toward the VL critical point of pure component 2.

The work of van Konynenburg and Scott stands out as a classic throughout all of thermodynamics. A basic understanding can be achieved by noting how phase behavior depends on the strength of the molecular

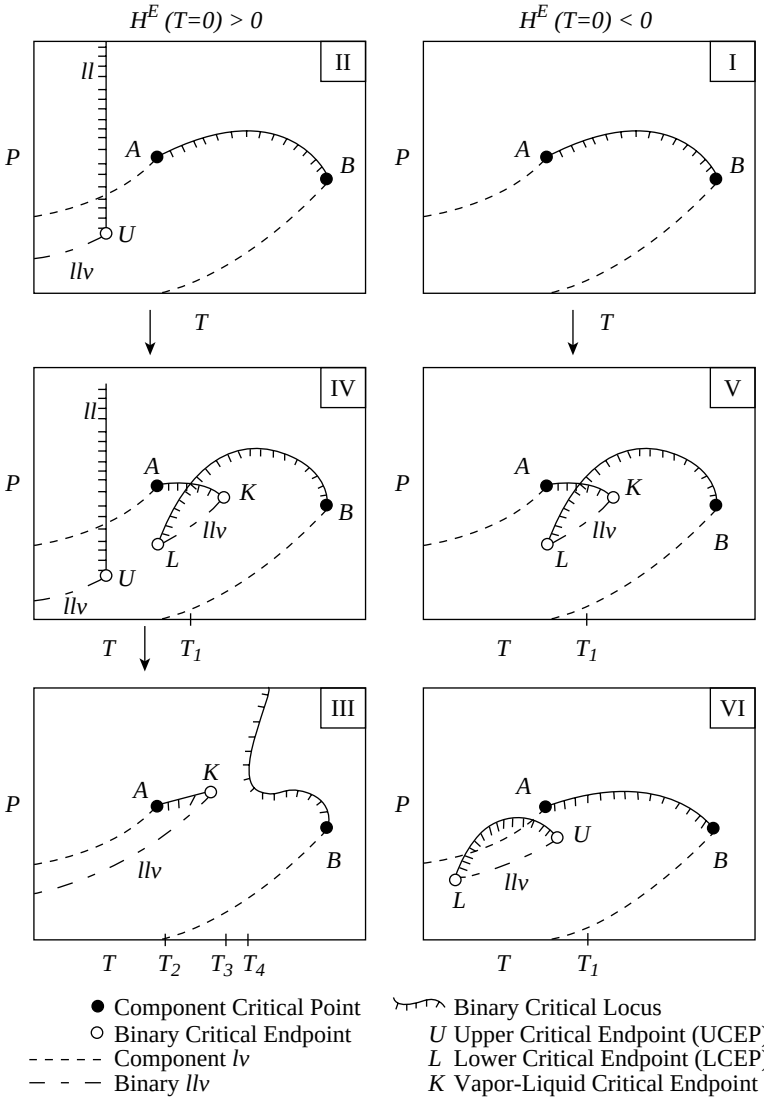

Fig. 2 Progression of binary phase behavior with increasing molecular asymmetry according to van Konynenburg and Scott. Arrows denote progressions of phase behavior expected by theory. Experimental progressions frequently differ. (From Ref.[77].)

interactions. Considering the quadratic mixing rule: $a = x_1^2 a_{11} + 2x_1 x_2 a_{12} + x_2^2 a_{22}$, with $a_{12} = (1 - k_{ij}) \times (a_{11} a_{22})^{1/2}$ we may observe that molecular attractions are weaker as k_{ij} becomes more positive. Strong molecular attractions are indicated by negative values for k_{ij}. van Konynenberg and Scott generalized their results by defining two dimensionless quantities describing the inherent difference between the two pure components, $\zeta \equiv (a_{11}/b_{11}^2 - a_{22}/b_{22}^2)/(a_{11}/b_{11}^2 + a_{22}/b_{22}^2)$, and the strength of their binary interaction by $\Lambda \equiv (a_{11}/b_{11}^2 - 2(a_{12}/b_1 b_2) + a_{22}/b_{22}^2)/(a_{11}/b_{11}^2 + a_{22}/b_{22}^2)$. By convention, the compound with the lower value of T_c is taken as component 1. Hence, a large value of ζ indicates that the components are very different in volatility. Note that $\Lambda = 0$ when $a_{12} = (a_{11} + a_{22})/2$, i.e., the arithmetic mean. A large positive value of Λ generally indicates weak binary attractions, but a better characterization of binary interaction is indicated by the curve for $k_{ij} = 0$. In the absence of any other guideline, the best approach is to follow the $k_{ij} = 0$ line when assessing the critical phase behavior for any given mixture.

The transition from I to II to III occurs as the binary interactions become weaker. This is especially clear when the pure components are similar in attractive interactions ($\zeta \sim 0$–0.4). Basically, the weakening binary attractions lead to less stable solutions. At high values for ζ, the differences between the pure components are so large that slight weakness in the binary attraction destabilizes the liquid phase. Indeed, types III–V all exhibit two liquid phases. This is surprising for the type V case, because the binary attractions are quite strong.

It is tempting to ascribe the trend in ζ to a difference in sizes of the molecules, because the larger molecules tend to have larger values for a. On the other hand, Fig. 4 assumes that the molecules have equal size; hence, there must be some other explanation. To clarify,

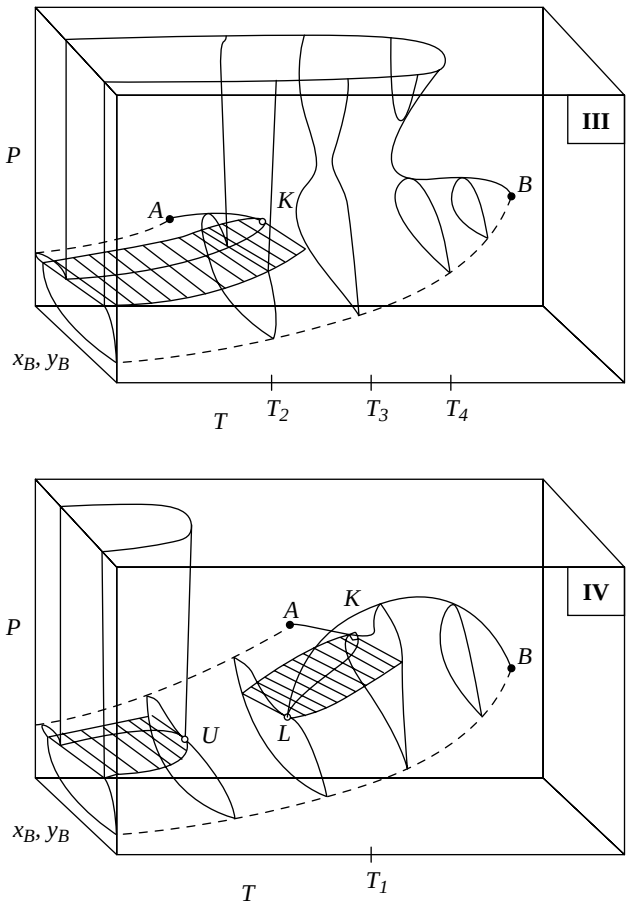

Fig. 3 Type III and IV phase behavior illustrated in three-dimensional diagrams. Symbols and labels are the same as Fig. 2. (From Ref.[77].)

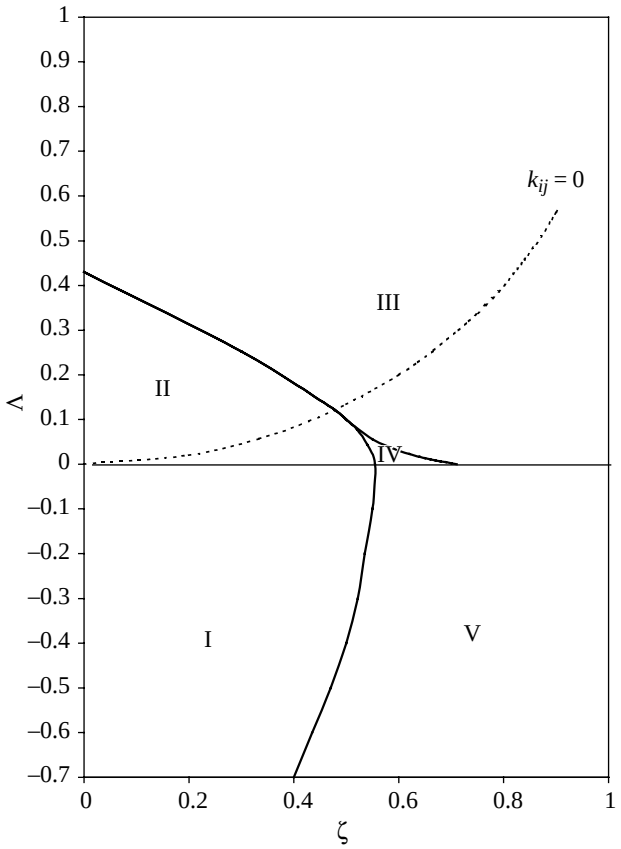

Fig. 4 van der Waals master diagram for equal-sized molecules. (From Ref.[4].)

Elliott and Lira[5] show that $a/b^2 \sim \delta^2$, where δ is the solubility parameter. For large molecules, the solubility parameter varies little with respect to molecular weight. Thus, increases in ζ correspond primarily to increases in cohesive energy density, not molecular size. Taking pentane as an example of component 1, we can estimate ζ from solubility parameters to be 0.16, 0.27, 0.33, 0.40, 0.52, 0.62, 0.84 for cyclohexane, benzene, acetone, n-hexanol, ethanol, methanol, and water. This provides an idea of the range of chemical functionalities addressed in Fig. 4.

The van der Waals equation was an excellent choice for van Konynenburg and Scott, but it does have its limitations. By choosing the van der Waals equation, the fundamental model was greatly simplified. Simplifying as much as possible is highly advisable given such a complex problem to begin with. Unfortunately, this choice results in a certain degree of ambiguity when it comes to classifying the phase behavior for a given mixture of interest. Because the van der Waals equation gives only qualitative accuracy, reliable values of the binary interaction parameters are rarely known for mixtures of interest. With these limitations, the accepted practice is to classify the phase behavior according to the experimental observations rather than relying on a strict interpretation of the van der Waals equation. For example, cyclohexane and benzene are best represented by $k_{ij} > 0$, but they are not believed to exhibit LL behavior. Hence, they are classified as type I.

One might assume that reproducing the van Konynenburg and Scott analysis for any new equation should be straightforward given the advances in computers since the work was originally performed in 1968. Figs. 5 and 6 shed light on why this is not the case. These figures show how subtle changes in the Gibbs energy lead to substantial changes in the phase behavior. In some cases, the important values of Gibbs energy look like little more than slips of the pen. In Fig. 5, a bend in the Gibbs energy at low x_2 indicates the existence of a vapor root, but the tangent line connecting this root to the liquid lies above the tangent line connecting the two liquid roots. As Gibbs energy must be minimized, the tangent line between the two liquid roots is favored if a sufficient amount of component 2 is present. Otherwise, the VL region is the most relevant. In Fig. 6, all three roots lie on a

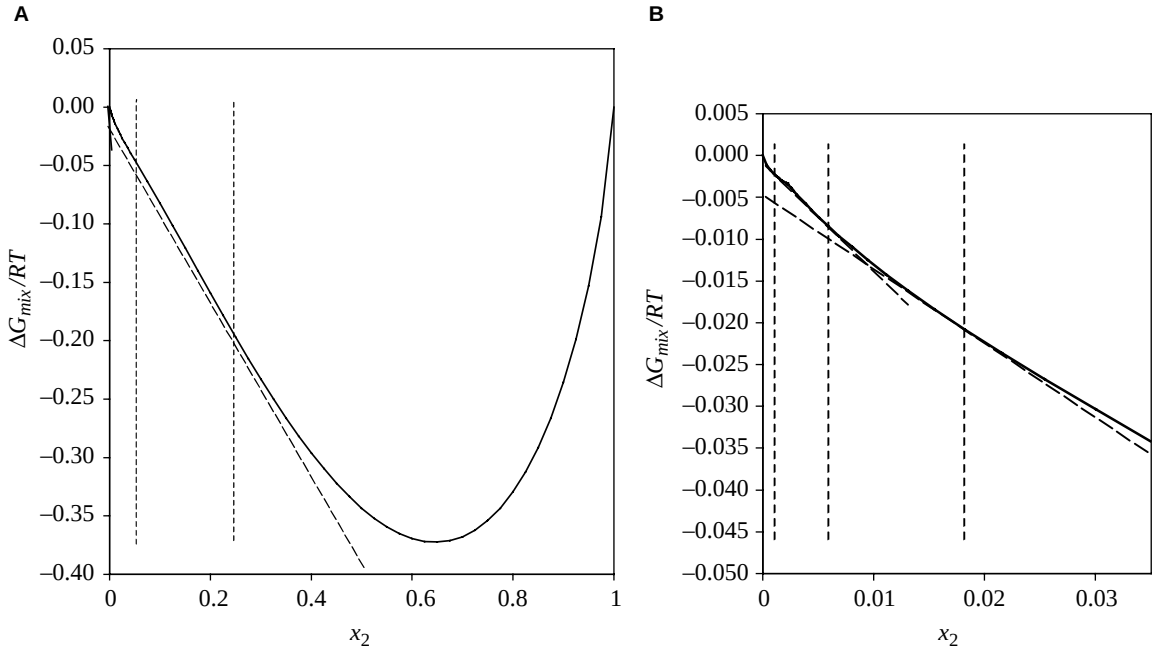

Fig. 5 Gibbs energy of a system inside the VLL region of a type IV or V system showing the LL tangent (A) and the VL tangent (B) at the same conditions of $T_r = 1.005$, $P_r = 1.0$. *(View this art in color at www.dekker.com.)*

single tangent line, indicating that this condition lies exactly on the liquid–liquid–vapor (LLV) line. Noting that Figs. 5 and 6 represent the same pressure at increasing temperatures, we may wonder what happens when the temperature is further increased at constant pressure. Basically, the middle root recedes from tangent line and we are left with equilibrium between the vapor and lower liquid. Note that van Konynenburg and Scott show this same transition analysis over a wider range of conditions, but their figures are highly idealized, masking the subtlety of the changes in Gibbs energy.

Figs. 5 and 6 illustrate instances of type IV or V behavior near the high-pressure LLV line. This LLV line is a short segment, in contrast to the low-pressure

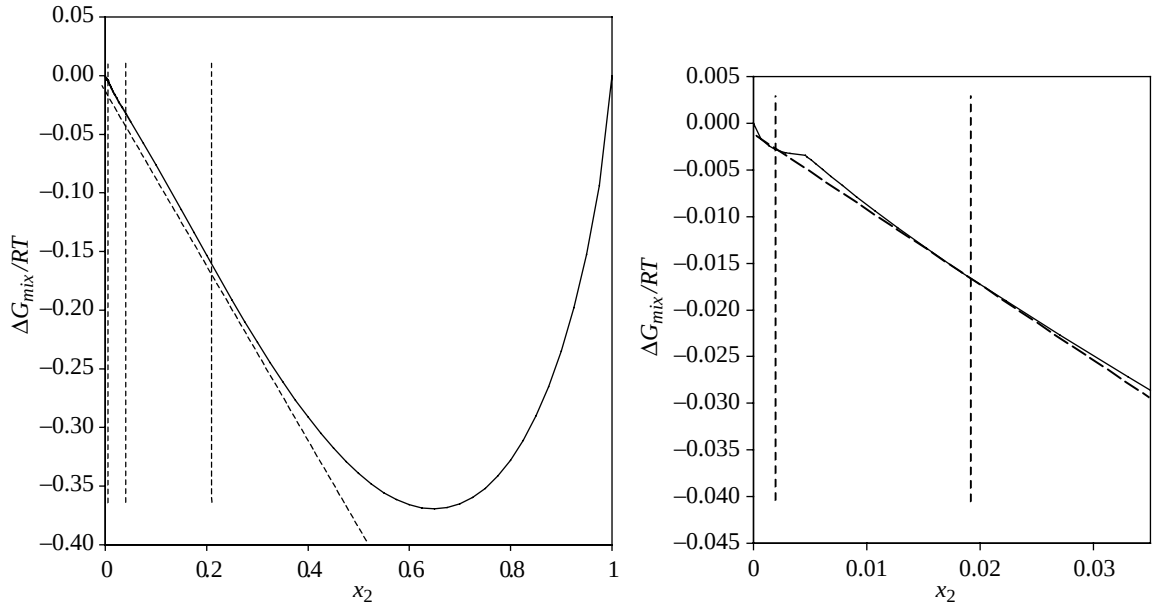

Fig. 6 Gibbs energy of a type IV or V system showing the LLV three-point tangent at $T_r = 1.010$, $P_r = 1.0$. *(View this art in color at www.dekker.com.)*

LLV line in types II–IV. The low-pressure LLV line is relatively easy to identify computationally, because the liquid binodal region increases in size as one lowers the temperature. Therefore, it is simple to find the LLV region at a low temperature, then steadily raise the temperature using the previous result as the initial guess for the next. Initially, locating the high-pressure LLV line is more difficult because it only exists over a narrow range of conditions. Kolafa et al.[10] have developed a modern program for mapping global phase diagrams. By incorporating hydrogen bonding into their equation of state, they were able to easily reproduce the qualitative features of closed loop (Type VI) diagrams.

Finally, we should address the trend as the size ratio varies. The most substantial alteration is the expansion of type IV behavior. We can estimate the result at $k_{ij} = 0$ by considering the critical loci (SRK) as computed by the Soave–Redlich–Kwong[11] equation of state. Soave's SRK equation was shown to accurately correlate the critical loci of a large number of systems.[12] Considering only the behavior along $k_{ij} = 0$, we obtain a plane with ζ on the abscissa and ξ on the ordinate, where $\xi \equiv (b_2 - b_1)/(b_2 + b_1)$. In this instance, we compute ζ and ξ from a and b parameters of the SRK equation, which are different from a and b parameters of the van der Waals equation. Fig. 7 is the result of this procedure.

Several caveats should be noted while referring to Fig. 7. First, van Konynenburg and Scott observe a narrow range of type IV behavior from $\zeta = 0.26$–0.30 that is qualitatively consistent with Fig. 7, but their value of ξ was 0.333. Fig. 7 indicates a value of $\xi = 0.1$ to match this ζ range. We may explain this by noting that the values of a and b parameters are different for the two equations of state. Second, types I and V are omitted from Fig. 7 although many phase diagrams have been classified as types I and V experimentally. Similar to van Konynenburg and Scott, we attribute this to interference from solid phase boundaries in the experimental systems, hypothesizing that an LL region must exist at $T \to 0$ when the geometric mean is applied. Hence, type II systems will be classified experimentally as type I if the LL region lies below the solid phase boundary, and similarly for type IV and V systems. Third, it should be noted that for the SRK equation, the $\xi - \zeta$ relation increases up and to the left along a homologous series; hence, the number of components in a series that overlap the type IV region may be greater than initially anticipated. On a related note, solute molecular weights greater than ~500 all lie in a tiny portion at the upper left corner of Fig. 7. Thus, a vast amount of polymer solution experience lies in a region of Fig. 7 where types II–IV are barely distinguishable based on the current analysis, and small variations in k_{ij} would drastically alter the phase behavior. Finally, one should note that negative values of ξ are omitted in Fig. 7.

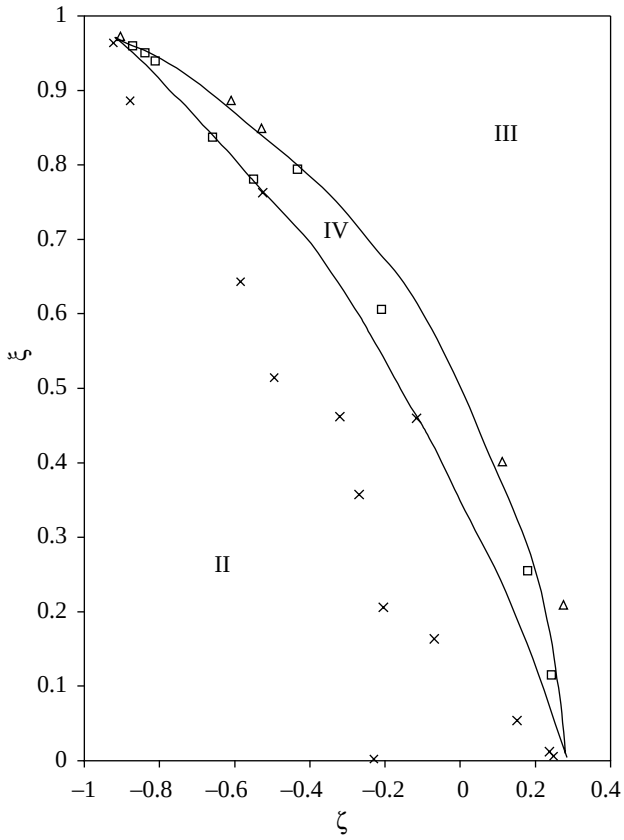

Fig. 7 SRK master diagram for phase behavior at $k_{ij} = 0$. X, Δ, □ are the computed type for II, III, and IV regions. Computations are based on n-alkanes with N_2, CH_4, C_2H_6, CO_2, CH_3OH, and H_2O as solvents.

A small number of the sampled binary combinations resulted in negative ξ values and no type IV behavior was observed, but the sampling was so sporadic as to be inconclusive.

With this background, the reader should be ready to consider the trends in phase behavior for a number of experimental systems. Several compilations are available for experimental systems and their type classifications.[7,13–16] These are typically in terms of homologous series, similar to the experimental programs themselves. We prefer to organize the list according to the type behavior. The type behavior plays a larger role the chemical processing.

Type I systems

A large number of these have been compiled by Rainwater[17] and Luks and Miller.[15] For the most part, these are mixtures of components with similar molecular weights and chemical structures like $N_2 + CH_4$, $N_2 + O_2$, or $\text{Refrigerant}_{22} + \text{Refrigerant}_{114}$. The components may differ structurally to an extent that the solution behavior would be classified as nonideal,

however, and azeotropes are possible. Some of the more unusual examples include: HCl + dimethyl ether, methane + pentane (and lower paraffins), ethane + n-heptadecane, propane + nonacosane, CO_2 + n-hexane, and N_2O + n-heptadecane[18] and ethyl ether + n-butanol. Simple systems like these can play important roles in refrigeration, especially if they form azeotropes. Applications of azeotropes in refrigeration are complicated by small variations in the azeotropic composition with respect to pressure. The result in the presence of a small leak is that the composition of the refrigerant varies depending on whether the leak is at high pressure or low pressure. This necessitates a protocol of replacing all refrigerant of an azeotropic system if any leak is suspected. Hence, even the thermodynamically simplest systems can induce frustration in a particular application.

Type II systems

The primary examples include CO_2 + n-heptane through CO_2 + n-dodecane. The CO_2 + n-hexane system is a prime example of a system that would very likely be type II if not for the interference of the solid phase boundary. The SRK equation of Fig. 7 overestimates the range of type II behavior for CO_2 systems, terminating with pentadecane instead of dodecane. Small positive values for k_{ij} would improve the likelihood of quantitative agreement in this regard, but distract from the utility of Fig. 7 as a general, qualitative guideline. CO_2 mixtures with 2-hexanol and 2-octanol also exhibit type II behavior. NH_3 + n-butane provides another interesting example of type II behavior. Other mixtures of NH_3 + higher hydrocarbons are likely to exhibit this type of phase behavior as well.

Type III systems

Type III behavior indicates the most extreme asymmetry between the components of a binary mixture. Nearly all H_2 systems supply striking examples of type III behavior. CO_2 mixtures with 2,5-hexanediol and 1-dodecanol are also classified as type III. The system CO_2 + n-tridecane is peculiar because it was classified by van Konynenburg and Scott as type III, whereas Enick et al.[19] have classified it as type IV, owing to experimental identification of a three-phase region. The system CO_2 + n-tetradecane is a variation on type III, where the solute-rich locus terminates in a solid(wax)–liquid–liquid boundary. Several important systems fall into a similar category. For example, CO_2 + naphthalene is commonly used as a model system for supercritical extraction. The naphthalene system differs from the n-tetradecane system in that the solute-rich locus terminates at a higher temperature than the solvent-rich locus, leaving an open gap. For CO_2 + tetradecane, on the other hand, the two loci overlap in temperature. Wax precipitation from natural gas (mostly CH_4) probably has a similar gap. In the temperature range of the gap, there is a large region of vapor + solid equilibrium, uninterrupted by liquid phases. The *x-P* plots commonly seen in the supercritical literature appear as *P-x* projections at constant temperature when considered in this light. These distinctions are clarified in Fig. 13.6 of Ref.[5]. Branching in the solute favors lower melting temperatures resulting in normal type III behavior, as exemplified by CO_2 + squalane.[20]

Type IV and V systems

We consider these two types simultaneously because they share their distinctive feature. That feature is an interruption in the critical locus where two liquid phases appear over a short range of compositions before the critical locus reappears as a liquid–liquid critical point. Unlike low-temperature LL behavior, varying the pressure has a strong impact on type IV or V liquid–liquid–equilibria, (LLE) making it appear or entirely disappear over a remarkably narrow range of pressures. Systems that exhibit type IV behavior include methane + 1-hexene and benzene + polyisobutylene, the only polymer solution mentioned by van Konynenburg and Scott. Peters has also speculated that methane and ethane mixed with alkylbenzenes will form type II–IV solutions, in contrast to the I, III, V solutions of the n-alkanes.[21]

The alkane mixtures provide the prototypical examples of type I → type V behavior. Methane + hexane (and higher alkanes), ethane + octadecane, and propane + pentatriacontane are all type V. The upper LL regions of these systems are noteworthy in that the temperature difference between the UCEP and the LCEP seems to monotonically increase with increasing carbon number.[21] Ultimately, this trend must reverse as type III behavior sets in, but no indication of this reversal has been observed experimentally. Mixtures of methane with hexane isomers provide unusual examples of type V phase behavior. Type V behavior is exhibited for all isomers except 2,2-dimethyl butane. Ternary mixtures of methane with the 2,2 and 2,3-isomers provide a rare example of tricritical behavior. Turning to another example, the type V LLV locus becomes extremely short as the asymmetry of the mixture increases to the point where transition to type III behavior is approached. Ethane + *p*-dichlorobenzene provides an example of this phenomenon, with an LLV locus extending over a mere 0.6 K.[22] Such an odd effect may seem to have little practical significance, unless one considers the impact of an unexpected precipitation on a critical pipeline.

A prominent chemical processing application of type V behavior is exemplified in the Selexol process. The Selexol process was originally based on type V behavior in propane + triglyceride systems and has also been applied to propane + fatty acids. Dimerization of the acids makes them perform effectively like ''diglycerides'' thermodynamically. Hixson et al. have published extensively on this process.[23,24] They have also developed the concept of using temperature gradients within an extraction column to enhance separations, a concept recently discussed in the context of SCF CO_2 extractions.[25] The glycerides partition favorably into the propane-rich phase. Downstream manipulations of the pressure and temperature lead to delicate fractionation of the glyceride constituents. As an example of a nutraceutical application, vitamin A has been produced in this way. Applications based on CO_2 or dimethyl ether remain as possibilities.

Summary of Phase Diagram Basics

Summing up, we reiterate that critical phase diagrams describe an array of subtle, complex behaviors. Some of these create opportunities for chemical processing like the Selexol process. Some characterize potential problems like wax precipitation. Either way, the phase diagrams provide concise insight into a broad scope of possibilities that researchers in high pressure chemical processing need to be aware of. It should be noted that the discussion here is actually quite circumscribed in that only binary mixtures have been explicitly considered. Recent work shows a quantum leap of higher order complexity when it comes to treating ternary mixtures and cosolvent effects.[26]

RESEARCH TOPICS

Beyond the basics, there are a number of efforts underway to advance the role of critical phase behavior in chemical processing. A few of these are already making an impact, but most remain as concepts under development. We briefly summarize key elements of these and provide links that should facilitate a broader understanding on subjects of interest. This list does not aspire to be comprehensive. Rather, it reflects the author's biased impressions of subjects that might resonate with developers of chemical processes. It is hoped that this brief survey will improve with feedback from readers and the passage of time.

Theory

Much of the traditional theory behind critical phase behavior has been discussed in the context of phase diagrams. This section is devoted to a brief review of fundamental studies that have been less fully developed when it comes to chemical processing in the critical region.

Among the early theoretical developments in SCF studies was the finding that solvent molecules tend to cluster around solute molecules,[27] giving rise to local density functionals that may deviate markedly from the bulk density. Similarly, local compositions differ markedly from bulk compositions. These composition enhancements have been demonstrated experimentally by fluorescence spectroscopy and theoretically by molecular simulation[28] and by integral equation theories.[29] This enhances the solubility of heavy solutes to a great extent. Another impact of the local composition is on reaction kinetics. One might suspect that reaction kinetics should follow the local composition rather than the bulk composition. In fact, this has been demonstrated experimentally and described theoretically.[30,31] There appears to be little recognition of these phenomena in chemical processing, but that may be because of lack of awareness on the part of reaction engineers. Alternatively, critical phase specialists may not be aware of high-pressure reactive processes that could benefit from this knowledge. Either way, this peculiar property of the critical region remains to be exploited in chemical processing.

One theoretical subject that has received much attention is the subject of equations of state. Equations of state based on conventional mixing rules, like the Peng–Robinson[32] or SRK equations, tend to underestimate clustering effects. Clustering is essentially a local composition effect. Another strong contributor to local composition anomalies is hydrogen bonding. The local composition mixing rules are typified by the Wong–Sandler modification of the Peng–Robinson equation (PRWS).[33] Methods like this are capable of correlating complex phenomena, but they show signs of detachment from physical reality. For example, the k_{ij} parameters tend to be extremely large and erratic in value. Nevertheless, this flexibility can be applied to clustering that arises from critical fluctuations or from hydrogen bonding, obviating the need to draw distinctions. At present, the PRWS approach is probably the least likely to fail when it comes to correlating complex phase equilibria. This makes it the next logical model to consider after trying a simple equation like the Peng–Robinson model. Hydrogen bonding equations of state are typified by the statistically associating fluid theory (SAFT) equation.[34,35] These models apply Wertheim's[36] perturbation theory to obtain an accurate characterization of the association and solvation interactions that are primarily responsible for the difficulties experienced in representing phase equilibria involving polar substances. These theories are very appealing from a chemical perspective and are promising for

predictions. The solvation parameters follow trends that would be expected from correlations of spectroscopic measurements like the Kamlet–Taft parameters.[37] One of the more important advantages of the SAFT approach is that extension to polymer solutions is entirely straightforward, which cannot be said of the PRWS approach. Furthermore, the formalism lends itself to treatment of copolymers just as straightforwardly. For example, Feelly et al.[38] were able to accurately predict copolymer solubilities in CO_2 over the range of 350–550 K and 1100–2100 bars using k_{ij} values calibrated for homopolymers. Optimization on the molecular scale is greatly facilitated by the SAFT approach, showing great promise for future development in chemical processing. A recent review of modifications and applications of the SAFT approach has been written by Muller and Gubbins.[39]

Petroleum Applications

Oil and gas recoveries provide examples of chemical processing at high pressure that arise quite naturally. A short list of related research topics would include CO_2 flooding for improved oil recovery, and wax and hydrate remediation in gas recovery.

The temperature and the pressure at which oil recovery takes place are steadily increasing as reserves are sought at progressively greater depths. The added expense of operating at these depths also intensifies motivation to enhance the productivity of each well as much as possible. One strategy for this enhancement has been to recover or generate CO_2 at the wellhead and inject it into the well to displace residual oil. The CO_2 is generally miscible with the oil, reducing its density and viscosity and facilitating recovery. The problem with this approach is that some of the CO_2 bypasses the oil and goes directly to the reservoir outlet. The method becomes ineffective when these ''fingers'' of bypass flow become numerous. To overcome the fingering problem, dissolving polymers into the CO_2 can enhance the viscosity. The problem then becomes improving polymer solubility. This has been a longstanding problem. Early work showed that additives like toluene were effective, but the amount required (>10 wt%) was too large to be economical.[40] An alternative approach is to customize the molecular structure to enhance solubility. Beckman et al. have found that fluorination promotes solubility to a sufficient extent that viscosity can be increased by a factor of 3 with 4 wt% polymer.[41] Unfortunately, fluorinated polymers are expensive. When considering the immense volumes of materials being pumped around in an oil field, a small percentage is multiplied by a very large number. To be economical, the viscosity enhancing agents need to be nearly as inexpensive as the oil itself. The subject of polymer solubility in CO_2 has stimulated research with biomedical applications. These are discussed in a later section.

Wax precipitation from natural gas is another longstanding problem being exacerbated by progressively deeper drilling. Assuming that natural gas is predominantly methane and the relevant phase diagram is similar to type III, it may be possible to surpass the critical locus at the elevated temperatures and pressures of reservoir conditions. As a related phenomenon, high-pressure synthesis of polyethylene from ethylene is known to operate in this upper region of the type III diagram.[6] All temperature and pressure drops would then result in precipitation in the recovery stream. Pedersen described one method of predicting solid–vapor precipitation based on the assumption of an ideal solution in the solid phase.[42] Recently, Coutinho et al.[43] have reported improved results when a predictive activity model is applied to the solid phase. The fluid phases have been accurately modeled with conventional equations and mixing rules in these instances. The availability of reasonable models for these systems provides opportunities to brainstorm through a number of prospective remedies. Promising strategies focus on precipitating at controlled locations and seeding heavy components that lower the viscosity of any wax that does form. With knowledge of the phase diagrams, it should be possible to accommodate wax precipitation problems with reasonable success.

Gas hydrates form when small molecules like nitrogen, methane, CO_2, or propane come in contact with water at pressures above 30 bars and temperatures of roughly 275 ± 30 K. The composition of the gas species in the hydrate is in the order of 5 wt%. Technically, hydrate description requires an entirely new family of phase diagrams. We defer to existing literature for a detailed discussion.[44] Like waxes, hydrates are a nuisance to gas recovery. A commonly suggested treatment is to dope the gas stream with methanol. Methanol disrupts the formation of hydrates, necessitating higher pressures before the hydrates can form. Recently, Peters et al. have reported that additives like cyclohexane or cyclobutanone can have the opposite effect, reducing the pressure or elevating the temperature of hydrate formation.[45] At first, this may seem like an added nuisance, but it adds a remediation strategy. If precipitation can be effected at controlled locations, then the problem may be remedied.

Bio/Medical Applications

The studies most commonly identified with supercritical fluids and critical phase behavior are those concerned with extraction of natural products. No review of this subject would be complete without

reference to the decaffeination of coffee.[46] A commercial process for many years, it still acts as a model system for treatment of natural products.[47] In this application, purification of the caffeine enhances the value of both the caffeine and the residue. More recent applications have focused on simply extracting the valuable component. Typical extracts have been alkaloids, triglycerides, fatty acids, and antioxidants. Any given issue of the *Journal of Supercritical Fluids* is likely to contain 3–4 articles on similar extractions. Fatty alcohols can be obtained from fatty acids by hydrogenolysis in near critical propane. The phase behavior of this system shows signs of type IV behavior with a pressure-dependent LL region near room temperature and 30 bars.[48] Apparently, these efforts are still largely academic. In a brief search, 72 patents since 1980 mentioned supercritical extraction in their titles. Many of the early patents were focused on upgrading fuels. Thirteen patents target specific natural products, with the earliest dating from 1989. Fatty acids and taxol related species are mentioned twice each. Three patents focused on flavors. The rest of the patents targeted esoteric species, with one recent patent focusing on a specific protein. None of the patents for natural products were from the United States. Three were from Europe, four from China, and six from Japan. This trend suggests that much of the chemical processing interest in natural products derives from overseas.

Greater interest in the United States has been focused on the formation of microparticles for encapsulation and time release applications. DeBenedetti et al. have described two processes for microparticle production: one by rapid expansion of supercritical solutions (RESS)[49,50] and one based on a supercritical antisolvent (SAS), for which they hold a patent.[51] In the RESS process, a homogeneous polymer + CO_2 solution is expanded through a nozzle, dropping the pressure and precipitating polymeric particles whose size and shape depend on the precise conditions of the expansion. Nineteen patents identified the concept of expansion from supercritical solution since 1988, the substantial majority of which targeted production of microparticles. In the SAS process, a homogeneous solution is exposed to a supercritical phase that does not dissolve the polymer, inducing precipitation. Eight patents identified the concept of SAS, including the original in 1993. Four of these were international patents and three were US patents. Five of these patents targeted drugs or proteins. Recent references to these applications provide links to further study.[52,53]

The attraction of CO_2 in these applications is its biocompatibility. Any residual CO_2 solvent will be readily metabolized. Use of CO_2 as a biocompatible solvent has required several adaptations to enhance the solubility of proteins and polymers in the CO_2 phase. Most of these have focused on fluorination,[54] although recent efforts have turned toward cheaper esters and ethers.[55] One such adaptation of CO_2 won a Green Chemistry Award for 2002.[56,57] Graft polymerization in CO_2 is another proven means of altering the compatibility and solubility.[58] Johnston et al. have demonstrated how fluorinated surfactants can be used to dissolve proteins into supercritical micelles.[59,60] Johnston is named in seven patents on drug and microparticle preparations. Taken together, the bio/medical applications appear to be some of the most promising for chemical processing in the near term.

Green Chemistry

Similar to CO_2's attractiveness from a biological perspective, it is also environmentally friendly relative to traditional solvents. This property suggests its extended use as a substitute in many applications where traditional solvents have been applied. Two examples can be cited from the paint and dry cleaning industries.[61]

Donohue and collaborators have developed a process for spray painting with CO_2 substituted in place of the usual solvents.[62,63] This is a fully developed, viable process, but it must compete with continually advancing technologies in the paint industry. The competing technologies are already reducing the proportions of solvent by lowering the molecular weight of the paint and making it reactive after coating.[64]

Dry cleaning with CO_2 is rapidly becoming a more competitive process. Two similar technologies were developed at Los Alamos and by DeSimone et al. These processes effectively use near-critical CO_2 for washing and a thermal cycle for regenerating the CO_2. This chemical process has received a surge of interest from ICI and Linde.[65] With this investment, it is likely that this process will increase market share over the near term. A related technology is dedicated to the use of CO_2 as a cleaning agent in the electronics industry. Los Alamos and DeSimone, among others, are now competing in the development of that processing technology.

Carbon dioxide is not the only nonflammable, biocompatible, and widely available solvent. Let us not forget about water. In particular, supercritical water oxidation and related reactive processes have shown a tremendous capacity for reducing toxic chemicals to innocuous constituents. Akiya and Savage have authored a recent review.[66] Of particular interest is the section on hydrolysis in SCF water. Numerous references are tabulated according to chemical family. With regard to the more toxic compounds, Klein et al. have been especially active for many years[67,68] and Tester et al. have focused on alkyl halides.[69]

Modell et al. have patented this technology for nonincineratory destruction of toxic chemicals.[70,71] Early work in this area was related to the supercritical extraction/depolymerization of coal. Lee et al. have found it possible to depolymerize scrap polymer such that clean monomers can be recovered, turning a liability into an asset.[72,73] This approach is especially interesting in the case of polyvinyl chloride (PVC). Whereas PVC normally degrades into polychlorinated hydrocarbons, the presence of oxygen and water promotes decomposition into the monomer and hydrochloric acid. Potential problems in this developing technology include clogging and corrosion.[74]

Summary of Research Topics

Widespread applications of small-scale critical phase technology, like dry cleaning and paint spraying, are likely to have a subtle, autocatalytic effect on general implementation. High-pressure processing equipment is generally perceived as being inherently high in capital cost. In actuality, doubling the mass of steel in one or two key components of an overall process makes a small difference in the overall cost. Major costs are involved, however, in custom developed equipment that requires repeated testing and redesign and cannot be mass produced. One way of representing this is by the size exponent of a cost estimation chart. An exponent of 0.24 indicates the importance of economies of scale for SCF equipment.[75] On the other hand, global demand for a specialty flavor or a nutraceutical is not the sort of thing that can be scaled to large values. Hence, one key to economical critical phase chemical processing is mass production of interchangeable components for small-scale operation. The economics and the prevalence of critical phase behavior in chemical processing could change substantially if such a development were to take place.

CONCLUSIONS

We have summarized briefly the key concepts and applications of a broad and complex subdiscipline of thermodynamics. Necessarily, selective judgments have been made as to what aspects of critical phase behavior are most important to chemical processing. Alternative perspectives on the role of critical phase behavior in chemical processing are readily available. For example, the role of reactive synthetic processes at critical conditions has received little attention here.[76] As one prospective source for further links, the article by Perrut provides an especially relevant survey.[75] Readers are encouraged to survey this literature for themselves and keep abreast of the latest developments. It is a subject of current research and its status in chemical processing is constantly evolving.

Cross-Linked Polyethylene

INTRODUCTION

In people's opinion, plastic is a light and weak substance that easily melts when warmed. And yet, cross-linking the carbon atoms suffices to transform such material into a superior material that may be resistant to temperature, pressure, corrosion, and that can be used in a variety of applications. In fact, polyethylene (PE) once cross-linked is advantageously employed in the fabrication of blanket insulation for electrical and telephone wires, pipes for the transport of cold and hot liquids, prostheses for the human body, and so forth. Since the late 1960s, when the European scientist Engel first succeeded in cross-linking PE, there has been a proliferation of cross-linking methods with the intention of fabricating a type of PE suitable for a specific need. There are many cross-linking methods; each method has advantages and disadvantages and no one method works well for every product. In fact, a cross-linked polymer obtained with one method may be excellent for one application, but it may be very inadequate for another application. It is important to choose the most effective method for the specific need and to comply with quality standards. Otherwise, a fixed sequence of operations alone does not ensure the product quality, but it is also important to characterize the products through appropriate testing and nondestructive evaluation. Another important point is with regard to the hazards and risks related to the substances, or devices, employed; manufacturers must comply with safety regulations and ecosustainability. The intended purpose of this article is to expose the reader to an overview of the existing methods and to give indications and suggestions about the most appropriate method for a specific application with the existing legislation involving both quality and safety aspects.

CROSS-LINKING METHODS

Polyethylene is certainly the most used kind of plastic. In fact, there are many things made of PE, from shop bags to envelopes for alimentary packaging, cases to hold and protect electronic devices, medical prostheses, and so forth. Indeed, the list could go on without end!

A long chain of carbon atoms (CH_2) represented as:

$$(-CH_2–CH_2–) \tag{1}$$

is also called linear, or high-density polyethylene (HDPE). However, the ethylene molecules do not always add on in a regular fashion, but sometimes, under high-pressure polymerization, ethylene molecules attach as short branches leading to low-density polyethylene (LDPE). Low-density polyethylene is much more economical to produce and can be used in many applications, which do not require specific material characteristics.

Since its accidental discovery in the early 1930s in Great Britain from the failure of a chemical reaction under pressure, researchers' efforts have been driven toward obtaining a PE with specific chemical, mechanical, and thermal characteristics for the fabrication of complex-shaped tools, or for use in adverse environmental conditions.[1] The fundamental way to improve material properties such as impact strength, chemical resistance, and thermal characteristics is via cross-linking. Indeed, the introduction of cross-linked polyethylene (PEX) in the early 1970s was another milestone in the plastic era. From that date, PEX has captured a giant share of the market because of its superior characteristics with respect to other plastics.

Modifications in the polymeric structure can be brought about by several methods, which differ from each other in two main factors. One factor is the state (i.e., molten or solid) of the polymer during cross-linking. The other factor is the type of activator used to promote cross-linking. In this article the different methods are grouped into two main categories:

- Chemical processes, which require a chemical initiator (peroxide or silane) to induce links in the polymer chain.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007720

- Radiation processes, which involve exposure to ionizing radiation from either radioactive sources or highly accelerated electrons, to liberate free radicals for cross-linking.

Chemical Processes

Cross-linking is activated by a chemical substance, which could be:

- A peroxide—the method is called peroxide initiated cross-linking. The resulting PE is also called PEX-A in the European standards.
- A silane—the method is called cross-linking via silane or moisture-based vinyl silane cross-linking. The resulting PE is also called PEX-C in the European standards.

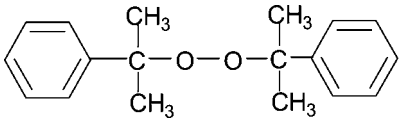
Peroxide processes

The basic process consists of the decomposition of a peroxide at high temperature and the creation of carbon bonds along the PE chain; cross-linking occurs in the molten state. This process was developed in the late 1960s in central Europe by the German scientist Thomas Engel and it is called the Engel process. Indeed, there are several different peroxide-based processes. In the Engel process, a granulated blend of PE, peroxide, and stabilizers is sintered together under high pressure; cross-linking occurs during extrusion through a long heated die. This process is generally used for the production of HDPE. In the Pont a'Mousson process, PE is mixed with peroxide, extruded, and cross-linked in a salt bath at high temperature; the resulting product is a low, or medium, density PE. In the Daoplas process instead, the peroxide is incorporated after extrusion and activated in equipment downstream (the extruder) at high temperature and pressure.

An organic peroxide is a carbon-based chemical that includes a minimum of two oxygen atoms bonded together (–O–O–).[2–4] The general formula is:

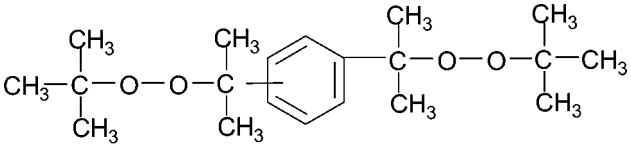
$$R^1\text{–O–O–}R^2 \qquad (2)$$

where R^1 and R^2 can be aryl, alkyl, or acyl groups. There are also peroxides with a second –O–O– bond and three R-groups. Owing to the chemical structure of such R-groups several different families such as alkyl, aryl, and acyl peroxides and peroxyketals are identified. The alkyl peroxides produce the most reactive free radicals and they are the most used for cross-linking.[4] Such peroxides may contain one –O–O– group, as in dicumyl peroxide:



(3)

or two –O–O– groups as in 1,3-1,4bis(*tert*-butylperoxyisopropyl) benzene:



(4)

The peroxyketals contain two peroxy groups bonded on the same carbon atom; this peculiarity causes instability and high reactivity and thereby complicates peroxide transportation, handling, and storage operations.

The peroxide cross-linking reaction occurs in three steps:

Step I: The addition of heat causes peroxide thermal decomposition (i.e., the oxygen bonds break via homolysis). One unpaired electron remains in each oxygen atom and promotes the formation of peroxide radicals.

Step II: Each peroxide radical reacts with the PE molecule, i.e., abstracts a hydrogen atom from the polymer chain, becoming a stable ROH species. The abstraction of hydrogen causes the formation of polymer radicals.

Step III: Two polymer radicals react with each other forming stable PEX.

Peroxides are mainly used for the production of HDPE pipes. The basic process consists of three steps.

- *Mixing*: The peroxide, in liquid or molten phase, is sprayed on PE granules.
- *Extrusion*: The compound (soaked granules plus eventual additives) is poured into the extruder where it is melted and shaped. The cross-linking reaction takes place either in the extruder (Engel) or in the downstream equipment.
- *Curing*: The extruded product enters the equipment where cross-linking is completed under controlled temperature and pressure. The use of high-pressure tanks is necessary for degassing of volatiles and avoiding the formation of voids inside the PEX.

Organic peroxides belong to the aromatic hydrocarbon/alkylbenzene/dialkylbenzene chemical family and are designated by the International Occupational Safety and Health Information Centre (CIS) with the symbols O (oxidizing), X_i (irritating), and N (environmentally

dangerous) and are collocated in the Hazard class 5.2. UN No. 3110. They are generally shock, heat and friction sensitive, and are incompatible with strong oxidizing agents, can react violently with reducing agents, heavy metals, concentrated acids, and concentrated bases, and may ignite organic materials on contact. Such substances can cause local irritations and burns of the skin and mucous membranes of the eyes and the respiratory tract. The risk and safety phrases are: R7-36-38-51-53 and S3-7-17-36-37-39. Thorough care and special technical regulations are required for transportation, handling, and storage.

Vinyl silane moisture

In this process, the cross-linking is activated by silane coupling agents. The organic moieties of silanes can react with many chemicals, including polymers, via typical organic chemistry reactions.[4–7] The organosilane molecule includes a central silicon atom (Si) bounded to two different categories of groups (vinyl and alkoxy), which exhibit different reactivity. The vinyl groups allow silane grafting to the PE backbone. The hydrolyzable alkoxy groups in the presence of water or moisture react (via condensation and hydrolysis) and generate a three-dimensional network of siloxane linkages.

The PE is cross-linked in the crystalline state. The use of silanes causes siloxane (Si–O–Si) bridges to form, which are less rigid than carbon-to-carbon (C–C) bonds induced by peroxides. On the other hand, because cross-linking is accomplished on the shaped product in the presence of water (70–95°C), there is a certain flexibility in the decision making about the desired degree of cross-linking. In fact, one may interrupt the process at a certain time to control the material rigidity. There are two main processes for cross-linking PE with moisture-cured vinyl silanes:

1. One-step (Monosil) process, which involves a continuous feeding of liquid silanes during extrusion. The extruder is equipped with a long barrier screw and an injection system. This speeds up production but poses safety problems owing to the volatile and flammable nature of silanes.
2. Two-step (Sioplas) process, which involves a step to prepare cross-linkable PE and another step to create the final product.

Step 1: A silane blend containing peroxide is melt processed with PE and formed into pellets, which can be stored for several months. Such copolymers can be obtained by two methods:

a. Reactor copolymers involving polymerization of ethylene with vinyl silane. Such technology produces stable copolymers with long shelf life. Conversely, polymerization in a high-pressure reactor results in highly branched products.
b. Silane-grafted PEs are fabricated in compounding equipment involving a single- or twin-screw extruder. Silane may be grafted to any ethylene-polymer, and so PEX of specific characteristics can be obtained. The resulting silane-grafted PE also contains hydrolyzable alkoxy groups, which, in the presence of water, react to join adjacent grafted PE molecules to form stable three-dimensional cross-linked networks of siloxane linkages.[6]

Step 2: The grafted PE pellets, combined with a catalyst masterbatch, is extruded and cured in a high-temperature water bath, or in a steam sauna, to reach the desired cross-linking level.

Polyethylene can also be cross-linked in a single step by using dry silane masterbatches (a powder composed of porous polymer carriers) with the dry silane process.[4]

Silane coupling agents possess the propensity to decompose in contact with atmospheric moisture and to produce hydrogen chloride, methyl alcohol, alkyl ethers of ethylene glycol, and other hydrolysis products. Under certain conditions autoignition can cause an explosion.[8] Thus, carefulness is essential in transportation, handling, and storage; personnel must wear protective equipment to avoid eye and skin contact. It is advised that silane coupling agents be kept away from fire and moisture.

Radiation Processes

These processes do not require addition of any chemicals to the original PE compound. The main effect of radiation is triggering of the chemical ionization process, which results in irreparable damage to the life sustaining chemistry of living organisms and the initiation of cross-linking in polymeric materials. Thus, radiation, apart from improvement of polymer characteristics, is used also for sterilization purposes and is particularly convenient for the cross-linking of PE for medical implants. Ionizing radiation results in energy transfer to the electrons orbiting the polymer nuclei, which causes excitation of the PE molecules. Two effects may be observed:

- Chain scission (radiolysis) with loss of hydrogen atoms and formation of free radicals; extensive chain scission entails reduction of molecular weight with material degradation.
- Cross-linking with merging of two hydrogen atoms to form a hydrogen molecule and merging of two

polymer radicals (via formation of carbon-to-carbon bonds). Cross-linking transforms a linear network into a three-dimensional one with an increase of the molecular weight.

Indeed, during radiation, both chain scission and cross-linking occur simultaneously and competitively.[9,10] The predominance of one, or the other, depends on many factors involving the sensitivity of the polymer to radiation effects (chemical yield), the irradiation dose, the dose rate, the presence of stabilizers or radical scavengers, steric hindrance effects, and the polymer radiation environment.[9] In the presence of oxygen, scission predominates over cross-linking, while in an inert environment, such as nitrogen, cross-linking predominates over scission.

There are two basic radiation methods: gamma radiation (γ) and electron beam radiation (EBR). The first involves exposure of products to a radioactive isotope as in Cobalt 60 (Co^{60}) or Cesium 137 (Cs^{137}). Electron beam radiation consists of bombarding the PE with high-energy electrons, which are accelerated to near light speed. Several kinds of accelerators are commercially available and classified as electrostatic direct current, electrodynamic direct current, radio-frequency linear accelerators, magnetic induction, and continuous wave machines. The target material is passed under the accelerator window by conveyors, reel-to-reel equipment, or other handling means. The governing parameters are electron energy, pulse current, dimensions of the irradiation window, conveyor speed, dose rangeability, beam distribution, properties of the material such as density and hydrogen content, and the number of transits under the window.[11] The dose, D, or energy per mass unit, is calculated by the relationship:

$$D = K\frac{I}{V} \tag{5}$$

with I being current intensity, V feed ratio, and K equipment factor.

Radiation is potentially hazardous and requires ad hoc facilities and procedures. Both γ-rays and electrons are highly penetrating; thus, a shielded environment with thick walls (i.e., 6 ft) constructed of high-density concrete and according to standard legislation is necessary. The product to be treated is loaded into carriers on a conveyor that passes into the cell through a labyrinth. Personnel in these facilities must comply with standard Health and Safety legislation.

Cross-linking of thin-film PE can also be induced by excimer UV lamp irradiation, for coating purposes, to change a hydrophilic surface into a hydrophobic one. With this method a PE film can be bonded to another material without adhesive.

APPLICATIONS

Cross-linked polyethylene is currently employed in civil engineering, electric/electronic fields, medicine, and the packaging industry, and as technology evolves it may be used in many other fields. However, each field has specific requirements and so a specific material must be fabricated with compliance to existing standards (i.e., ASTM F648 for Surgical Implants, ASTM F876 for PEX Tubing, ASTM F877 for PEX Hot and Cold Water Distribution Systems, ASTM D3555 for Wire and Cable Insulation, and so forth). Potentially, the thermomechanical characteristics of PEX can be tailored by appropriate selection of compound ingredients, cross-linking level, and sequence of manufacturing operations. Herein, the attention is focused on three main applications, pipes, electrical cable insulation, and medical implants.

Pipes

Since the introduction of PEX in the early 1970s, plastic pipes became a viable alternative to traditional materials such as copper and clay and cement. Cross-linked polyethylene was immediately considered as a good compromise between safety and economy. On the one hand such material has high resistance to chemical and electrochemical corrosion (due to a bad electric conductor), low encrustation tendency and low head losses, long-term pressure resistance, noise dampening-elastic properties. On the other hand it is light, flexible, and easy to transport and install because it can be delivered in coils; this also minimizes the number of joints and, in turn, the leakage rates.[6,12]

Polyethylene pipes are grouped in classes according to their lifetime rating. The currently used classes are PE80 and PE100, which should withstand a hoop stress of 8 and 10 Mpa, respectively, for 50 yr at room temperature and include a safety factor that accounts for the variability of the working conditions. Now, other classes are under development.[12] Cross-linked polyethylene pipes can fail in a ductile way under high stress, or in a brittle way at low stress. The second failure is caused by slow crack growth (SCG), which represents the weakness of PEX pipes and is most probably induced by defects, or solid particles, such as residual catalyst, attached to the inner pipe surface.[13] To improve stress cracking resistance, a third-generation PE, also called bimodal PE, has been developed.[13] A desired molar weight distribution is obtained with a combination of fractions of branched high- and linear low-molecular-weight PEs. The higher-molecular-weight fraction enhances strength while the linear lower-molecular-weight fraction facilitates processing.

Pipes may be susceptible to gas permeability, which can lead to two adverse effects. One concerns permeability to oxygen, which, in closed circuits such as underflow heating, or radiation heating, causes the steel components to corrode. The other drawback is with regard to the fouling of potable water by carbon dioxide, nitrogen, and other gases from contaminated soil. A possible solution may be the adoption of multilayer structures involving a copolymer of ethylene and vinyl alcohol between two PEX layers. Thus, gas permeation is avoided by the hydrophilic barrier while permeation to liquids is prevented by the hydrophobic PEX.

Electrical Cable Insulation

Application of PE in the insulation of electrical cables requires giving the material specific characteristics such as thermal stability under load, heat resistance, and heat shrinkability. This is attained through four main steps: compounding, forming, cross-linking, and expansion. In particular, fabrication of heat shrinkable cables is based on the shape-memory phenomenon. The technological process consists of conveying elongational stresses into the preform by expanding and then cooling it under stress.[14] The frozen stresses are released when the cable is reheated (during application) causing shrinkage. Generally, both LDPEs and HDPEs are used for cable insulation.

When PEX was first introduced in the electric cable insulation field (almost 40 yr ago) it appeared as the solution to many problems because of its excellent dielectric strength, low dielectric permittivity, low loss factor, high resistance to chemicals, and good mechanical properties. Indeed, substitution of impregnated paper and mineral oil filled cables with PEX for insulation of underground high-voltage electric wires offers many advantages in manufacturing, transportation, installation, and environmental benefits because of the elimination of oil leakage. Unfortunately, many premature failures occurred before the expected duration of 40 yr. The failures were caused by electrical treeing initiated by water treeing. This problem raised a question of great concern among power utilities worldwide.

Many studies have been developed to understand the complex mechanism of tree inception and propagation with insulation breakdown, and to search for any solution without changing material (i.e., without discarding PEX). It is supposed that, under normal operating voltage stress, breakdown channels originate at the tip of defects present in the form of microvoids, gas cavities, conducting inclusions, or intrusions in the insulation structure.[15,16] Water trees are then supposed to consist of tracks of oxidized (hydrophilic) polymer within the hydrophobic PEX. Such tracks do not cause insulation failure but under favorable conditions (lightning surges), evolve into an electrical tree with deleterious consequences.[16] The growth of water trees may be contrasted by hydrophilic clusters, but additives, while improving water tree resistance also reduce hydrophobic and dielectric characteristics. Thus, technology is still being sought to increase tree resistance without affecting valuable PEX characteristics.

Medical Implants

Ultra-high-molecular-weight polyethylene (UHMWPE) was introduced in hip arthroplasty in the early 1960s by the English surgeon Sir John Charnley as a solution to severe hip arthritis and is still the current material of choice for the bearing surface in total joint replacement prostheses. The majority of total hip prostheses implanted in the following three decades have included an acetabular UHMWPE cup articulating against a femoral ball of cobalt–chromium alloy. Wearing of UHMWPE components was observed with undesirable biological response and in 1994 the National Institutes of Health (NIH) officially assessed the tissue inflammation and bone resorption (osteolysis) as caused by the PE wear debris.[17,18]

In 1998, the development of a highly cross-linked polyethylene covered by a U.S. patent was a milestone in arthroplasty.[19] The benefits in wear resistance have led to a proliferation of cross-linking technology into hip and knee replacements. Chemical cross-linking typically involves the generation of noxious fumes and sensitizing by-products of peroxide degradation. Thus, almost all manufacturers use ionizing radiation. Trade names like Crossfire™ (75 kGy gamma radiation and 25 kGy gamma radiation sterilization under nitrogen environment), Durasul™ (95 kGy EBR and ethylene oxide sterilization), Longevity™ (100 kGy EBR and gas plasma sterilization), and Marathon™ (50 kGy gamma radiation and gas plasma sterilization) are commercially available.

It has to be noted that in addition to potentially improving the wear resistance, cross-linking can adversely affect other physical properties such as tensile strength and elongation with susceptibility to crack formation at the articulating surface.[20,21] Another great problem is oxidation induced by the free radicals, which remain entrapped within the crystalline phase of the UHMWPE during radiation. To minimize such undesirable effects it was suggested to remelt the material after gamma irradiation to extinguish the residual free radicals and then to sterilize with ethylene oxide or gas plasma to avoid the reintroduction of free radicals that would occur during radiation sterilization.[20] Another method was warm irradiation with adiabatic melting to make cross-linked UHMWPE with high-energy (10 MeV, 40 kW) EBR without sacrificing the mechanical properties.[21]

The method suitability was assessed through simulator studies that otherwise seemed incapable of predicting the in vivo performance.[22] In fact, there are many factors, apart from the material properties and manufacturing processes, such as the surgical technique and the patient response, which complicate the determination of a cause–effect relationship. Such considerations prompted in June 1999 a Safety Notice from the Medical Devices Agency (MDA SN1999) cautioning careful monitoring of postimplant patients with highly cross-linked UHMWPE components.[23] Despite many studies concerning material improvements in total joint replacement, failures continue to occur and some questions remain about the UHMWPE cross-linking level and procedure to prevent wear. Of course, the patient's response is a primary factor, and ascertaining the benefits of a kind of prosthesis will need several years of clinical data.

TESTING

A product of given characteristics can be obtained by mixing pellets of different polymers, additives such as colorants, stabilizers, antioxidants, flame-retardants, and so forth. Thermomechanical modifications can be brought about either by silanes or peroxides or by exposure to ionizing radiation. A product of good quality is certainly the result of experience, ability, and good knowledge of the interactions between the different substances, and also characterization of final products with the most effective techniques is of vital importance. Many techniques, collected in Table 1, are available for the characterization of PEX.[23–29]

Chemical Analysis

This analysis consists basically of the evaluation of chemical modifications induced in PE by cross-linking methods. The most important parameter to measure is the gel content (fraction or gel%), which indicates the cross-linking degree. It is generally measured, following the ASTM D 2765 standard, as the percentage of the original weight of a sample after extraction for 24 hr in boiling toluene (or xylene) and successive drying in a vacuum oven at 90°C. The variation of gel% with curing time (silane cross-linking) and irradiation dose (EBR) for LDPE is shown in Fig. 1. Cross-linking of 70% can be obtained with exposure to a radiation dose of 90 kGy, or 50 hr curing in hot water with silane. However, the main difference between the two methods is that in EBR the cross-linking degree can be easily increased by increasing the dose. Instead, in the silane method, lengthening curing has no significant effect; an increase in the cross-linking degree requires the addition of an increased percentage of silane to the compound.

Another important parameter is the swelling ratio. A sample is placed in a solvent and the variation of its height is monitored as a function of time through a contact probe. A relationship between sample and solvent allows for the evaluation of the cross-link density and the chain length between cross-links. The technique is named swell ratio testing (SRT) in the American ASTM F2214-02, or hot set test (OST) in the German DIN 57472 Standard.[23,24]

Of vital importance, especially for medical implants, is quantifying the presence of free radicals, which can react with oxygen forming carbonyls and cause material

embrittlement. This is done with resonance spectroscopy. The chemical structure of a molecule can also be analyzed by Fourier transform infrared spectroscopy. Many radiolytic products are visible in the infrared spectrum and can be detected by an infrared detector like the mercury–cadmium–telluride detector. The absorbance is proportional to the concentration of the chemical species active at the selected frequency. Again, for medical implants a trace element analysis is performed to ensure absence, or allowed percentages, of some substances like titanium, calcium, chlorine, etc.

Mechanical Analysis

The mechanical properties, such as tensile, compression, shear, and fatigue strengths are fundamental for the product's lifetime. Each product must be tested by taking into account the effective operative stresses. A hip cup should allow a patient to take as many as a million steps a year. Pipes and cable insulation for underground conveyance must perform properly in severe soil conditions and seismic zones; pipes should resist scratches and stresses due to high pressure and temperature. Tensile, compression, elongation, and fatigue tests are commonly performed according to well-traced guidelines to evaluate the mechanical characteristics of materials and their suitability for different applications. The hardness is generally evaluated with the Profiler-P10 and with imprints obtained statically and dynamically. The hardness coupled with mechanical properties is helpful in predicting the material's response to the interaction with other objects, or substances.

A novel method is the small punch analysis, or pin on disk test, which is used to evaluate the weight loss of friction material.[10] It is performed with a metallic pin in friction contact on a sample (small disk); the pin, moving cyclically, yields a stress–strain curve related to the specimen wear. This test is generally performed on retrieved, or aged, UHMWPE components.

Physical Analysis

The density, ρ_p, or specific gravity, can be evaluated by applying the Archimedean principle in water:[24]

$$\rho_p = \rho_w \frac{W_{pa}}{W_{pa} - W_{pw}} \tag{6}$$

where ρ_w is the density of water and W_{pa} and W_{pw} are the weight of the polymer in air and water, respectively.

Morphological modifications arising through cross-linking can be observed by scanning electronic microscopy (SEM). Three images are shown in Fig. 2 for pure LDPE (A), silane grafted and cured in hot water for 80 hr (B), and electron beam irradiated at a dose of 80 kGy (C). A fragment of each material was gold-coated and viewed by SEM. Changes in crystallinity can be observed by transmission electronic microscopy.

Thermal Analysis

Several methods may be used to analyze the material behavior under controlled temperature variations. Differential scanning calorimetry (DSC) is the most utilized thermal analysis technique. It consists of observing and recording (thermogram) exothermic and endothermic phenomena that occur in a sample sealed in an aluminum sample chamber under temperature variations. It is possible to evaluate glass transition temperature (T_g), melting point (T_m), crystallinity degree from the fusion enthalpy, and crystallization temperature (T_c). Typical outputs are shown in Fig. 3 for thermo shrinking insulation of low-voltage cables cross-linked via silane grafting and curing for 91 hr in hot water (A) and electron beam irradiation at a dose of 129 kGy (B). The different heat flow levels are linked to the different cross-linking mechanisms. In fact, irradiation was performed at ambient temperature while the material was in the solid state; instead, curing in hot water, when the material was not completely solid and had poor structural stability, probably led to the formation of molecular defects. Indeed, the response to DSC measurements is strictly related to molecular structure; a low-density material behaves differently from a high-density one.[25]

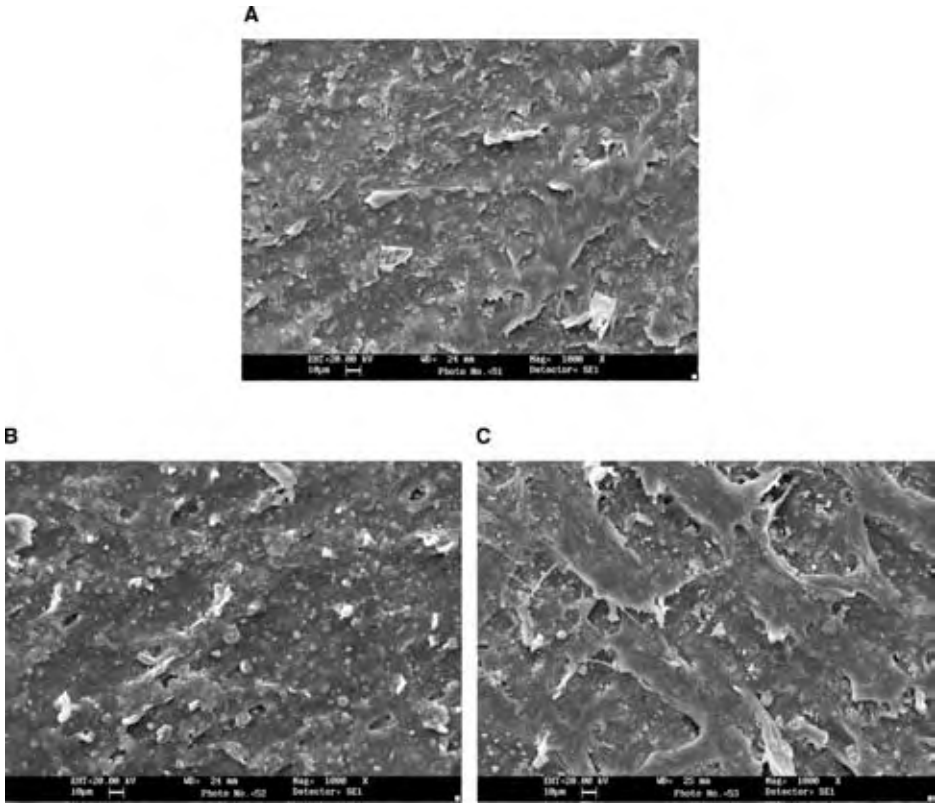

Fig. 2 Scanning electron microscopy images: (A) pure LDPE; (B) silane grafted and cured in hot water; and (C) electron beam irradiated.

The dynamic mechanical analysis gives detailed information about the viscoelastic properties of a sample when heated, cooled, or held under isothermal conditions. The three α, β, and γ peaks displayed by the material before melting can be used to evaluate the effects on the PE molecular structure of additives and cross-linking methods. With the thermogravimetric analysis, information about weight loss, degradation onset temperature, and degradation rate of a sample when heated, or held isothermally, in nitrogen (or argon) atmosphere is attained. The dimensional variations of a sample when it is heated, cooled,

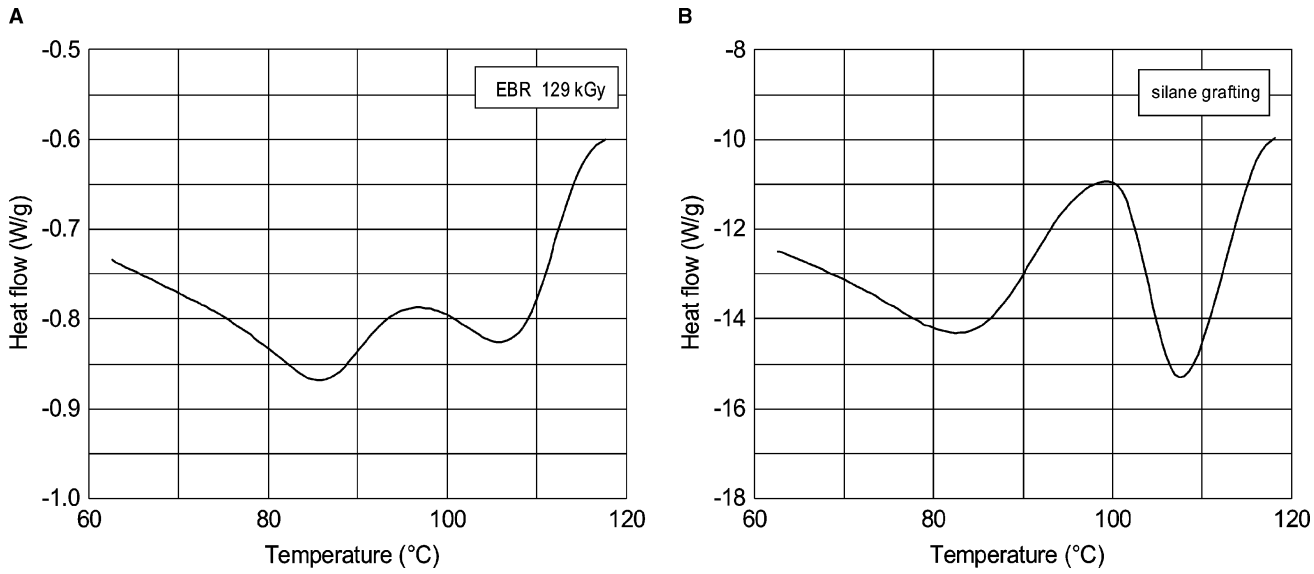

Fig. 3 Differential scanning calorimetry profiles: (A) electron beam irradiation and (B) silane grafting and curing in hot water.

or held under isothermal conditions are observed by the thermomechanical analysis technique.

Nondestructive Evaluation

Cross-linked polyethylene may include impurities and voids from which the major causes of premature failures (SCG in pipes, treeing in electric cables, and cracking in medical implants) can originate. Thus, nondestructive evaluation with effective techniques that can discover defects at the incipient stage, before the component is put in operation, is of vital importance. Conventional ultrasound (up to 10 MHz), which is the current technique for detection of flaws in metal piping and vessels, is limited by the attenuated nature of polymers. A scanning acoustic microscope with operating frequencies up to 100–150 MHz has been found to be more effective.[27]

Another technique that has proved to be practical for the evaluation of PEX is photothermal radiometry, commonly known as lockin thermography, which is the multiplexed version. Studies present in the literature demonstrate the success of such a technique when investigating the effect of molecular orientation in stretched PE, the loss of mechanical properties, local material inhomogeneities due to extrusion and cross-linking processes, as well as material differences linked to the different compounds.[28,29] The test procedure consists of acquiring phase (or amplitude) images while the specimen surface is thermally stimulated with a sinusoidal heat flux. Two phase images, taken at a heating frequency $f = 0.12$ Hz, are shown in Fig. 4 for LDPE cross-linked with EBR. The first image (A) shows a piece of commercial (Megarad, Italy) low-voltage electric cable insulation after expansion to three times its original diameter; it is possible to see yield tracks that are probably due to local material inhomogeneities or nonuniform distribution of forces during enlargement. The second image (B) refers to a sheet irradiated at increasing dose from right to left; it is possible to see dark zones on the left due to material degradation under overdose.

Lockin thermography can be exploited for characterization of PEX through the variation of the phase angle. In fact, the local phase angle variation is well correlated to the local variation of the elastic modulus under variation of irradiation dose, as shown in Fig. 5; more specifically, a differential phase angle (with respect to the phase angle of untreated material) is considered. The modulus of elasticity is evaluated at 150°C above the melting point to relate it directly to the cross-linking degree.[26] Through the variation of the phase angle the variation of the material density can also be evaluated as demonstrated in Ref.[28] for a retrieved UHMWPE hip cup after 9 yr of implantation.

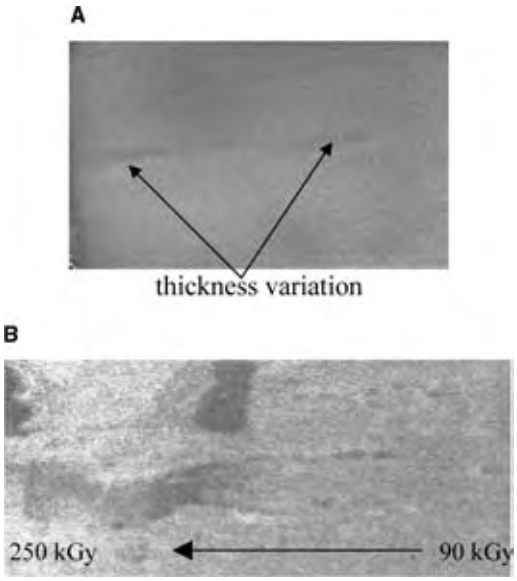

Fig. 4 Phase images for $f = 0.12$ Hz. (A) post expansion cable insulation; and (B) sheet irradiated at increasing dose from 90 kGy (right) to overdose (left). *(View this art in color at www.dekker.com.)*

The electric utility industry is today forced by the Market Directive to adopt condition-based maintenance to ensure steady supply. The method universally adopted to ensure proper installation of cable system accessories and to periodically determine the state of the insulation for decision making about repairing or replacing before failure occurs is partial discharge (PD). This method is based on the time-of-flight principle of induced PD signals; a time variation is attributed to local faults. Calibration is needed to establish a correct relationship between the magnitude

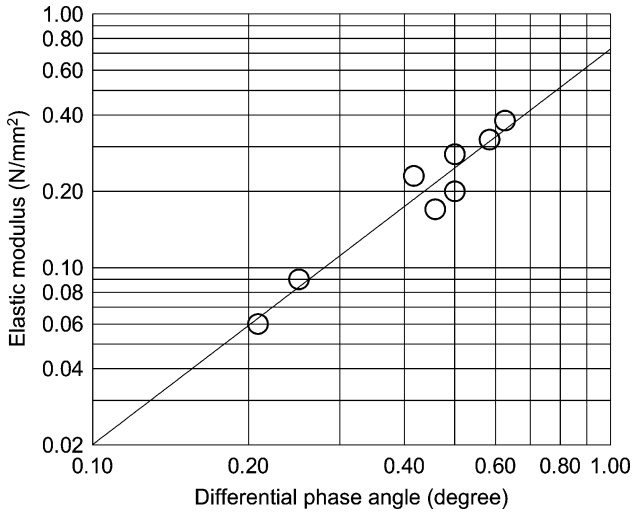

Fig. 5 Differential phase angle against modulus of elasticity for LDPE for varying the electron beam dose.

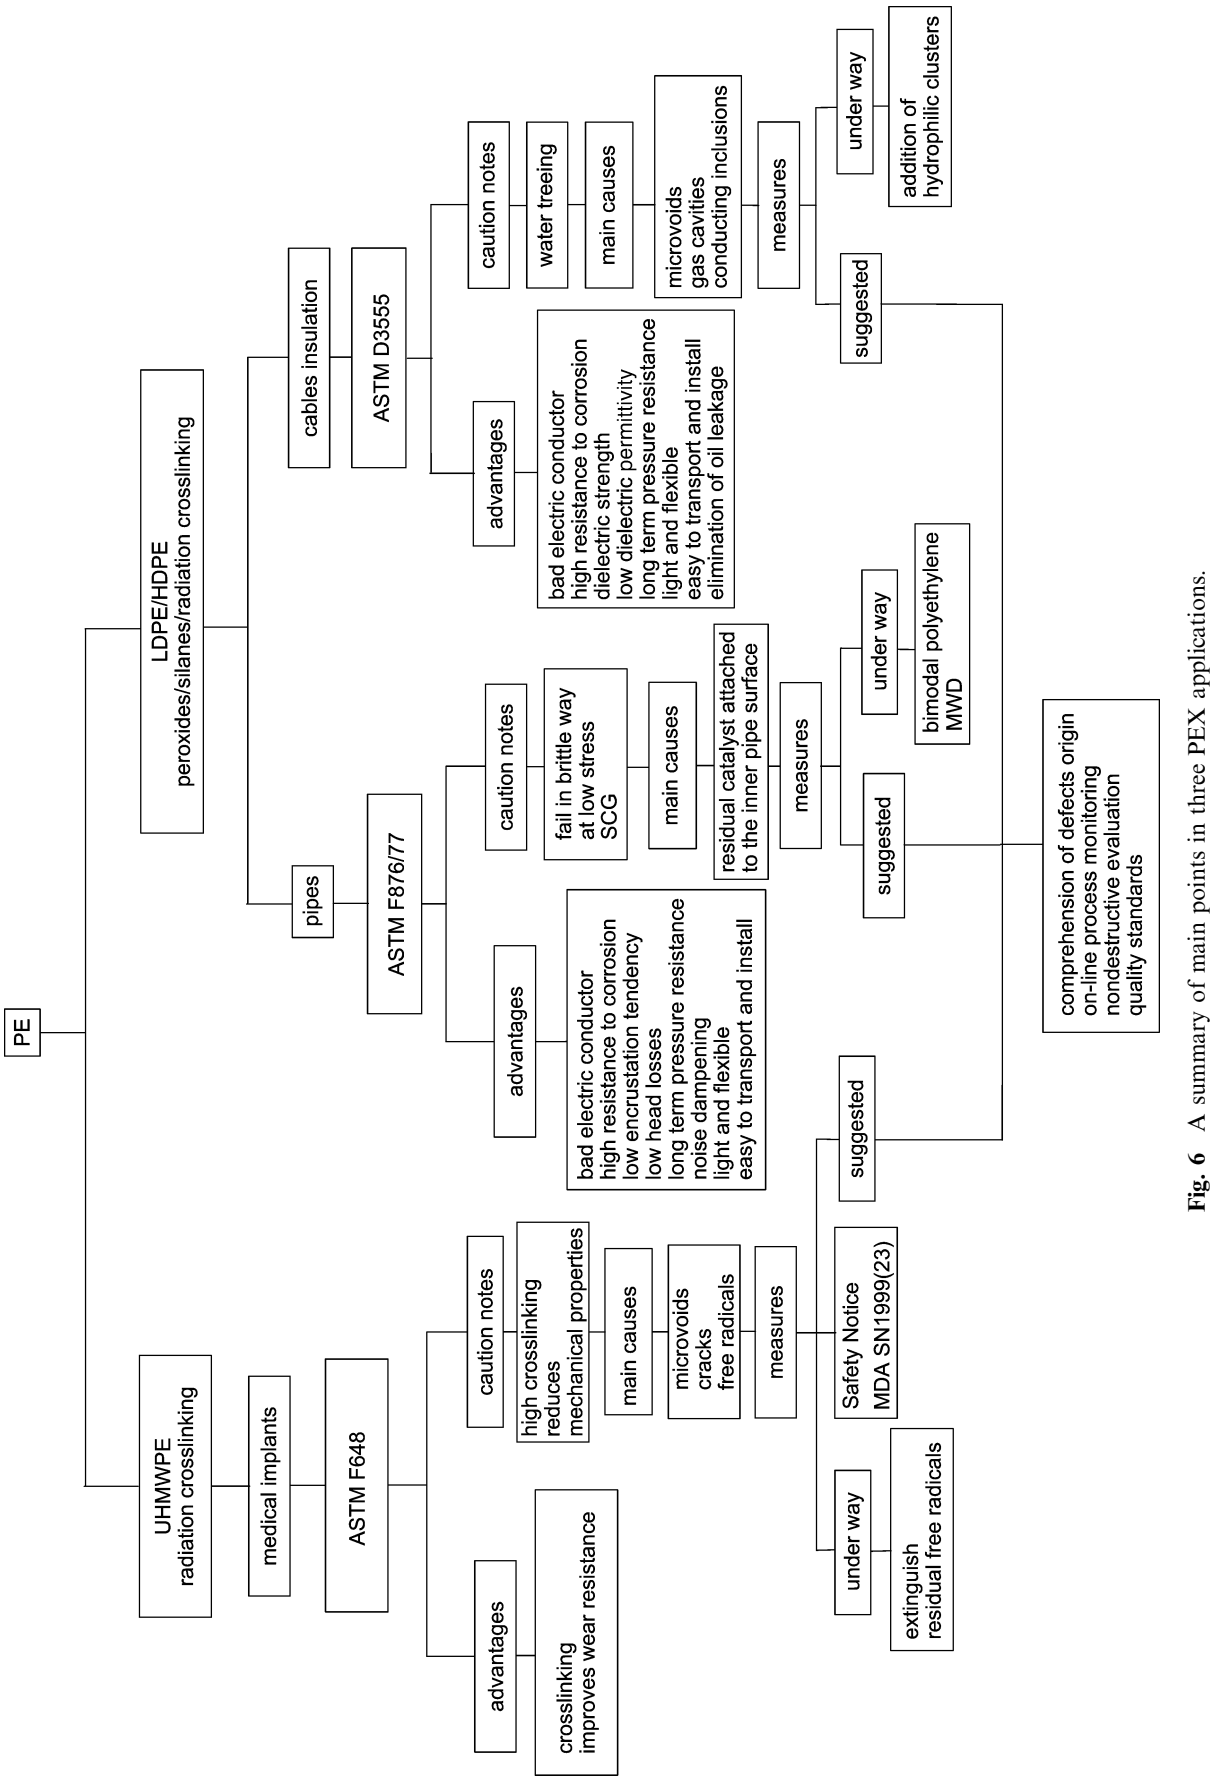

Fig. 6 A summary of main points in three PEX applications.

of the discharge in the cable sample and the signal received; quantitative measurements are complicated by interference and noisy environments. Recently, a new on-site and on-line calibration method, which allows overcoming of the problems of previous methods, has been developed.[30] The insulation deterioration for water treeing is associated with a change in dielectric properties such as loss factor ($\tan\delta$) and capacitance to be measured with dielectric spectroscopy.

CONCLUSIONS

The benefits of PEX over other plastics has led to a proliferation of cross-linking technologies and, of course, each manufacturer claims the superior quality of its product. Indeed, PEX can be advantageously used in many applications owing to caution in:

- Selection of the compound ingredients; fractions of LDPEs and HDPEs; and specific additives such as stabilizers, antioxidants, flame-retardants, and so forth.
- Selection of the most suitable cross-linking method (peroxide, silane, or radiation) that gives the material the thermomechanical properties adequate for the specific application.
- Complying with local and international standards (DIN, UNI, UNE, BS, ASTM) regarding mechanical and physical properties to ensure a safe life without unexpected failure and meet hygienic requirements (ANSI, NSF) to avoid health effects.

Application of PEX in three main fields: piping, cable insulation, and medical implants has been examined. Many premature failures of PEX products in each field were reported in the literature; the origin was recognized in the presence of defects forming during fabrication. A summary with advantages and caution notes is sketched in Fig. 6. It seems that production standards are established mainly on the basis of destructive tests and statistical inference with little attention to in-process monitoring and nondestructive evaluation. In this context, infrared thermography, as a remote imaging system of temperature mapping and nondestructive evaluation, may be advantageously exploited.

ACKNOWLEDGMENTS

The authors wish to express their gratitude to: Megarad s.r.l. (Italy) for supplying specimens and related information, Dr. Paolo Suriano for assistance in performing DSC and mechanical tests, and Dr. Benedetto De Vito for the SEM images.

INTRODUCTION

Crystal growth is not only a physical process that is interesting to science, but also a technologically important subject in the chemical and material industry. In this entry, we give an introduction to crystal growth physics including the thermodynamics and kinetics for nucleation and growth. Growth mechanisms, surface roughing, and growth inhibitions are also reviewed. Finally, the technologies of crystal growth and the current issues are also discussed.

BACKGROUND

Crystals are solids in which molecules are arranged in a regular, repetitive three-dimensional (3-D) pattern, and crystal growth is a process of building up this structure. In nature, the building units (unit cells) of the crystals are divided into only seven kinds, the so-called seven crystal systems. The molecules can be placed at cell corner, face, or center. Hence, a total of 14 so-called Bravais lattices can be produced. Because of the repetitive nature of the unit cells, crystals can take on characteristic and interesting forms, for example, the colorful and beautiful shine of various gem stones like diamond, ruby, and sapphire. Although the basic structure unit determines the intrinsic properties of a material, the ultimate form and properties of the crystal are determined by the growth process. For example, the formation of beautiful snowflakes can have all kinds of morphologies, and this is controlled by growth conditions. Even in biology, the formation of structures of oyster shells, corals, ivory, and bones is determined by crystal growth, which has evolved to a well-known field called biomineralization.[1,2]

Crystal growth is not only a physical process that is interesting to science, but also a technologically important subject in the chemical and materials industry. Crystals, especially semiconductor single crystals, are important materials in modern technology since the invention of transistors at Bell Laboratories.[3–8] Most of the modern electronic, optical, and optoelectronic devices, as well as integrated circuits and optics, are built upon on the substrate sliced from a single crystal. The miniaturization of the devices and circuits requires large and perfect single crystals, and this has promoted the fast development of crystal growth technology in the past two decades. Crystal production globally is estimated at more than 200,000 tons/yr, of which the largest fraction of about 60% is the semiconductors silicon, GaAs, InP, GaP, and its alloys. In fact, for the solar cells alone, more than 10,000 tons of silicon per year has been used globally. Quartz is the second largest commodity crystal and its production rate is more than 300 tons/yr in the world. Table 1 gives a brief view of the typical single crystals available in the market including their applications and growth methods, which will be discussed later.[3–6] Besides quartz, other oxide crystals such as $LiNbO_3$ and $LiTaO_3$ play an important role in wireless communication, particularly in the surface acoustic wave (SAW) filters.[9] Even for sapphire crystals, their use as substrates for the growth of GaN film used in blue and white light emitting diodes (LEDs) has increased dramatically in recent years.[10,11] Besides the bulk single-crystal growth, it is one of the myths of the thin-film technologies that the crystals are grown layer by layer on an oriented substrate, the so-called epitaxy. The epitaxial growth, especially from the vapor phase, has been routinely used for making LEDs, diode lasers, and quantum-well devices.[12]

Crystal growth starts with the first-order phase transition from an either homogenous or heterogenous nucleation, followed by the construction (growth) of surfaces and morphologies. The growth can be carried out by solidification from a melt, growth from a supersaturated solution, condensation from a vapor phase, or grain growth from solid phases. In terms of thermodynamics, as illustrated in Fig. 1, the crystallized phase

Table 1 Typical commercial crystals: Their market share, applications, and growth methods

Crystals (% market share)	Examples	Applications	Growth methods
Semiconductor (60%)	Si, SiGe, GaAs, InGaAs, InP	ICs, transistors, solar cells, diodes, etc.	Czochralsiki (Cz), Bridgman one melting
Scintillation crystals (12%)	$Bi_4Ge_3O_{12}$, Lu_2SiO_5, BaF_2, CaF_2, $PbWO_4$, Tl:CsI, Na:CsI, NaI	Radiation detectors, positron emission tomography (PET)	Cz, Bridgman
Optical crystals (10%)	Sapphire, CaF_2, BaF_2, MgF_2, MgO, quartz, Si, Ge, ZnSe, ZnS, $CaCO_3$, YVO_4, $LiNbO_3$, α-BaB_2O_4 (BBO), $Y_3Al_5O_{12}$ (YAG)	Substrates, lenses, mirror, prisms, wave plate, polarizer, etc.	Bridgman, Cz, Kyropoulos
Acoustic crystals (10%)	$LiNbO_3$, $LiTaO_3$, quartz	SAW filter, sensor, etc.	Cz, Bridgman
Nonlinear optics and laser crystals (5%)	YAG, KH_2PO_4 (KDP), $Bi_{12}SiO_{20}$ (BSO), $KTiOAsO_4$ (KTA), β-BBO, LiB_3O_5 (LBO), $KTiOPO_4$ (KTP), $AgGaS_2$, $ZnGeP_2$, Mg:$LiNbO_3$, Nd:YVO_4, Nd:YAG, Nd:$GdVO_4$, Ti:sapphire	Laser applications, optical communication, etc.	Cz, solution growth
Jewelry (3%)	Sapphire, ruby, amber, $MgAl_2O_4$, $CaCO_3$	Decoration, watch window	Cz, Vernuil

should be more stable. In other words, the solution phase has a higher Gibbs free energy because of supersaturation or undercooling. The starting phase can be different for the same crystal. For industrial applications, growth from the melt remains the major method for semiconductors and oxides. If the molten state of the material is not thermodynamically stable or an undesirable phase is expected to be encountered during cooling down, growth from a solution or a vapor phase at a lower temperature is preferred. For a material having high vapor pressure, vapor growth can also be a convenient approach. For the growth of a single crystal, a seed is often required to avoid parasitic nucleation.

Crystal growth is also a convenient way for purification, which is known as recrystallization, because of the different solubility of a solute in the solution and the solid phases. In metallurgy, purification of metals by melting and solidification is a common process. Organic chemists prefer the recrystallization from solution. By repeating the solidification or recrystallization process several times, the purity of the material could be greatly improved.[13] The best example is the zone refining process, a technique of fractional crystallization developed by Pfann.[14] This economical and continuous process has been widely used in industry. Materials with purity up to 6 or 7 N have been routinely produced. Without these high-purity materials, the modern semiconductor industry would not be possible. Furthermore, because of its purification (or concentration) nature, crystal growth or crystallization is essentially a chemical process for the production of a wide range of specialty chemicals and pharmaceuticals. This kind of application is usually referred to as industrial or mass crystallization, which concerns the

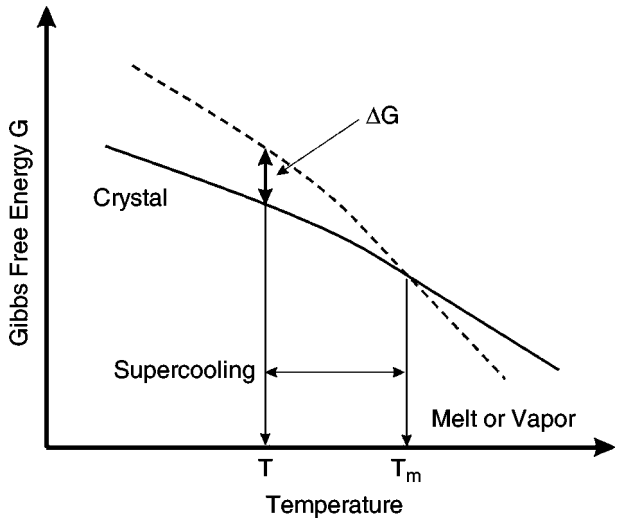

Fig. 1 The Gibbs free energy as a function of temperature for solid and fluid phases.

nucleation and growth of a huge number of small crystals with sizes around 200–1000 micron.[15,16]

Crystal growth is a science of great depth and breadth, and the technology for crystal growth has been developed for a century. Many extensive texts have been written, e.g., Refs.[3,5–8]. Several journals, as well as handbooks, have been published on the subject.[17] Therefore, this entry attempts to give a brief overall view of the subject for beginners. We shall start with some fundamental concepts for crystal growth. Based on the point of view of thermodynamics and kinetics, we will discuss when and how the growth can proceed and what form the crystal can take. The effect of impurities is discussed briefly. Segregation for melt growth is also introduced, followed by the role of dopant mixing. Last, some typical growth methods used in laboratories and industries for growing single crystals are introduced. However, vapor growth, industrial crystallization, and biomineralization are not discussed here.

THERMODYNAMICS AND KINETICS

Driving Force for Nucleation and Crystal Growth

As mentioned for Fig. 1, the first-order transition from a fluid phase to a solid phase requires an excess Gibbs free energy ΔG, in other words, the supersaturation σ or supercooling ΔT, for nucleation and the following growth. The driving force per unit area, f, is proportional to the Gibbs free energy difference per molecule as shown below:

$$f = -\Delta G/V = kT \ln(1 + \sigma)/V \sim (kT/V)\sigma \quad (1)$$

where V is the volume per molecule, k the Boltzmann constant, T the temperature, and σ the dimensionless supersaturation defined as $\sigma = P/P^{\text{sat}} - 1$ for the gas phase or $C/C^{\text{sat}} - 1$ for the solution phase. P is the partial pressure and C the solute concentration. For the growth of a single crystal in applications, the supersaturation is usually kept small to avoid parasitic nucleation. Therefore, $\ln(1 + \sigma)$ approaches σ and the driving force is proportional to supersaturation as shown in Eq. (1). For melt growth,

$$f \sim (\Delta H/V)\sigma$$

where ΔH is the latent heat per molecule and $\sigma = \Delta T/T_{\text{m}}$, the dimensionless supercooling.[18] When a driving force is large enough to overcome the interfacial energy for forming the crystal, nucleation occurs and crystal growth can then continue.

Nucleation

Nucleation is the first step of the first-order phase transition, but a barrier exists in the formation of embryos for the new phase. The interfacial energy is always a positive term to destabilize the nuclei. But once the nuclei grow large enough, the free energy drops rapidly with the new phase formation. The critical size enabling the nucleus to dissolve or to grow is at the local maximum of the Gibbs free energy. A schematic of the Gibbs free energy as a function of the nucleus size is shown in Fig. 2. It should be pointed out that the interfacial energy is closely related to the geometry of the nucleus. With foreign particles or substrates, the interfacial energy between the nucleus and the foreign media can be significantly reduced.[19] This can be interpreted by the larger bonding energy between the nucleus and the foreign molecules than the salvation energy. On the other hand, if a lattice-matched substrate is used, the barrier for forming nucleus is significantly reduced, and this is the reason that the seeded growth can be carried out at a small supercooling or supersaturation. The classic nucleation theories give the critical radius with the following form for a spherical nucleus:[19]

$$r_{\text{c}} = 2V\gamma/\Delta G \quad (2)$$

where γ is the interfacial energy; again, ΔG measures the free energy for phase change. The corresponding nucleation barrier is given as the following:

$$\Delta G_{\text{n}} = (16/3)\pi\gamma^3(V/kT\sigma)^2 \sim \gamma^3/\sigma^2 \quad (3)$$

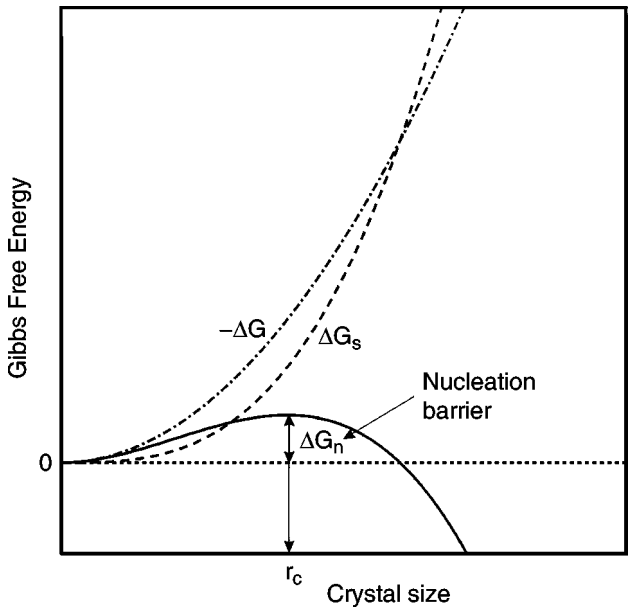

Fig. 2 Gibbs free energy as a function of crystal size during nucleation.

Or, in general $\Delta G_n = B\gamma^3/\sigma^2$, where B is a factor depending on the nucleus geometries. With this energy barrier, the steady-state nucleation rate can be obtained with the form of

$$J_n = A\exp(-\Delta G_n/kT) = A\exp[-B\gamma^3/(kT\sigma^2)] \quad (4)$$

where A is a constant.[19] For 2-D nucleation, Liu et al. have shown that the nucleation barrier is proportional to γ^2/σ.[20] Direct validation of the nucleation theories is difficult because of lack of direct observation and measurements. However, in an experimental model system of a colloidal monolayer, the 2-D theory has been found to be in good agreement with the nucleation data.[21] Further discussion can be found elsewhere.[2,22] The induction period for nucleation that takes the reciprocal of nucleation rate is often used.[15,16] For single-crystal growth, a longer induction period indicates a more stable solution which makes the growth easier.

Growth Kinetics

After nucleation, crystal growth continues from the nucleus surface. When the crystal surface is rough, the growth kinetics is usually simple because the growth sites are randomly distributed. The growth rate is in general proportional to the local driving force. However, in reality, the crystal surface consists of steps, with terraces and kinks, as well as adatoms and vacancies, as illustrated in Fig. 3. The preferred growth sites are the kinks due to more bonding to grasp the adatoms. The growth requires adsorption and then surface diffusion of atoms to the growth sites. The simple step model with surface diffusion can lead to a simple linear law for the growth, i.e., the growth rate being linearly proportional to the supersaturation σ, similar to the one in the rough surface formed by kinks.[18] However, when the surface is smooth at the end of step growth, the kinetics depends on the growth mechanisms. A new 2-D nucleation is a way to start the next layer, as illustrated by Fig. 4A. However, this often requires a substantial supersaturation (10–30%), which is less common. An outlook of an as-grown 4-*N*,*N*-dimethylamino-4′-*N*-methyl-stilbazolium tosylate (DAST) crystal from methanol shows several nucleated crystals on the surface under large supersaturation (10%). Very often the growth can still continue even with only 1% or less supersaturation, and this is possible through the spiral growth of a screw dislocation.[23]

Based on the spiral growth, Burton, Cabrera, and Frank proposed a model (referred to as the BCF theory) considering the transport of solute molecules from the bulk solution to the surface, and then surface diffusion to the kinks of the spiral generated steps from a screw dislocation.[23] A schematic of the spiral generated step is shown in Fig. 4B. Such a mechanism requires a much smaller driving force than the 2-D nucleation and is a favorable growth mode in nature. The BCF theory also predicts a quadratic kinetics at low supersaturation. The BCF theory has been quite successful in comparison with experimental observation and measurements (detailed discussions can be found in, e.g., Refs.[24,25].). For melt growth, the growth

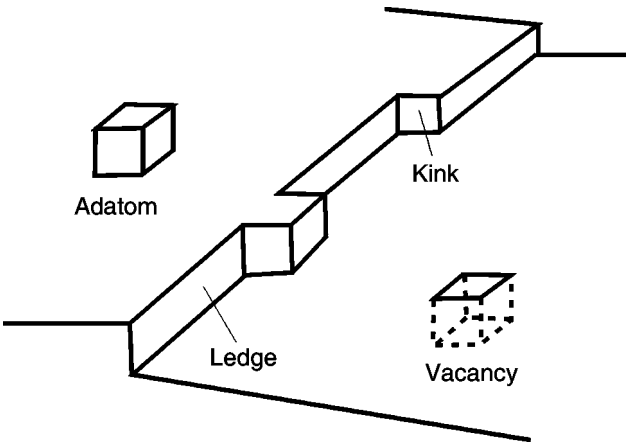

Fig. 3 A simple surface model on the crystal surface.

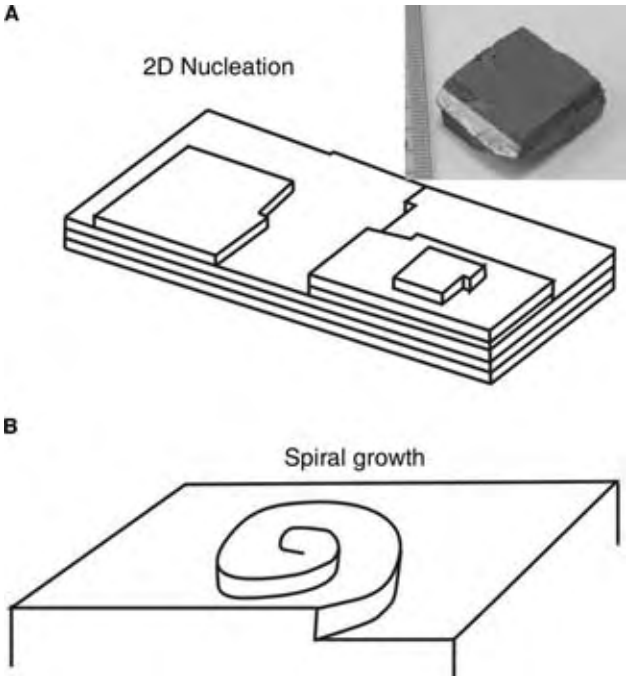

Fig. 4 Growth mechanisms: (A) surface nucleation and (B) BCF spiral growth; an as-grown DAST crystal showing the 2-D nucleation is also illustrated.

rate based on screw dislocations is also quadratic, and confirmed by many examples. The typical growth curves based on different mechanisms are illustrated in Fig. 5, where the growth on the kinks or a rough surface is referred to as the adhesive growth. The consideration of multiple screws can lead to a more complicated kinetic behavior. Nevertheless, the BCF theory lays the foundation for crystal growth theory, and has a strong impact in metallurgy, materials science, and the semiconductor industry.

Moreover, the steps and dislocations appear randomly on the crystal surface, their growth rates (flow) in a particular direction do not occur at the same speed. In some cases, the step growth is inhibited by impurities. Then, step bunching can occur and lead to macrosteps, as illustrated in Fig. 6, which can be visible up to several millimeters. An SEM image of the macrosteps on the surface of a DAST crystal is also illustrated in Fig. 6. Similarly, growth hillocks can also be generated from the spiral growth because the growth speed near the screw center is faster. Furthermore, the step growth can be affected further by fluid flow leading to the formation or dissipation of the kinematic waves, thus roughening or smoothening the crystal surface.[26,27] An extensive and thorough review of the growth mechanisms has been given by van der Eerden.[28] Recently, the use of atomic force microscopy in the observation of the growth steps has led to significant progress in understanding the growth mechanisms.[29,30] Some computer modeling studies have also been presented based on the various models, and the simulated results give a deeper insight of the growth dynamics, e.g., Refs.[31,32].

In the melt growth, the driving force is usually high so that the equilibrium growth habit is suppressed, and in most cases the interface is rough. Nevertheless, if the growth front is curved, and the thermal gradient is low,

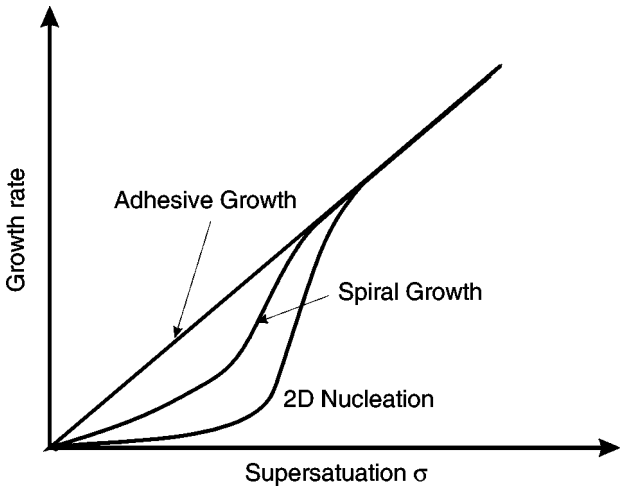

Fig. 5 Growth rate dependence on the supersaturation for various growth mechanisms.

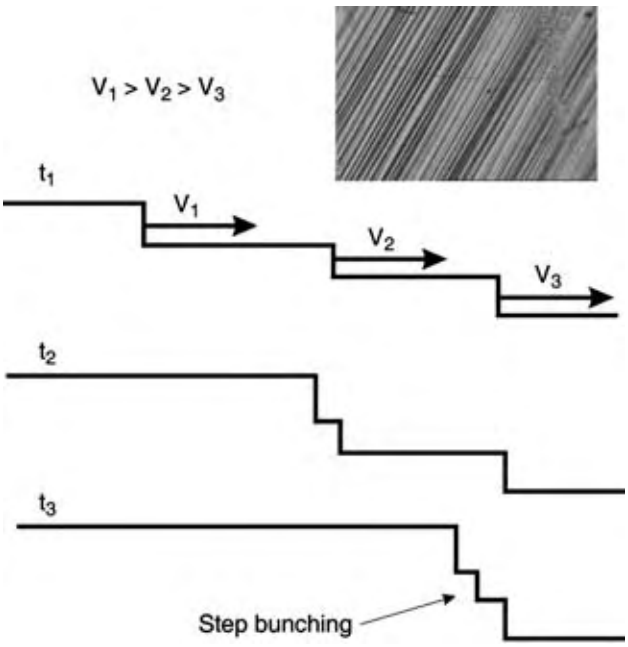

Fig. 6 Step bunching mechanism forming macrosteps; the photograph shows the typical macrosteps (several microns) on the surface of a DAST single crystal.

facets, as the result of step or spiral growth, may appear in some parts of the interface. Because the segregation in the rough and faceted surface is different, faceting can affect significantly the crystal quality and dopant segregation.

Growth Inhibition

The step growth can be inhibited by many factors, especially by impurities and foreign particles. Several mechanisms exist, such as step pinning, incorporation, kink blocking, and surfactant effects.[33] Step pinning, as sketched in Fig. 7 (top), and its effect on the growth rate is also shown schematically. As shown, once the impurities are adsorbed on the surface, the step needs to grow around the pinning points. If the impurity level is low, the average pinning distance is much greater than the radius of curvature, and the step can advance freely. However, with a high impurity level, if the supersaturation is low, the growth can be stopped almost completely forming the so-called dead zone.[34] The dead zone size increases with the impurity concentration. The step spinning can change the face speed, and the impurity pinning can be quite selective to faces depending on the bonding nature. Therefore, the final crystal shape, as a result of face competition, can be changed as well.

Growth inhibition is often observed in biomineralization.[2] Because the incorporation of extraneous ions

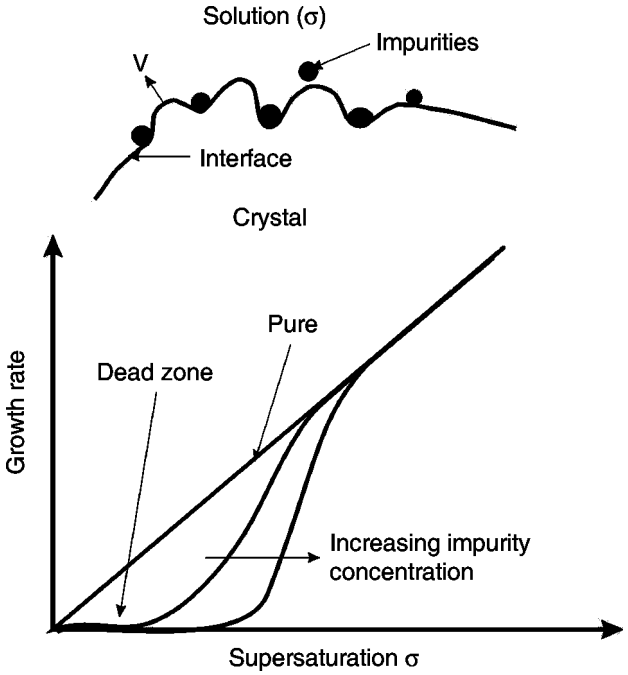

Fig. 7 Step-pinning inhibition of the growth rate due to impurities.

is very selective to the nature and surface binding sites, the growth of some crystallographic planes is inhibited, leading to an extraordinary outlook of the mineral structure. Furthermore, block incorporation of the organic macromolecules can also lead to intercalated structures.

Surface Smoothness

When the growth takes place at low temperature, such as the solution growth of organic crystals, the resultant crystal surface is often smooth. However, at high temperature, this is not always true. In fact, at absolute zero temperature (0 K), a surface at equilibrium should contain no growth steps. At higher temperature, there are adatoms due to thermal energy, and the adatom density ρ_a can be described by the Gibbs formula as:[18,35]

$$\rho_a = \exp(-\Delta G_a/kT) \tag{5}$$

where ΔG_a is the Gibbs free energy needed to extract an atom from a step to make it an adatom. Detailed calculations of the energy involved are required to estimate the roughening transition temperature, which provides a thermodynamic criterion for a smooth surface formation.[18,35] Jackson took a rather different approach to estimate the transition.[36] He formulated an α factor that takes into account the contact nature of the solution and the surface. The α factor is defined as:

$$\alpha = (\Delta H/kT)f_k \tag{6}$$

where ΔH is the latent heat of the phase change and f_k (<1) is a crystallographic factor representing the fraction of all first neighbors lying in a plane parallel to the crystal surface. With a large α factor ($\alpha \gg 2$), the surface is almost smooth because of the strong bonding energy as compared to the thermal fluctuation. This is typical for organic crystals. For most of the metallic materials, α factors are low, so that their surfaces are rough and less prone to faceting. There are also other advanced theories and computational approaches to predict the surface roughness.[28,35] Nevertheless, the Jackson's α factor provides a first estimate of the surface quality.

Growth Morphology

The growth kinetics mentioned above can be different for different crystallographic planes. When the surface is not rough, the facets, or singular surfaces, corresponding to a minimum surface energy determine the final form of the grown crystal. According to the Gibbs's criterion, for a crystal containing facets, the criterion of the crystal shape is given by:

$$\min \sum_i \gamma(n_i)A(n_i) \tag{7}$$

where $A(n_i)$ is the area of a facet of orientation n_i. The geometry features of the crystal shape that minimizes surface free energy were developed by Wulff in 1901 (also see the detailed description by Bennema).[37] His theorem states that, as illustrated in Fig. 8, under equilibrium, there is a point, i.e., the Wulff point, such that the perpendicular distance l_i from any surface

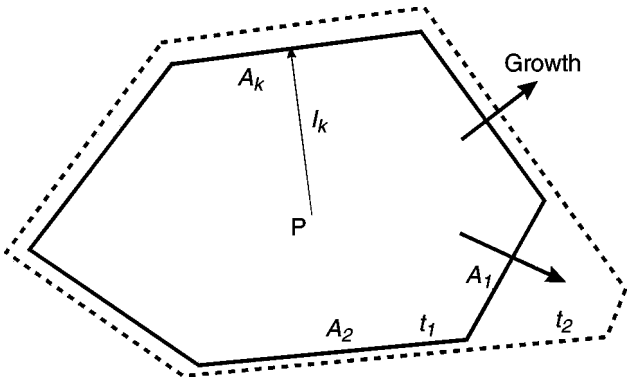

Fig. 8 Equilibrium shape of a crystal and competition of the faces.

tangent plane of orientation n_i to the Wulff point is proportional to γn, such that

$$\frac{\gamma(n_1)}{l_1} = \frac{\gamma(n_2)}{l_2} = \cdots = \frac{\gamma(n_i)}{l_i} \quad (8)$$

Then, the smallest polyhedral bounded by the tangent planes having the smallest volume at $\sum_i l_i A(n)_i/3$; is the equilibrium shape of the crystal. Unfortunately, the nature is not so simple, because crystal growth is not at an equilibrium condition. Because the driving force is inversely proportional to l_i, when the crystal is small, the driving (restoring) force back to the equilibrium is high. Therefore, the equilibrium shape of a small crystal can be maintained. Once the crystal size gets bigger, the restoring force becomes smaller, and the crystal shape is often a result of the competition of the plane growth. As illustrated in Fig. 8 at t_2 ($t_2 > t_1$), the lower growing planes will survive at the final shape. Again, when the growth of some planes is inhibited by impurities or foreign macromolecules, the crystal morphology can be affected significantly. A recent review by Winn and Doherty, though focused on organic solution growth, is a good reference to learn more about the prediction of crystal morphology.[38]

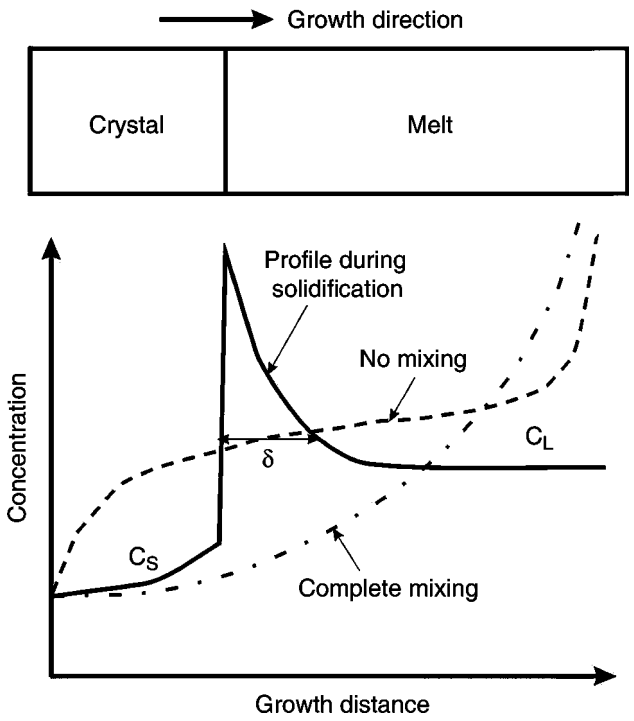

Fig. 9 A schematic sketch of distribution and segregation of impurities during normal freezing. The dashed lines show the final concentration distribution for the cases of complete and no mixings in the melt, respectively.

Segregation and Morphological Instability

In most of the industrial applications, dopants are added into the crystals for tailoring their electrical or optoelectronic properties. However, because of the different dopant solubility in the crystal and in the liquid, dopant segregation (inhomogeneity) during growth is inevitable. This is a problem particularly for a batch growth process. Let us take the normal freezing, as illustrated in Fig. 9, as an example. The crystal growth starts from one end to the other by solidification. With an initial dopant concentration in the melt at C_0 and no solid-state diffusion, the axial dopant segregation with complete dopant mixing (without solid-state diffusion) can be described by the Schiel equation:[39,40]

$$C_s = C_0(1 - f_s)^{k-1} \quad (9)$$

where f_s is the fraction of solidification and k the segregation coefficient. The segregation coefficient k is the ratio of the dopant solubility in the solid and that in the melt. The schematic dopant distribution for $k < 1$ having complete dopant mixing in the solid after solidification is illustrated by the lower dashed line in Fig. 9. However, in practice, the dopant is not completely mixed in the melt. A dopant boundary layer is established in front of the interface during solidification, as illustrated by the solid line in Fig. 9. The dopant concentration profile for the case of no mixing is illustrated by the upper dashed line. The Schiel equation is often used to fit the dopant profile in the crystal by using the segregation coefficient as a parameter, even though, the dopant is not well mixed. The fitting value is often referred to as the effective segregation coefficient k_{eff}. Burton et al. further proposed a simple model (the so-called BPS theory) to correlate the effective segregation coefficient with convection, which is characterized by a boundary layer thickness δ, as:[41]

$$k_{\text{eff}} = \frac{k}{k + (1 - k)e^{-V\delta/D}} \quad (10)$$

where V is the solidification speed and D the dopant diffusivity in the melt. Although the BPS theory is not quite correct for the closed system, it still gives a good physical insight for the dopant segregation under convection. Apparently, from Eq. (10), to improve axial dopant uniformity, one can increase the solidification speed or reduce dopant mixing (having a thicker boundary thickness), so that k_{eff} can be closer to unity. In other words, if the solidification distance is long enough, the axial dopant distribution can be rather uniform. Hence, the reduction of mixing, such as the growth in space, has been an active research topic in crystal growth. Suppressing the flow by magnetic

fields, and thus reducing axial segregation, has also been extensively used in practice.[42]

Furthermore, because of the dopant segregation, the dopant boundary layer affects the solidification temperature (T_L) in front of the growth interface. If the thermal gradient G_T is smaller than the gradient of the solidification temperature at the growth front, constitutional supercooling can occur.[43] This can be described by:

$$G_T \leq m\,dC/dz \tag{11}$$

where m is the slope of the liquidus temperature in the phase diagram. Once the supercooling is large enough to overcome the interfacial energy, the microscopically planar interface can break down into cellular cells or dendrites. Mullins and Sekerka gave an excellent analysis on the morphological instability, which predicts the onset wavelength that forms a steady cellular array.[44]

Despite the segregation in the axial direction, segregation can also occur in the lateral (or radial) direction because of the nonuniform dopant boundary layer. The control of lateral segregation is extremely important in industry to ensure that the wafers cut from the ingot have a good uniformity, especially for large wafers. The interface shape and the convection in the bulk phase are the key factors affecting the lateral segregation. Extensive research efforts through computer modeling have been made to control the transport processes and the interface shape for improving crystal uniformity.[45,46]

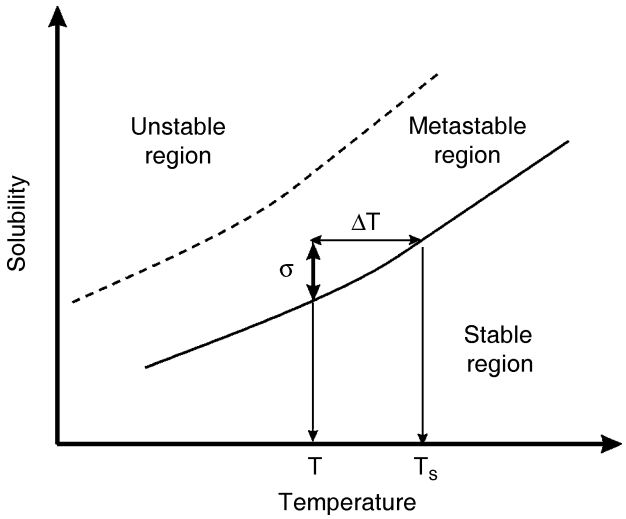

Fig. 10 Stability diagram for solution growth.

CRYSTAL GROWTH METHODS

There are many ways to grow crystals. However, the growth of a bulk single crystal remains a special interest to industry because of the need of single-crystal substrates for device applications. As mentioned previously, a good growth method provides uniform supersaturation or supercooling around the seed crystal, while the other place remains undersaturated or superheated to avoid parasitic nucleation. Some growth techniques have been widely adopted in industry. They can be divided into three categories, namely, the solution growth, melt growth, and vapor growth. Here, we give

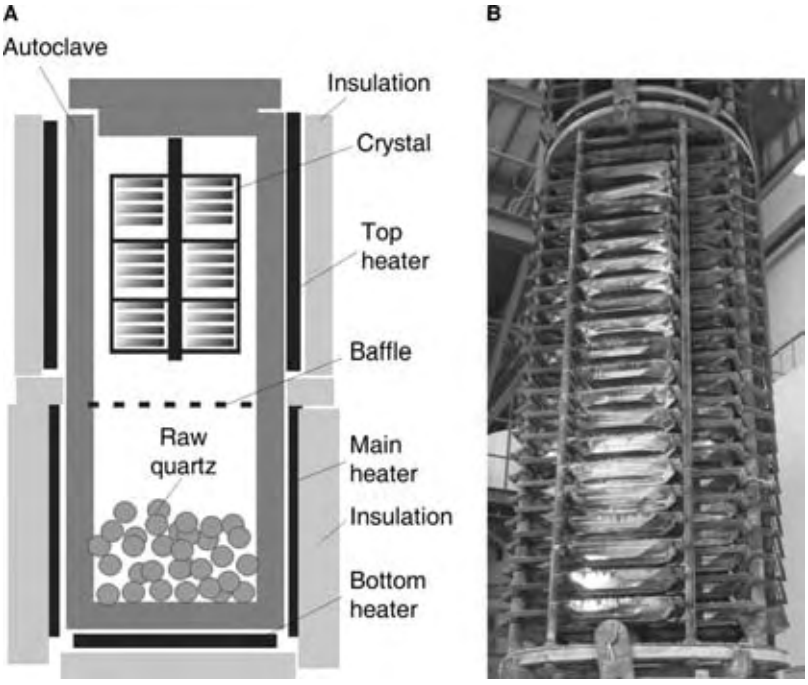

Fig. 11 (A) Schematic sketch of hydrothermal growth of quartz crystals. (B) The crystal basket after growth. (Courtesy of Hantek Inc., Taiwan.) *(View this art in color at www.dekker.com.)*

a brief introduction to the solution growth and melt growth methods through their major applications. The discussion of the growth from the vapor phase can be found elsewhere.[5–7]

Solution Growth

Growth of a bulk crystal from the solution is straightforward. A seed can be selected from the crystallization of a supersaturated solution by slow cooling or slow evaporation of solvent. Then, the growth of a bulk crystal can be carried out from the seed crystal by controlling the solution at the metastable region, as shown in Fig. 10; outside the metastable zone, the growth of crystals from the seeds only is not possible. To maximize the growth speed (production rate), the solubility needs to be as large as possible. This could be achieved by using either a better solvent or a higher temperature or pressure. The growth of quartz in an autoclave is a typical example. Because of its piezoelectric properties and low cost, quartz, next to silicon, is the second most widely used electronic material. More than 300 tons of single crystals have been used each year. Even at high temperature and pressure in an autoclave, to have enough solubility, the natural quartz nutrient, lascas, needs to be dissolved by forming a complex in alkali metal hydroxide or carbonate aqueous solution. A schematic of the hydrothermal growth is illustrated in Fig. 11A. In practice, hundreds of thin plate seed crystals are placed in the growth zone for growth, and the growth takes several months. A crystal basket taken out from the autoclave after growth is shown in Fig. 11B. The inner volume of the autoclave is up to $3.5\,m^3$. The temperature difference between the two zones is the chief process control for the growth rate, and the baffle in between is to reduce the thermal mixing of both zones. Two similar processes, the low and

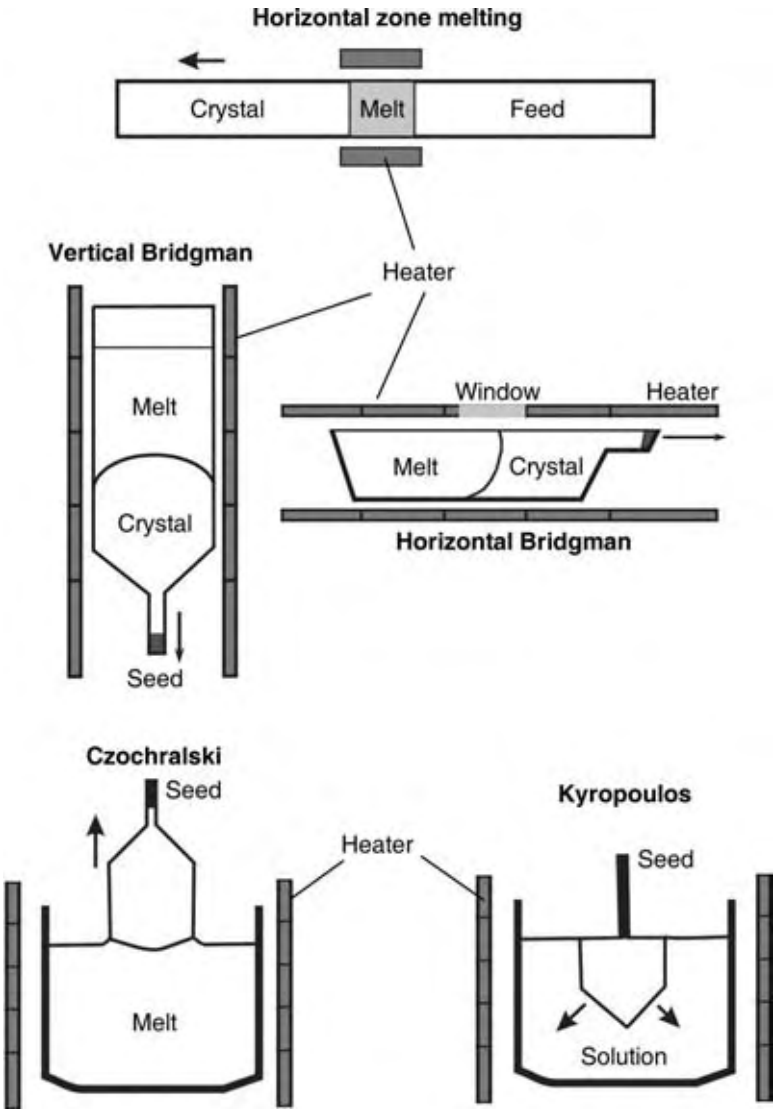

Fig. 12 Major melt growth methods. *(View this art in color at www.dekker.com.)*

high pressure, are widely used in industry.[47] The low-pressure process operated at about 70–100 MPa uses up to 1.0 M sodium carbonate solution, and the temperature at the growth chamber is around 345°C with a temperature difference of 10°C from the nutrient chamber. On the other hand, the high-pressure process operated from 100 to 150 MPa uses up about 1.0 M sodium hydroxide solution and grows the crystal at 360°C. The growth rate is about 1 mm/day.

High-temperature solution growth has also been adopted to grow many kinds of crystals, but often at normal pressure. An extensive introduction is given by Elwell and Scheel.[48] Besides the growth at high temperature, there are a number of important crystals that can be grown from low-temperature solutions. The most well-known one is the growth of potassium dihydrogen phosphate (KDP), an important nonlinear optical crystal for laser applications. Significant progress has been made because of the development of the fast growth process using a careful control of solution purity and particles.[49,50] By removing particles and clusters through reheating and filtration of the circulated solution, the growth rate up to 60 mm/day is possible for KDP.[51]

Melt Growth

The growth of a bulk crystal from the melt is the fastest approach because of the higher growth temperature and the larger driving force. Typical melt growth methods are illustrated in Fig. 12. The zone melting method at the top of the figure is more popular for purification instead of growing crystals. For purification, multiple zones are usually adopted.[14] The Bridgman method, both vertical and horizontal, has several unique advantages as compared with other methods. This method is simple and does not require skillful crystal growers. Hence, a fully automatic operation can be easily achieved. As illustrated in the figure, this technique melts the material in an ampoule and solidifies it directionally from one end to the other by moving the ampoule (or heating profile). Because a very low thermal gradient can be used, this technique is particularly useful for the crystals vulnerable to thermal stresses, such as III–V or II–VI compound semiconductors. Large-size (up to 8 in. diameter) GaAs single crystals with low dislocation density have been grown.[52] Lately, the etched-pit density (EPD) has been reduced to $10^4/cm^2$ for 8 in.-diameter crystals.[53] The horizontal configuration is less popular in applications, because the D-shaped crystals obtained from the horizontal boat are more difficult in postprocessing.

The most popular technique in melt growth, as shown in Fig. 12 (bottom), is the Czochralski (Cz) method; the Kyropulos method is quite similar but the growth is proceeded by slow cooling. Fig. 13A shows a typical industrial puller for the growth of 8 in.-diameter silicon; a photograph of a silicon crystal after growth is also shown in Fig. 13B. The Cz

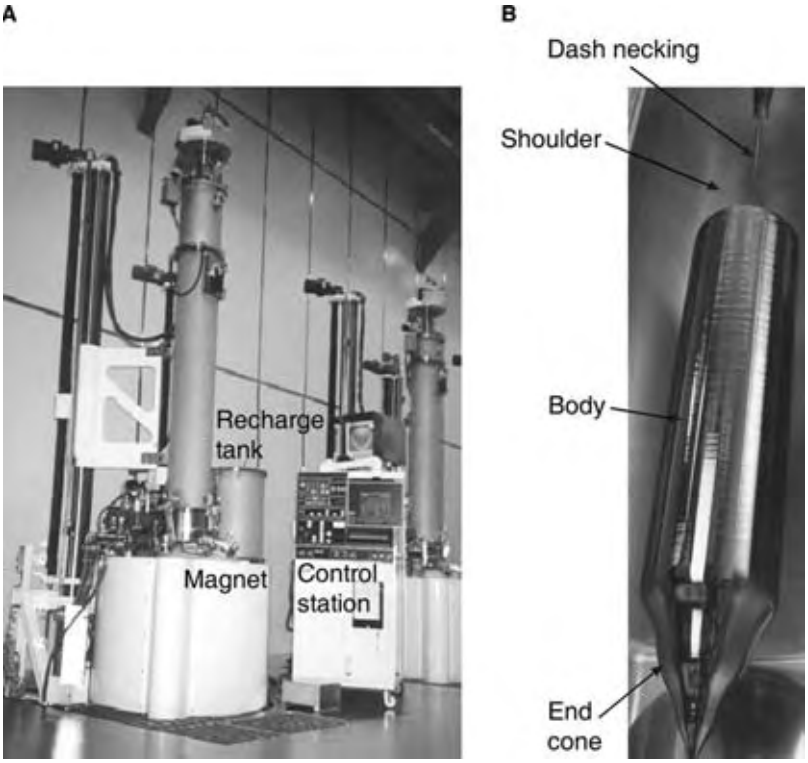

Fig. 13 (A) An outlook of a commercial puller having magnetic fields and recharge tank. (B) An as-grown 8 in.-diameter silicon single crystal. (Courtesy of Taisil Electronic Materials Inc., Taiwan.) *(View this art in color at www.dekker.com.)*

process was first introduced by Czochralski for the kinetic study of crystallization.[54] The development of the technology for semiconductors was credited to Teal and Little.[55] They started using a seed crystal to define the crystal orientation, and introduced the concepts of diameter control and dopant distribution by controlling the temperature and the crystal/crucible rotation. However, a dislocation-free single crystal was not possible until a necking procedure was proposed by Dash in 1958.[56] Before the growth, when the seed crystal is dipped into the melt, the thermal shock can generate defects, especially in the form of dislocations. The Dash necking is to let the seed grow with a small diameter, so that the dislocation lines can extend and end at the surface quickly. After some distance of necking, a dislocation-free crystal is obtained. Then, the shouldering procedure is to reach the full diameter. The body, the part that can be sliced into wafers, is pulled up to a desired length. To finish the growth, the end coning is required before detaching the crystal from the melt surface. Again, this is to minimize the thermal shock during detachment. Over three decades of development, dislocation-free silicon single crystals up to 16 in. in diameter have been grown,[57] while 8–12 in.-diameter silicon crystals have been produced routinely for integrated-circuit applications.

Besides silicon, the Cz method has also been used extensively for compound semiconductors, such as GaAs and InP. Up to 8 in.-diameter GaAs and 6 in.-diameter InP ingots with an excellent quality have been grown, and are now available in the market.[58] Furthermore, many oxide crystals used in solid-state lasers, SAW devices, and nonlinear optics are often grown by this technique as well. Other examples are summarized in Table 1. It should be pointed out that the Czochralski method is a meniscus control process in which the crystal shape is determined by the meniscus. Therefore, the on-line control of the crystal diameter is possible by either monitoring the optical ring (mainly for silicon) of the meniscus or weighting the growing crystal. The control variable can be either the pulling speed or the melt temperature.

CONCLUSIONS

In this article, we give a brief overall view of the crystal growth. The fundamental and application aspects are discussed briefly. In general, crystal growth starts from the nucleation of a thermodynamically stable or metastable phase. Once the driving force overcomes the interfacial energy for forming a new crystal, crystal growth can proceed, but is still limited by the supply of the nutrient through mass transport and the growth kinetics on the crystal surface. The impurities and foreign particles play a crucial role on the growth kinetics and thus the final morphologies. Indeed, how the foreign molecules attach to the crystal surface is a chemistry issue. Therefore, pH, temperature, and solvent are effective parameters to modify the crystal morphologies. By choosing a proper template the metastable form of the crystals could be obtained. In industrial applications, crystal growth is also an important process to purify the materials. Several economical continuous processes have been adopted, such as zone refining, fractional recrystallization, sublimation, etc. Furthermore, the growth of a high-quality bulk crystal is important for many modern technologies. In addition to a proper growth method, high-purity raw materials and a clean growth environment, skillful techniques, and process control are necessary. Because the growth takes time, it always needs to compromise between the quality and the yield. The beautiful appearance of a crystal also requires a perfect structure for applications. The requirement of the crystal quality increases dramatically as the device size diminishes. The stringent specifications for the substrates continue to challenge crystal growers to optimize the process and develop new processes in the future.

Cumene Production

Robert J. Schmidt
UOP LLC, Des Plaines, Illinois, U.S.A.

INTRODUCTION

The history of the cumene market has been examined in great detail with much discussion regarding product usage, emerging markets, and process economics over the past 10–20 yr.[1] With more than 90% of the world's phenol production technology currently based on the cumene hydroperoxide route, it is the focus of this entry to review the latest technology improvements in cumene processing made over the past 10 yr. Current state-of-the-art processes for the production of cumene as a feedstock for phenol involve zeolitic catalyst technology offerings from UOP, Badger Licensing (formerly ExxonMobil and the Washington Group), and CDTech based on zeolitic catalysis. Much of the improvements in these technologies relate to yield, stability, and operating costs.

CUMENE PRODUCTION

Cumene is produced commercially through the alkylation of benzene with propylene over an acid catalyst. Over the years, many different catalysts have been used for this alkylation reaction, including boron trifluoride, hydrogen fluoride, aluminum chloride, and phosphoric acid. Cumene processes were originally developed between 1939 and 1945 to meet the demand for high-octane aviation gasoline during World War II.[2,3] By 1989, about 95% of cumene demand was used as an intermediate for the production of phenol and acetone. Today, nearly all cumene is used for production of phenol and acetone with only a small percentage being used for the production of α-methylstyrene. The demand for cumene has risen at an average rate of 2–4% per year from 1970 to 2003.[4,5] This trend is expected to continue through at least 2010.

Currently, over 80% of all cumene is produced by using zeolite-based processes. Early processes using zeolite-based catalyst systems were developed in the late 1980s and included Unocal's technology based on a conventional fixed-bed system and CR&L's catalytic distillation system based on an extension of the CR&L MTBE technology.[6–9] At present, the Q-Max™ process offered by UOP and the Badger Cumene Technology developed by ExxonMobil and offered by Badger Licensing represent the state-of-the-art zeolite-based catalyst technologies. A limited number of cumene units remain using the fixed-bed, kieselguhr-supported solid phosphoric acid (SPA) catalyst process developed by UOP and the homogenous $AlCl_3$ and hydrogen chloride catalyst system developed by Monsanto.

Solid Phosphoric Acid Catalyst

Although SPA remains a viable catalyst for cumene synthesis, it has several important limitations: 1) cumene yield is limited to about 95% because of the oligomerization of propylene and the formation of heavy alkylate by-products; 2) the process requires a relatively high benzene/propylene (B/P) molar feed ratio on the order of 7/1 to maintain such a cumene yield; and 3) the catalyst is not regenerable and must be disposed of at the end of each short catalyst cycle. Also, in recent years, producers have been given increasing incentives for better cumene product quality to improve the quality of the phenol, acetone, and especially α-methylstyrene (e.g., cumene requires a low butylbenzene content) produced from the downstream phenol units.

For the UOP SPA catalyst process, propylene feed, fresh benzene feed, and recycle benzene are charged upflow to a fixed-bed reactor, which operates at 3–4 MPa (400–600 psig) and at 200–260°C. The SPA catalyst provides an essentially complete conversion of propylene on a one-pass basis. A typical reactor effluent yield contains 94.8 wt% cumene and 3.1 wt% diisopropylbenzene (DIPB). The remaining 2.1% is primarily heavy aromatics. This high yield of cumene is achieved without transalkylation of DIPB and is a key advantage to the SPA catalyst process. The cumene product is 99.9 wt% pure. The heavy aromatics, which have a research octane number (RON) of about 109, can be either used as high-octane gasoline-blending components or combined with additional benzene and sent to a transalkylation section of the plant where DIPB is converted to cumene. The overall yield of cumene for this process based on benzene and propylene is typically 97–98 wt% if transalkylation is included or 94–96 wt% without transalkylation. Generally, it has been difficult to justify the addition of a transalkylation section to the SPA process based on the relatively low incremental yield improvement that it provides.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120026490

$ALCL_3$ AND HYDROGEN CHLORIDE CATALYST

Historically, $AlCl_3$ processes have been used more extensively for the production of ethylbenzene (EB) than for the production of cumene. In 1976, Monsanto developed an improved cumene process that uses an $AlCl_3$ catalyst, and by the mid-1980s, the technology had been successfully commercialized. The overall yield of cumene for this process can be as high as 99 wt% based on benzene and 98 wt% based on propylene.[10] Detailed process flow information is widely published in the literature for this technology.[11] Dry benzene, both fresh and recycled, and propylene are mixed in an alkylation reaction zone with an $AlCl_3$ and hydrogen chloride catalyst at a temperature of less than 135°C and a pressure of less than 0.4 MPa (50 psig).[11] The effluent from the alkylation zone is combined with recycled polyisopropylbenzene and fed to a transalkylation zone also using $AlCl_3$ catalyst, where polyisopropylbenzenes are transalkylated to cumene. The strongly acidic catalyst is separated from the organic phase by washing the reactor effluent with water and caustic. The distillation section is designed to recover a high-purity cumene product. The unconverted benzene and polyisopropylbenzenes are separated and recycled to the reaction system. Propane in the propylene feed is recovered as liquid petroleum gas (LPG).

ZEOLITE CATALYSTS

In the past decade, beta zeolite (given the universal BEA) has rapidly become the catalyst of choice for commercial production of EB and cumene. Mobil invented the basic beta zeolite composition of matter in 1967.[12] Since that time, catalysts utilizing beta have undergone a series of evolutionary steps leading to the development of the state-of-the-art catalysts such as QZ-2000™ catalyst and QZ-2001™ catalyst for cumene alkylation.

Much of the effort between 1967 and the early 1980s involved characterization of the perplexing structure of beta zeolite. It was quickly recognized that the BEA zeolite structure has a large-pore, three-dimensional structure, and a high acidity capable of catalyzing many reactions. But it was not until early 1988 that scientists at Exxon finally determined the chiral nature of the BEA structure, which is shown in Fig. 1.

While the structure of beta was being investigated, new uses for this zeolite were being discovered. A major breakthrough came in late 1988 when workers at Chevron invented a liquid phase alkylation process using beta zeolite catalyst. Chevron patented the process in 1990.[13] While Chevron had significant commercial experience with the use of Y (FAU) zeolite in liquid phase aromatic alkylation, Chevron quickly recognized the benefits of beta over Y as well and other

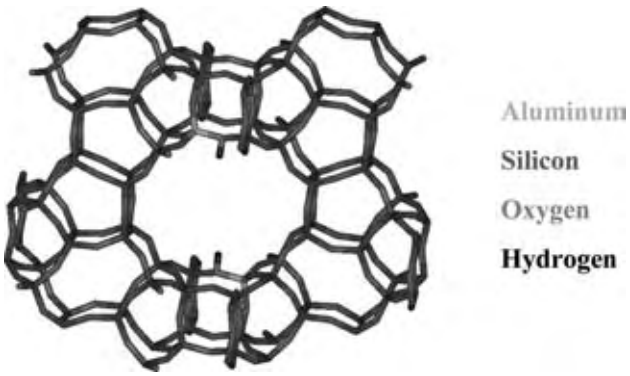

Fig. 1 Beta zeolite. *(View this art in color at www.dekker.com.)*

acidic zeolites used at that time, such as mordenite (MOR) or ZSM-5 (MFI).

Fig. 2 shows a comparison of the main channels of these zeolites. Chevron discovered that the open 12-membered ring structure characteristic of beta zeolite coupled with its high acidity made it an excellent catalyst for aromatic alkylation. These properties were key in the production of alkyl aromatics such as EB and cumene in extremely high yields and with product purities approaching 100%. Moreover, Chevron discovered that the combination of high activity and porous structure imparted a high degree of tolerance to many typical feed contaminants.

From a technical perspective, the process developed by Chevron was a breakthrough technology in that the high cumene yields and purities were not attainable by the other vapor phase or liquid phase processes of the day. Nevertheless, the manufacturing cost of beta zeolite was still too high for catalyst producers to make a commercially viable catalyst. UOP, however, developed new manufacturing technology to make a beta zeolite based catalyst a commercial reality. In 1991 a new cost-effective synthesis route was invented by Cannan and Hinchey at UOP.[14] The new synthesis route patented the substitution of diethanolamine, a much less expensive templating agent, for a substantial fraction of tetraethylammonium hydroxide, which had been used in the synthesis previously. Moreover, the route further enables the use of tetraethylammonium bromide (instead of the hydroxide) as an additional cost saving approach. Finally, the new synthesis route allows the practical synthesis of beta over a wider range of silica to alumina ratios, a factor that has a profound effect on the catalyst's performance.

Subsequently, UOP sought to develop zeolitic catalysts that would overcome the limitations of SPA including a catalyst that is regenerable, produces higher cumene yield, and decreases the cumene cost of production. More than 100 different catalyst materials were screened, including mordenites, MFIs, Y-zeolites,

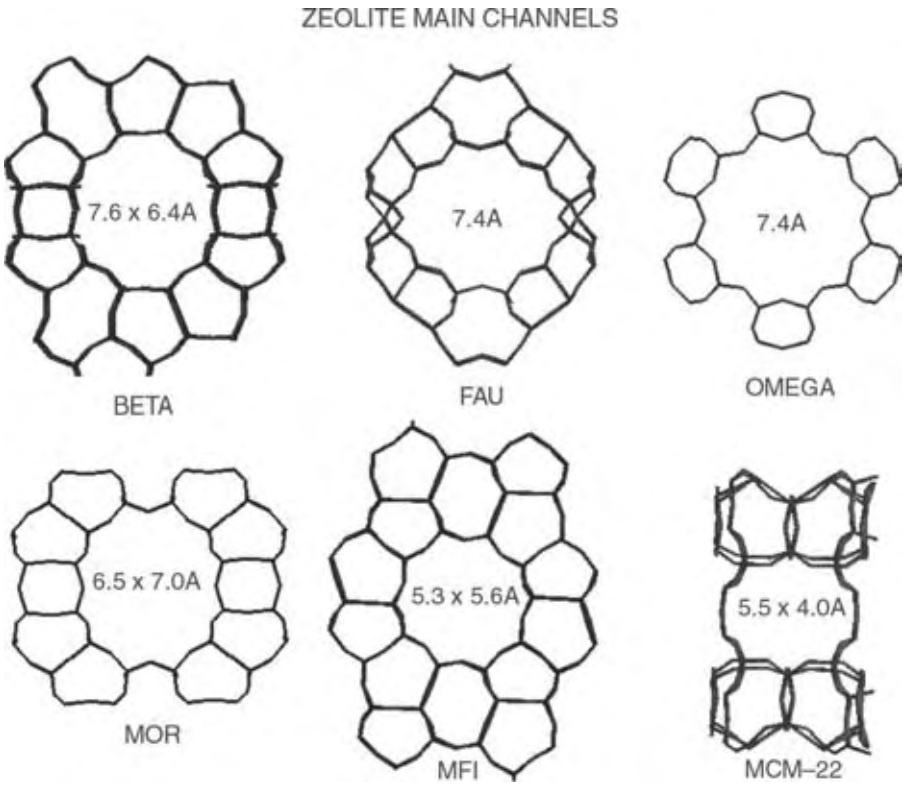

Fig. 2 Comparison of various zeolites. *(View this art in color at www.dekker.com.)*

amorphous silica–aluminas, and beta zeolite. The most promising materials were modified to improve their selectivity and then subjected to more rigorous testing.

On the process side, Unocal developed an early liquid phase fixed-bed reactor system based on a Y-type zeolite catalyst in the 1980s.[15] The higher yields associated with the liquid phase based process were quickly recognized and adapted by the industry with the selectivity to cumene generally falling between 70 and 90 wt% based on converted benzene and propylene dependent on operating conditions. Major side products in the process are primarily polyisopropylbenzenes, which are transalkylated to cumene in a separate reaction zone to give an overall yield of cumene of about 99 wt%. The distillation requirements involve the separation of propane for LPG use, the recycle of excess benzene to the reaction zones, the separation of polyisopropylbenzene for transalkylation to cumene, and the production of a purified cumene product.

By 1992, UOP had selected the most promising catalyst, based on beta zeolite, for cumene production and then began to optimize a liquid phase based process design around this new catalyst. The result of this work led to the commercialization of the UOP Q-Max process and the QZ-2000 catalyst in 1996. More recently in 2001, UOP commercialized a new alkylation catalyst, QZ-2001, which offers improved stability and operation as low as 2 B/P molar feed ratio. The low B/P feed ratio (2) represents the lowest in the industry and affords cumene producers the option to expand capacity and/or revamp existing fractionation equipment with significant cost savings.

The Q-Max process flow scheme based on a liquid phase process is shown in Fig. 3. The alkylation reactor is divided into four catalyst beds contained in a single reactor vessel. Fresh benzene feed is routed through the upper-mid section of the depropanizer column to remove excess water that may be present in the fresh benzene feed. Relatively dry benzene is withdrawn from the depropanizer for routing to the alkylation reactor. Recycle benzene to the alkylation and transalkylation reactors is recovered as a sidedraw from the benzene column. A mixture of fresh and recycle benzene is charged downflow into the alkylation reactor. Propylene feed is divided into portions and injected into the alkylation reactor between the catalyst beds and each portion is essentially completely consumed in each bed. An excess of benzene is used in the alkylation reactor to avoid polyalkylation and to help minimize olefin oligomerization. The alkylation reaction is highly exothermic and the temperature rise in the reactor is controlled by recycling a portion of the alkylation reactor effluent to the reactor inlet to act as a heat sink. In addition, the inlet temperature of each downstream bed is reduced to the same temperature as the first bed inlet by injecting a portion of cooled reactor effluent between beds.

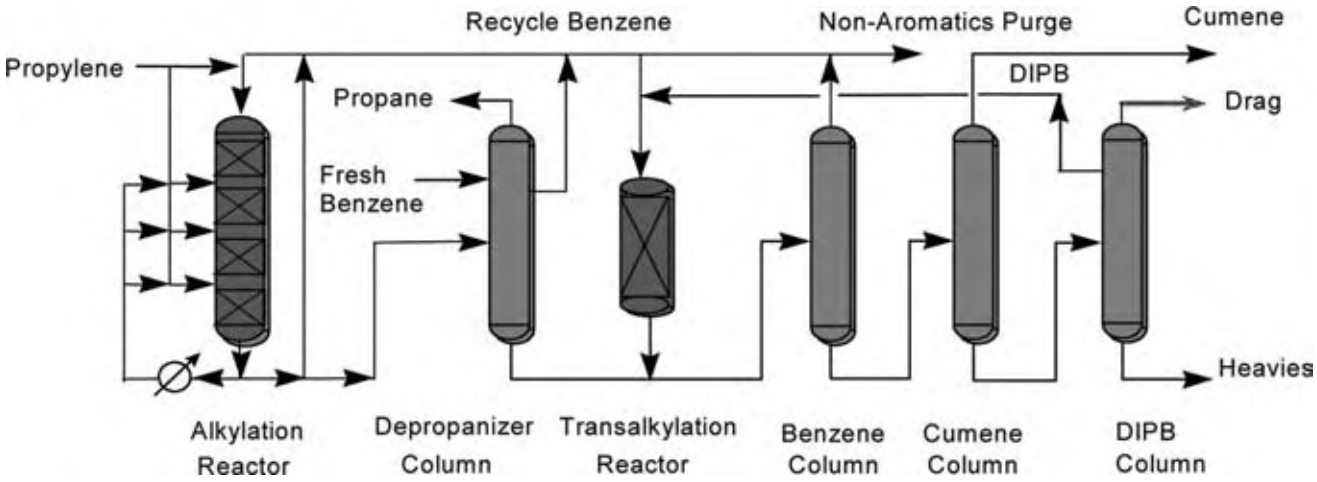

Fig. 3 Q-Max process. *(View this art in color at www.dekker.com.)*

Effluent from the alkylation reactor flows to the depropanizer column, which removes any propane that may have entered with the propylene feed along with excess water that may have entered with the fresh benzene feed. The bottom stream of the depropanizer column goes to the benzene column where excess benzene is collected overhead and recycled. Any trace nonaromatics that may have been in the fresh benzene feed can be purged from the benzene column to avoid an unacceptable accumulation of nonaromatic species in the benzene recycle stream. The benzene column bottom stream goes to the cumene column where the cumene product is recovered overhead. The cumene column bottoms stream, which contains predominantly DIPB, goes to the DIPB column. If the propylene feed contains an excessive amount of butylenes, or if the benzene feed contains an excessive amount of toluene, higher levels of butylbenzenes and/or cymenes can be formed in the alkylation reactor. These compounds are distilled out and purged from the overhead section of the DIPB column. The DIPB stream leaves the DIPB column by a sidedraw and is passed to the transalkylation reactor. The DIPB column bottom stream consists of heavy aromatic by-products, which are normally blended into fuel oil. Steam or hot oil typically provides the heat requirements of the product fractionation section.

The sidedraw from the DIPB column containing mainly DIPB combines with a portion of the recycle benzene and is charged downflow into the transalkylation reactor. In the transalkylation reactor, DIPB and benzene are converted to additional cumene. The effluent from the transalkylation reactor is then sent to the benzene column.

QZ-2000 or the newer QZ-2001 catalyst can be utilized in the alkylation reactor while QZ-2000 catalyst remains the catalyst of choice for the transalkylation reactor. The expected catalyst cycle length is 2–4 yr, and the catalyst should not need replacement for at least three cycles with proper care. At the end of each cycle, the catalyst is typically regenerated ex situ via a simple carbon burn by a certified regeneration contractor. However, the unit can also be designed for in situ regeneration. Mild operating conditions and a corrosion-free process environment permit the use of carbon–steel construction and conventional process equipment.

An alternative zeolite process was developed by CR&L and licensed by CDTech and is based on the concept of catalytic distillation, which is a combination of catalytic reaction and distillation in a single column.[6–9] Catalytic distillation uses the heat of reaction directly to supply heat for distillation of the reaction mixture. This concept has been applied commercially for producing not only cumene but also EB and methyl *tert*-butyl ether (MTBE). The use of a single column that performs both the reaction and the distillation functions has the potential of realizing substantial savings in capital cost by essentially eliminating the need for a separate reactor section. Unfortunately, many available zeolite catalysts that are ordinarily very effective in promoting alkylation in a fixed-bed environment are much less effective when used in the environment of the catalytic distillation column. Also, a separate fixed-bed finishing reactor may be required to ensure that complete conversion (100%) of the olefin occurs to avoid yield losses of propylene to the LPG product stream. As such, the amount of catalyst and physical size of the distillation column may be substantially larger than the benzene column used in the conventional fixed-bed process. Thus, the savings realized by the elimination of the reactor section may be more than offset by the increased catalytic distillation column size, catalyst cost, and addition of a finishing reactor. Depending on the relative values

and trade-off of these considerations including utility values, catalytic distillation may still be an appropriate option for producers in certain circumstances, although market interest in this process option for cumene production has been low in recent years.

Zeolitic Alkylation Chemistry

The production of cumene proceeds by a modified Friedel–Crafts alkylation of benzene with propylene. This reaction can be promoted with varying degrees of effectiveness using many different acid catalysts. The basic alkylation chemistry and reaction mechanism are shown in Fig. 4. The olefin forms a carbonium ion intermediate, which attacks the benzene ring in an electrophilic substitution. The addition of propylene to the benzene ring is at the middle carbon of C3 olefin double bond, in accordance with Markovnikov's rule. The presence of the isopropyl group on the benzene ring weakly activates the ring toward further alkylation, producing DIPB and heavier polyalkylate by-products.

Because new high-activity beta zeolite catalysts such as QZ-2000 catalyst are such strong acids, they can be used at lower reaction temperatures than SPA catalyst or other relatively lower-activity zeolites such as MCM-22 catalyst.[16,17] The lower reaction temperature in turn reduces the olefin oligomerization reaction rate, which is relatively high for SPA catalyst. The result is that beta zeolite catalysts tend to have higher selectivity to cumene and lower selectivity to both nonaromatics that distill with cumene (such as olefins, which are analyzed as Bromine Index, and saturates) and heavy by-products. For example, although butylbenzene is typically produced from traces of butylene in the propylene feed, there is always the potential also for butylbenzene to form through the oligomerization of propylene to nonene, followed by cracking and alkylation to produce butylbenzenes and amylbenzenes. As a result of having relatively high activity and operating at relatively low temperature, beta zeolite catalyst systems tend to eliminate oligomerization. This results in essentially no butylbenzene formation other than that formed from the butylenes in the propylene feed. The cumene product from a beta zeolite based process such as the Q-Max process unit fed with a butylene-free propylene feedstock typically contains less than 15 wt ppm butylbenzenes.

The Q-Max process typically produces near-equilibrium levels of cumene (between 85 and 95 mol%) and DIPB (between 5 and 15 mol%). The DIPB is fractionated from the cumene and reacted with recycle benzene at transalkylation conditions to produce additional cumene. The transalkylation reaction is believed to occur by the acid catalyzed transfer of one isopropyl group from DIPB to a benzene molecule to form two molecules of cumene, as shown in Fig. 5

Beta zeolite catalyst is also an extremely effective catalyst for the transalkylation of DIPB to produce cumene. Because of the high activity of beta zeolite, transalkylation promoted by beta zeolite can take place at very low temperature to achieve high conversion and minimum side products such as heavy aromatics and additional *n*-propylbenzene as highlighted in Fig. 6. Virtually no tri-isopropyl benzene is produced in the beta system owing to the shape selectivity of the three-dimensional beta zeolite structure, which inhibits compounds heavier than DIPB from forming.

As a result of the high activity and selectivity properties of beta zeolite, a beta zeolite based catalyst

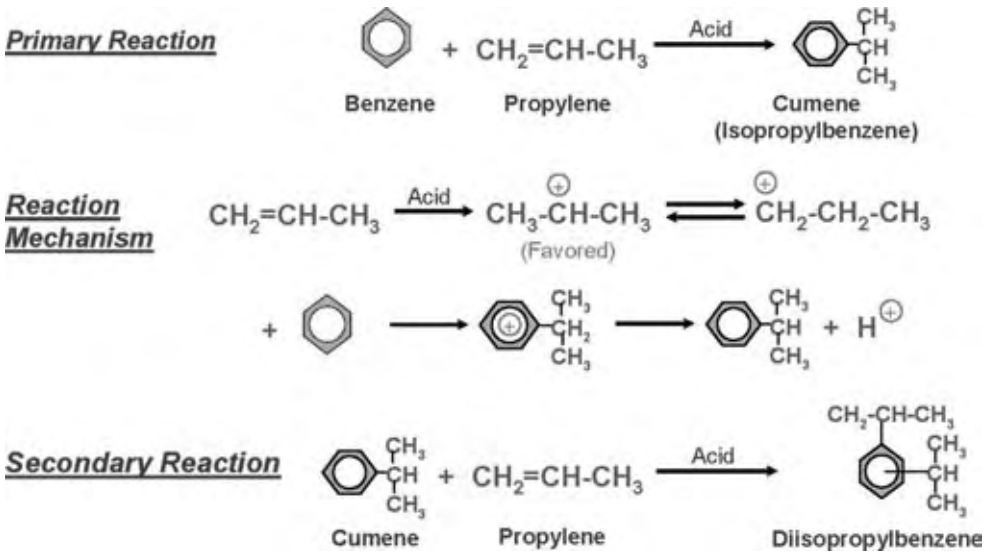

Fig. 4 Alkylation chemistry. *(View this art in color at www.dekker.com.)*

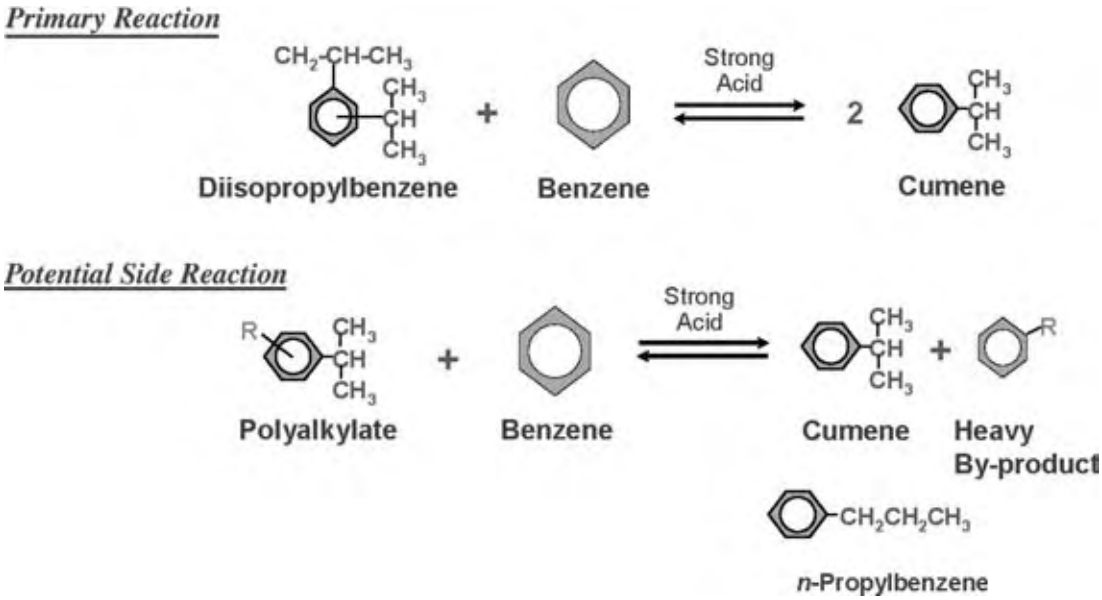

Fig. 5 Transalkylation chemistry. *(View this art in color at www.dekker.com.)*

(e.g., QZ-2001 catalyst or QZ-2000 catalyst) is specified for both the alkylation and the transalkylation sections of the Q-Max process.

With both alkylation and transalkylation reactors working together to take full advantage of the QZ-2001/QZ-2000 catalyst system, the overall yield of cumene based on benzene and propylene feed in the Q-Max process can be at least 99.7 wt% or higher. Because the Q-Max process uses small, fixed-bed reactors and carbon–steel construction, the erected cost is relatively low. Also, because the QZ-2001/QZ-2000 catalyst system is more tolerant of feedstock impurities (such as water, *p*-dioxane, sulfur, etc.) compared to other catalysts available, the Q-Max process requires

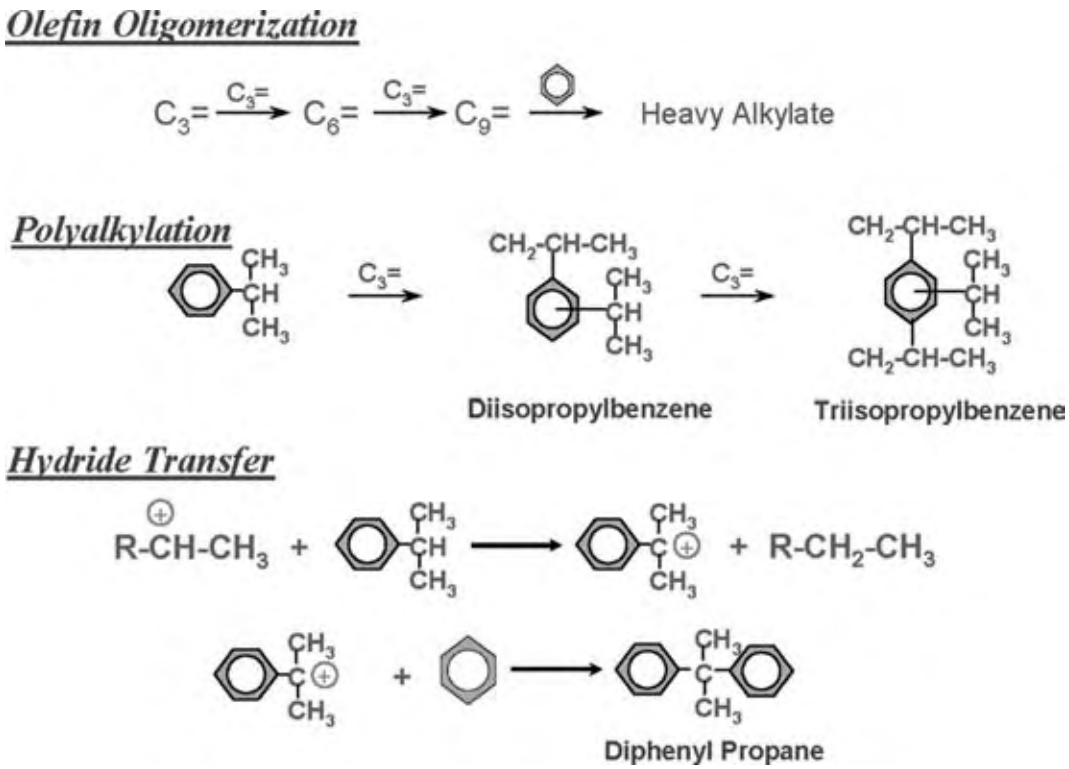

Fig. 6 Possible alkylation side reactions. *(View this art in color at www.dekker.com.)*

minimal pretreatment of the feeds, which further minimizes the capital costs.

This is in distinct contrast to other technologies based on zeolites other than beta where extensive feed contaminant guard beds are required to protect the catalyst from rapid and precipitous deactivation and loss of conversion when exposed to trace amounts of sulfur, water, oxygenates, and nitrogen.

Cumene Product Impurities

Beta zeolite catalyst can be optimized to nearly eliminate all undesirable side reactions in the production of cumene. The improvement in beta zeolite catalyst quality has occurred to the point that any significant impurities in the cumene product are governed largely by trace impurities in the feeds. The selectivity of the catalyst typically reduces by-products to a level resulting in production of ultrahigh cumene product purities up to 99.97 wt%. At this level, the only significant by-product is *n*-propylbenzene with the catalyst producing essentially no EB, butylbenzene, or cymene beyond precursors in the feed. Fig. 7 shows the reactions of some common feedstock impurities that produce these cumene impurities.

Beta Catalyst Resistance to Feed Contaminants

Beta zeolite is a large pore zeolite with optimized acid site densities that exhibits:

- Good mass transfer properties.
- Significant reduction in undesirable polymerization and by-product side reactions.
- High tolerance to feedstock impurities and poisons.

The resistance of new zeolitic catalysts to temporary and permanent catalyst poisons is essential to the economic and commercial success of a zeolitic based cumene process. The following commercial data obtained using beta zeolite as a catalyst illustrates the outstanding ability of beta zeolite to cope with a wide range of feedstock contaminants:

Cyclopropane

n-Propylbenzene (nPB) is formed by alkylation of benzene with cyclopropane or *n*-propanol, and by anti-Markovnikov alkylation of benzene with propylene. Cyclopropane is a common impurity in propylene feed and approximately half of this species is converted to nPB in the alkylation reactor. Essentially, all alkylation catalysts produce some nPB by anti-Markovnikov alkylation of propylene. The tendency to form nPB rather than cumene decreases as the reaction temperature is lowered, making it possible to compensate for cyclopropane in the feed to some extent. As the operating temperature of zeolitic alkylation catalyst is decreased, the deactivation rate increases. However, because of the exceptional stability of the beta zeolite catalyst system, a unit operating with beta zeolite catalyst can be operated for extended cycle lengths and still maintain an acceptable level of nPB in the cumene product. For example, with FCC-grade propylene feed containing typical amounts of cyclopropane,

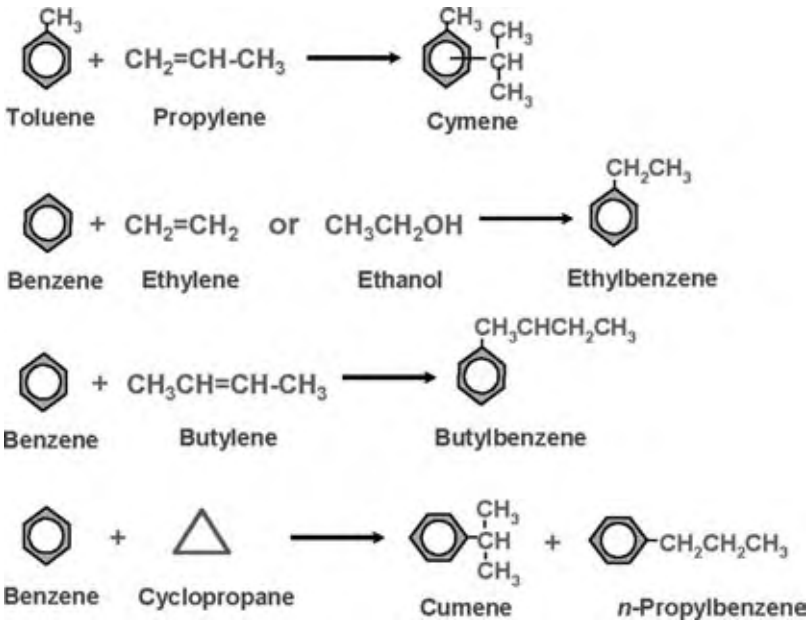

Fig. 7 Reactions of feed impurities. *(View this art in color at www.dekker.com.)*

a beta zeolite based process can produce an overall cumene product containing 250–300 wt ppm nPB while achieving an acceptable catalyst cycle length.

Water

Water can act in this environment as a Bronsted base to neutralize some of the weaker zeolite acid sites. This effect is not harmful to any appreciable extent to the beta zeolite catalyst at typical feed stock moisture levels and under normal alkylation and transalkylation conditions. This includes processing of feedstocks up to the normal water saturation condition (typically 500–1000 ppm) resulting in 10–150 ppm water in the feed to the alkylation reactor dependent on feed and/or recycle stream fractionation efficiency.

Oxygenates

Small quantities of methanol and ethanol are sometimes added to the C_3s in pipelines to protect against freezing because of hydrate formation. Although the beta zeolite catalyst is tolerant of these alcohols, removing them from the feed by a water wash may still be desirable to achieve the lowest possible levels of EB or cymene in the cumene product. Cymene is formed by the alkylation of toluene with propylene. The toluene may already be present as an impurity in the benzene feed, or it may be formed in the alkylation reactor from methanol and benzene. Ethylbenzene is primarily formed from ethylene impurities in the propylene feed. However, similar to cymene, EB can also be formed from ethanol.

p-Dioxane is sometimes present in benzene from extraction units that use ethylene glycol based solvents. It is reported to cause deactivation in some zeolitic alkylation catalysts even at very low ppm levels. However, beta zeolite catalyst appears to be tolerant to *p*-dioxane at levels typically found in benzene extraction processes and does not require costly removal of this impurity.

Sulfur

Sulfur has no significant effect on beta zeolite catalyst at the levels normally present in olefin and benzene feeds considered for cumene production. However, even though the beta zeolite catalyst is sulfur tolerant, trace sulfur that makes its way into the finished cumene unit product may be a feed quality concern for downstream phenol processors where the typical sulfur specification is <1 ppm. The majority of sulfur compounds associated with propylene (mercaptans) and those associated with benzene (thiophenes) are converted to by-products outside the boiling range of cumene. Because some sulfur compounds form by-products that boil within the boiling range of cumene, the sulfur content of the cumene product depends on the sulfur content of the propylene and especially benzene feeds to a certain extent. Sulfur at the levels usually present in propylene and benzene feeds considered for cumene production will normally result in cumene product sulfur content that is within specifications.

Unsaturates

Use of beta zeolite catalyst does not require the benzene feed to be clay treated prior to use in alkylation service. Some of the unsaturated material in the benzene can lead to the formation in the alkylation reactors of polycyclic-aromatic material which will get preferentially trapped in some zeolites having relatively small-sized pores. This can lead to increased deactivation rates in such small-pore zeolites. Beta zeolite's large pore structure makes it possible to more easily handle this polycyclic-aromatic material and as a result does not require further treatment of the benzene feed to remove unsaturated material. In addition, alpha-methylstyrene (AMS) is produced by alkylation of benzene with methylacetylene or propadiene. Some of the AMS alkylates with benzene, forming diphenylpropane, a heavy aromatic that leaves the unit with the DIPB column bottoms.

Nitrogen, Metal Cations, and Arsine

The presence of trace amounts of organic nitrogen compounds and metal cations in the benzene feed or arsine in the olefin feed has been known to neutralize the acid sites of any zeolite catalyst. Good feedstock treating practice or proven guard-bed technology easily handles these potential poisons. For example, basic nitrogen, which can sometimes be present in the benzene fresh feed, is easily removed using very low-cost UOP guard-bed technology. To facilitate monitoring of feeds for potential nitrogen based contaminants, UOP has developed improved analytical techniques to help in the evaluation. These methods include UOP 971 (''Trace Nitrogen in Light Aromatic Hydrocarbons'' by Chemiluminescence) used to detect total nitrogen down to 30 ppb and UOP 974 (''Nitrogen Compounds in Light Aromatic Hydrocarbons'' by GC) used to detect individual nitrogen species down to about 100 ppb.

CURRENT STATE-OF-THE-ART CUMENE TECHNOLOGY

Currently, the major processes for cumene production are liquid phase technologies offered by UOP and

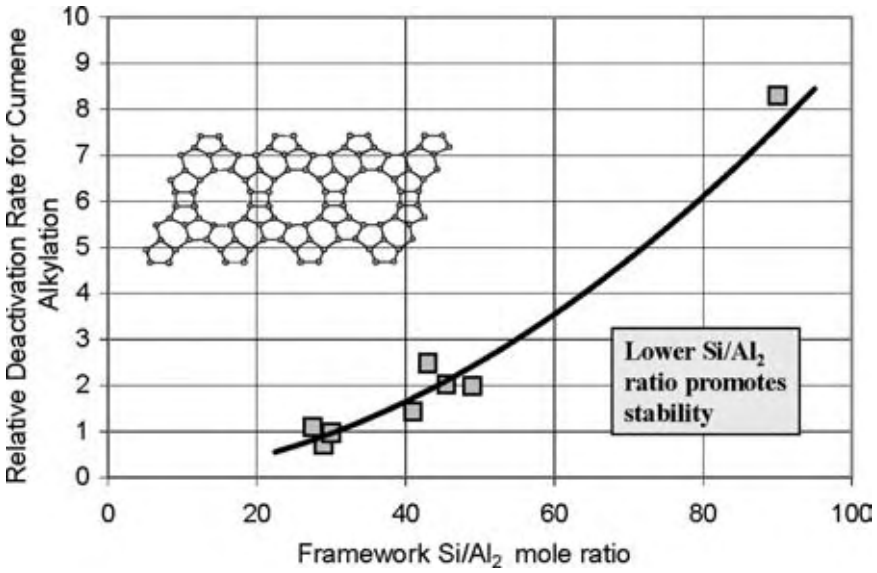

Fig. 8 Effect of framework Al on beta catalyst stability. *(View this art in color at www.dekker.com.)*

Badger Licensing (ExxonMobil technology) based on beta zeolite (such as QZ-2001 and QZ-2000 catalysts) and MCM-22 catalyst, respectively. Over the past decade, great progress has been made in improving and optimizing catalyst formulations for use in applications to produce cumene from benzene alkylation. For example, the ability to synthesize beta zeolite in a wide range of Si/Al_2 ratios has given catalyst designers the ability to tailor the zeolite into a form that optimizes activity and selectivity. A parametric study on the effects of Si/Al_2 ratio on activity and selectivity was published by Bellusi.[18] In this work, it was found that as the silica to alumina ratio was increased from 28 to 70, there was a decrease in both activity and selectivity toward isopropylbenzene-type compounds. Additionally, the less active catalysts had a greater tendency toward oligomerization and were more prone toward coking.

This study parallels work performed at UOP, where, through the use of nonconventional synthesis techniques, samples have also been prepared with Si/Al_2 ratios as low as 10. Through this work it has been found that with a Si/Al_2 ratio of 25, the catalyst maintains sufficient activity to achieve polyalkylate equilibrium (e.g., DIPB equilibrium) and, at the same time, minimizes the formation of heavier diphenyl compounds (and hence maximizes yield) in cumene service.

Perhaps the most critical understanding was developed with regard to the need to minimize the Lewis acidity of the catalyst and at the same time maintain high Brønsted acidity. Studies at UOP demonstrated that olefin oligomerization was directly related to the

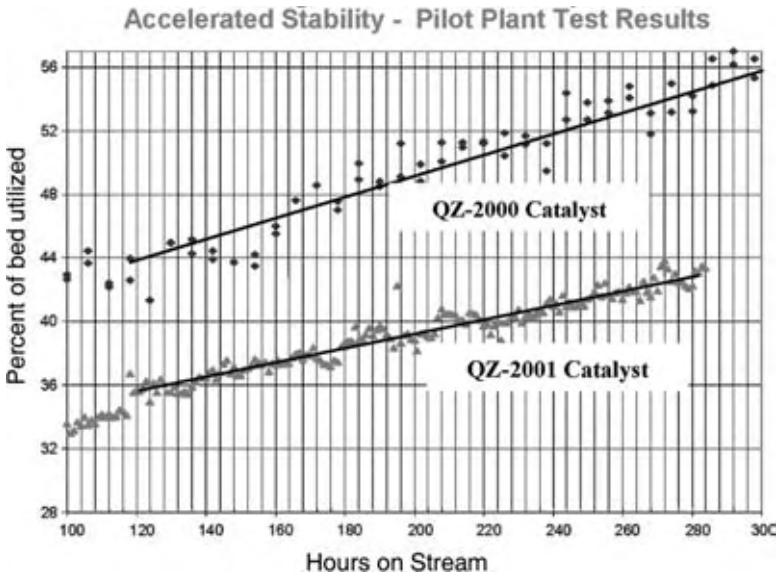

Fig. 9 Stability of QZ-2001 catalyst vs. QZ-2000 catalyst. *(View this art in color at www.dekker.com.)*

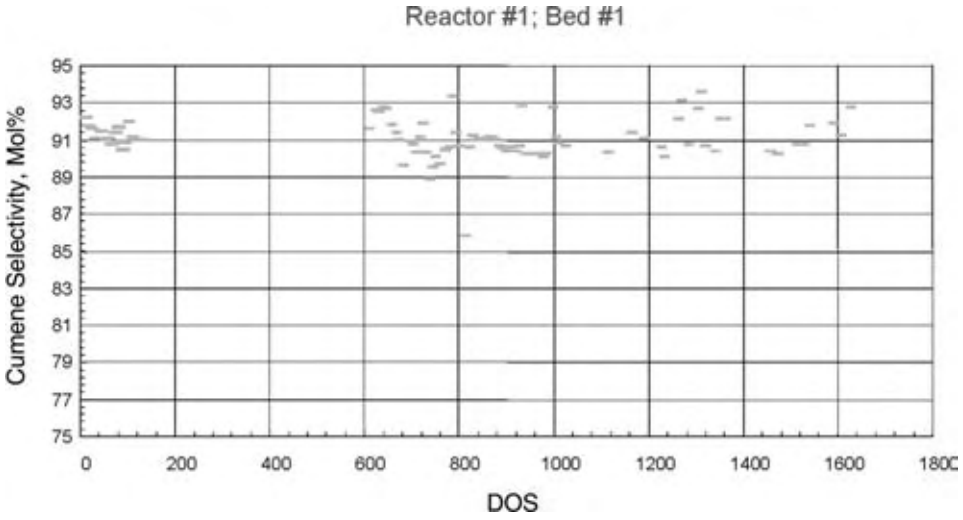

Fig. 10 JLM commercial data on catalyst stability. *(View this art in color at www.dekker.com.)*

Lewis acid function of the catalyst. Olefin oligomerization reactions can lead to the formation of heavy compounds (coke type precursors), which have a negative effect on catalyst stability. Thus, minimization of the Lewis character of the beta leads to a catalyst with high stability. Generally, Lewis acidity in beta zeolite has been attributed to the existence of nonframework aluminum atoms. The most common mechanism for the formation of nonframework alumina is through steam dealumination during the catalyst calcination step of the manufacturing process. By careful control of the temperature, time, and steam levels during the manufacturing process, it is possible to produce a catalyst that is extremely stable at typical alkylation conditions.

From a commercial standpoint this knowledge has had the additional benefit of developing a regeneration protocol that is extremely robust. It has been demonstrated in commercial in situ and ex situ procedures that the beta zeolite catalyst can be regenerated with excellent results providing complete restoration of fresh catalyst performance. The feature of complete regenerability is another attribute that distinguishes beta zeolite catalysts from other commercially available zeolite catalysts such as MCM-22 catalyst, where significant activity and selectivity can be lost upon regeneration.[19] The ability to regenerate catalyst is essential in a commercial environment to provide additional flexibility to cope with a wide range of feedstock sources, feedstock contaminants, and potential operational upsets.

The historical development of beta zeolite showed that early versions of beta catalyst demonstrated less than optimum performance when compared to today's state-of-the-art formulation. Fig. 8 is a plot of the relative stability of beta zeolite as a function of the Si/Al_2 ratio of the beta zeolite structure in which the dominating influence of this parameter is evident. Uop has learned to stabilize the zeolite structure through careful process and chemical means. This has resulted in a catalyst system that is extremely robust, highly regenerable, and tolerant of most common feedstock impurities.

Additional studies of beta zeolite have come to similar conclusions. For example, Enichem has found that beta zeolite is the most effective catalyst for cumene alkylation

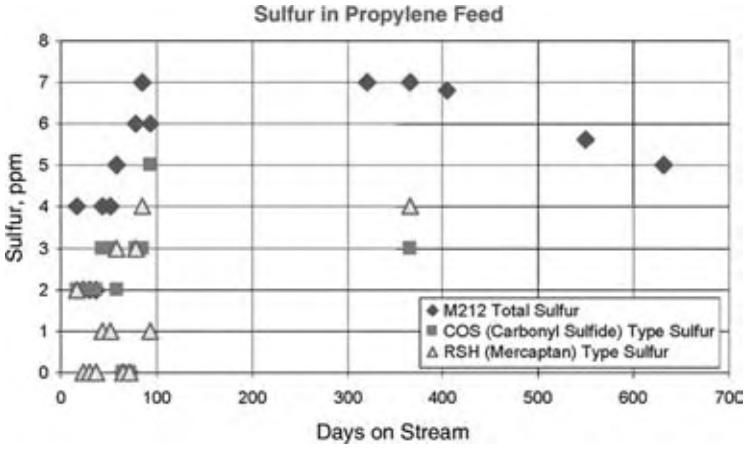

Fig. 11 JLM commercial data on sulfur in propylene feed. *(View this art in color at www.dekker.com.)*

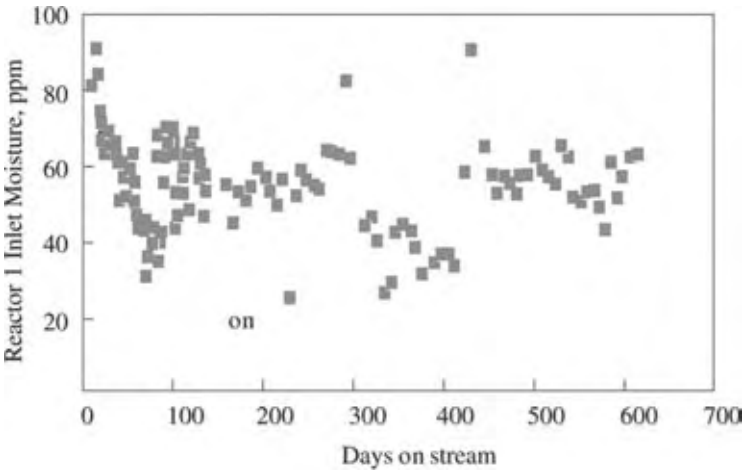

Fig. 12 JLM commercial data on alkylation reactor moisture content. *(View this art in color at www.dekker.com.)*

among other zeolites tested including Y, mordenite, and an isostructural synthesis of MCM-22 catalyst.[20]

The principles described above also led to the development of the new-generation QZ-2001 alkylation catalyst.[21] In Fig. 9, results from accelerated stability testing of QZ-2000 and QZ-2001 catalysts demonstrate the superior stability of the latest catalyst system. QZ-2001 catalyst exhibits as much as twice the stability when compared to QZ-2000 catalyst. The benefit afforded by QZ-2001 catalyst can be utilized by cumene producers in several ways. It can be taken directly through reduction of the catalyst loading for a specific run length, or alternatively as a convenient way to increase run length, or to increase throughput through the cumene unit, by allowing operation at a lower B/P feed ratio.

Long-Term Stability of Beta Zeolite Catalyst

Commercial operation with a wide variety of olefin feedstocks from different sources has demonstrated the flexibility of beta zeolite in the Q-Max process. Refinery grade, chemical grade, or polymer grade propylene feedstocks have been successfully used to make high-quality cumene product in the Q-Max process.

A good example of the ruggedness of the beta zeolite catalyst can be found in the case of JLM's Blue Island (Illinois) Q-Max operation. The operation started in August 1996 as the first Q-Max process operation with UOP beta zeolite catalyst. Initial operating results were reported in 1997.[22] The unit has continued to operate with stable performance for more than 7 yr without catalyst regeneration in spite of the presence of significant levels of feed contaminants.

Excellent monoalkylation selectivity has also been observed over many years of service in the JLM operation as shown in Fig. 10. Under the normal operating conditions of the unit, an equilibrium cumene selectivity of about 91 mol% is predicted. Thus, results clearly show that the beta zeolite catalyst is active enough to achieve near-equilibrium selectivity. This is an important feature of the catalyst as the amount of dialkylate that must be processed in the transalkylator and the subsequent cost of processing this material are minimized.

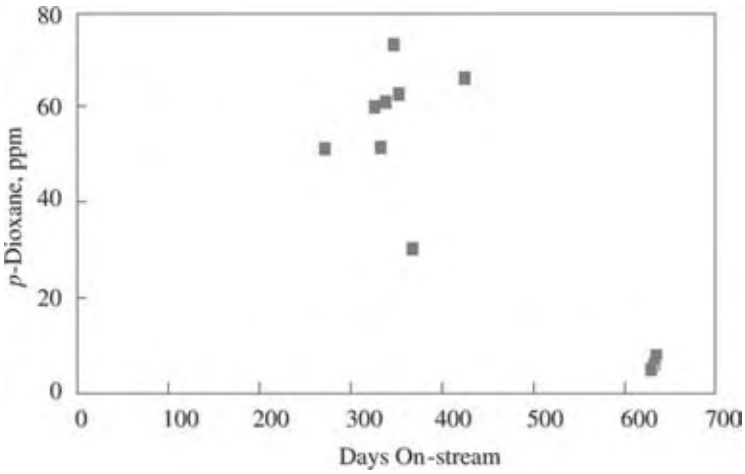

Fig. 13 JLM commercial data on benzene feed *p*-dioxane content. *(View this art in color at www.dekker.com.)*

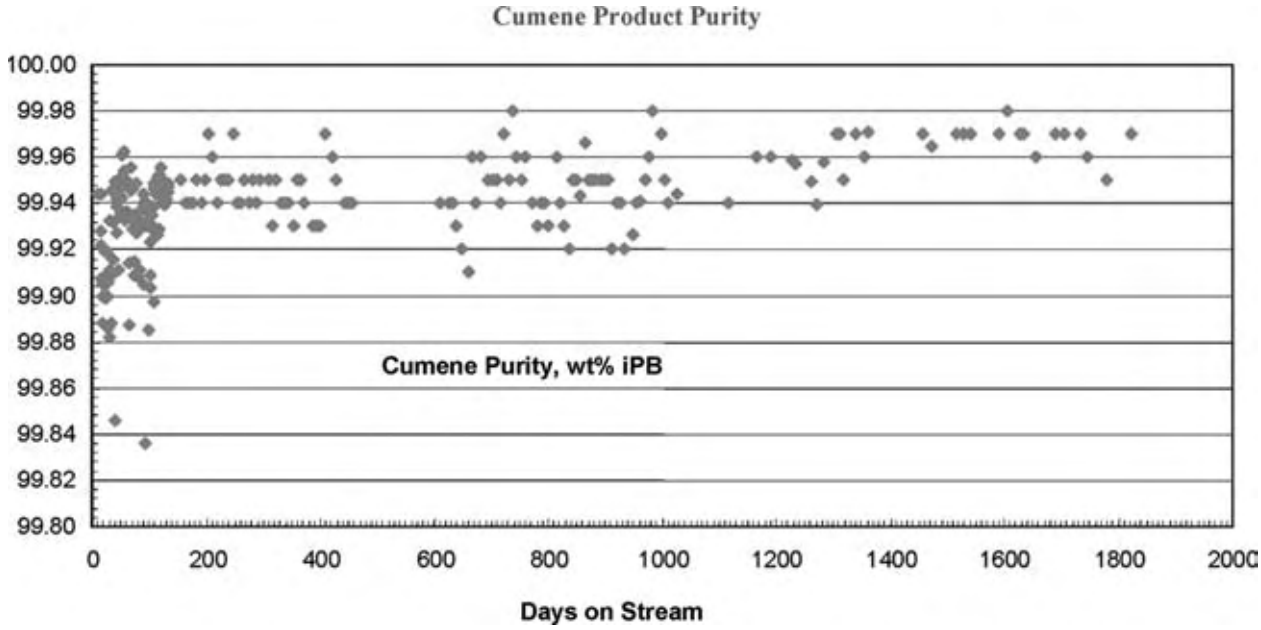

Fig. 14 JLM commercial data on cumene product purity. *(View this art in color at www.dekker.com.)*

Feed contaminants such as sulfur, water, and *p*-dioxane were monitored very closely during the first 2 yr onstream as shown in Figs. 11–13.

The impact of these impurities on cumene product quality was negligible during this period. The customer was able to maintain extremely high-quality cumene throughout the life of the beta catalyst, as shown in Fig. 14.

Another important observation is that sulfur levels from 3 to 7 ppm, moisture levels of 30–70 ppm, and even *p*-dioxane excursions up to 70 ppm had virtually no impact on catalyst stability or performance, as seen in Figs. 10 and 15. Note that the alkylation catalyst selectivity and catalyst bed inlet temperature and weight average bed temperature remain virtually unchanged after years of operation.

Beta Zeolite Catalyst Regeneration

As a result of beta's high activity and robustness, catalyst requirements are minimized. At the end of

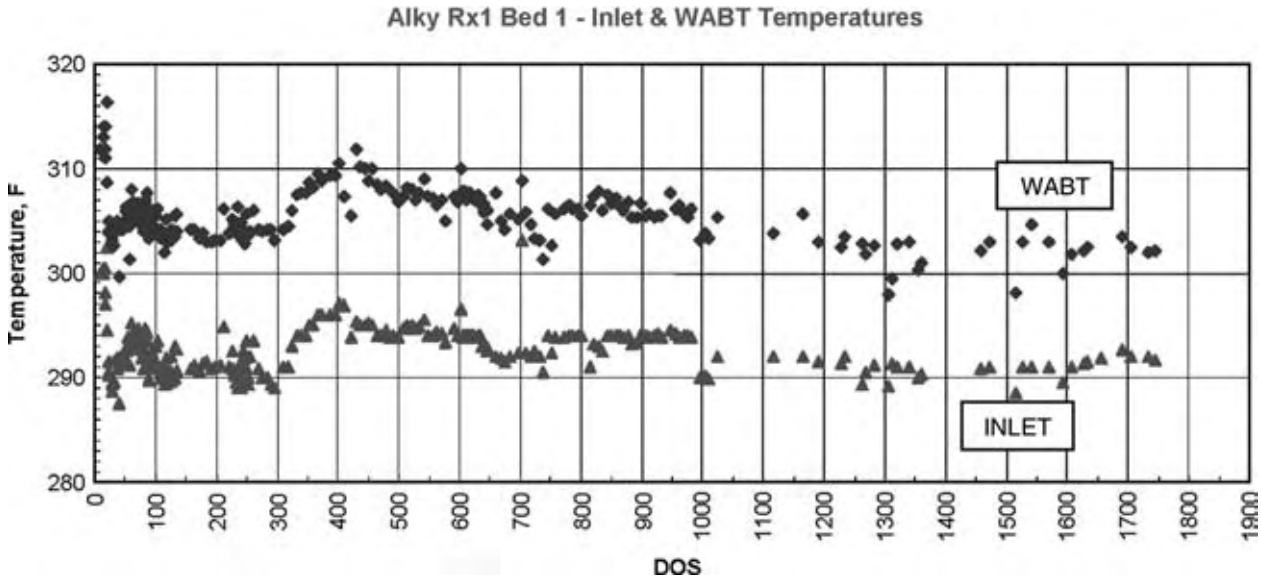

Fig. 15 JLM commercial data. *(View this art in color at www.dekker.com.)*

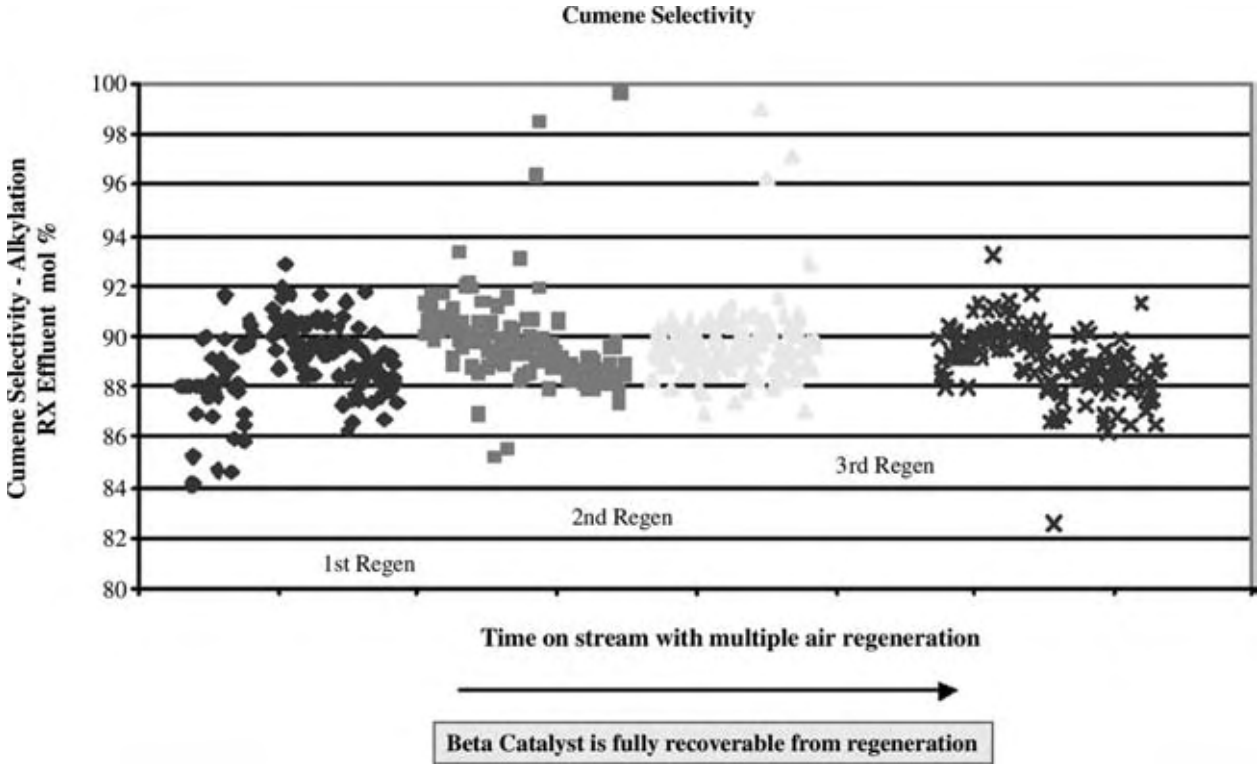

Fig. 16 Commercial Q-Max process data. Effect of in situ QZ-2000 catalyst regeneration on cumene selectivity. *(View this art in color at www.dekker.com.)*

each cycle, the catalyst can be regenerated ex situ by a certified regeneration contractor. The regenerability of beta zeolite catalyst provides an ultimate life of three cycles or more if appropriate processing and regeneration guidelines are followed. If desired, the Q-Max process unit can be designed to accommodate in situ catalyst regeneration. Both options have been successfully demonstrated in commercial operation.

Figs. 16 and 17 show an example of the performance of QZ-2000 catalyst after multiple in situ

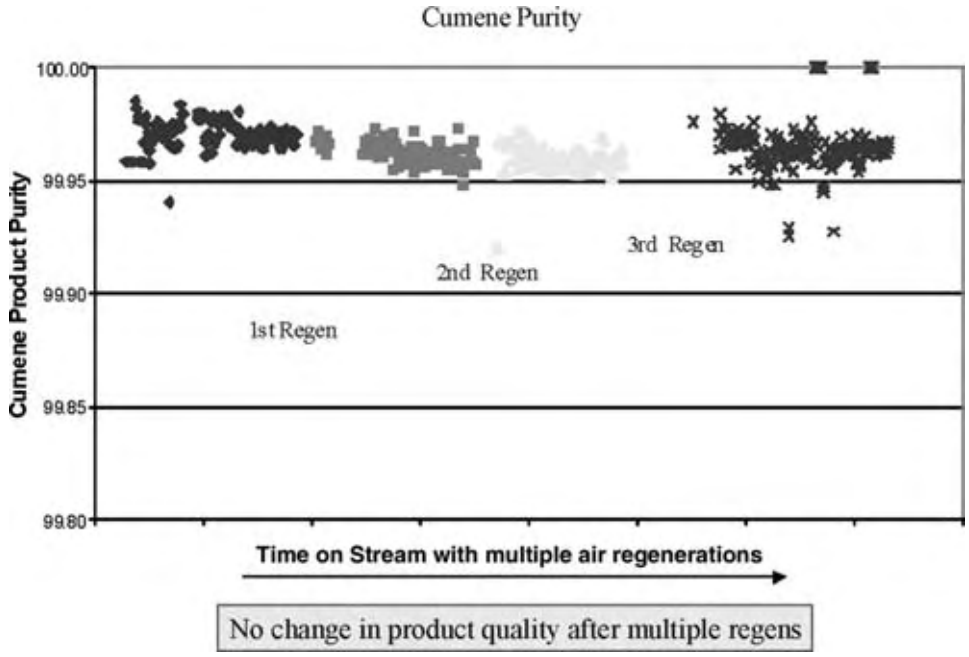

Fig. 17 Commercial Q-Max process data. Effect of in situ QZ-2000 catalyst regeneration on cumene purity. *(View this art in color at www.dekker.com.)*

regenerations in a commercial cumene unit. The cumene unit experienced premature deactivation because of excessive basic nitrogen levels in the feed as well as unsatisfactory plant operation.

Taking advantage of the in situ regeneration capability, the customer opted to regenerate the catalyst three times during this period. The results show the remarkable resilience of the beta zeolite catalyst to the stresses of regeneration with virtually no loss in monoalkylate selectivity or cumene product quality as a result of repeated regenerations.

CONCLUSIONS

Fixed-bed zeolitic cumene technology is the process of choice for the cumene/phenol industry. Most of the previously installed cumene capacity based on older $AlCl_3$ and SPA technologies has now been replaced with the newer zeolitic technology over the past 10 yr. The result is greatly improved yields and reduced operating and capital costs. UOP's Q-Max process based on beta zeolite has emerged as the leader for cumene technology. This is primarily due to the high activity, robustness, and lower operating costs associated with operating a beta zeolite based catalyst system.

Dehumidification

Louay M. Chamra
B. Keith Hodge
Southeast Cooling, Heating and Power Application Center, Department of Mechanical Engineering, Mississippi State University, Mississippi State, Mississippi, U.S.A.

INTRODUCTION

People who experience hot, muggy weather or cold, clammy weather readily understand the discomfort associated with high humidity conditions. Humidity affects our comfort both directly and indirectly in various ways. Controlling humidity in a conditioned space can be important for a wide variety of comfort- and health-related reasons. In addition, humidity control is important in transport and manufacturing processes. Traditional concerns include moisture damage during marine transport, humidity damage for moisture-sensitive artifacts, process improvement for certain manufacturing sectors (confectioneries, electronics, and pharmaceuticals), and product protection from degradation (some foods, grains, and seeds) and from corrosion.

Studies conducted over the last few decades have shown that active humidity control is required in modern, sealed buildings. These studies investigated humidity control using cooling coils [direct expansion (DX) or chilled water], desiccant dehumidification units, mechanical ventilation devices, and humidification units. Additionally, the use of hygroscopically active materials (such as plaster, brick, and ceramic) to control the relative humidity of the surfaces has been considered. This topic is divided into three sections—cooling coil units, desiccant dehumidification devices, and hygroscopically active materials.

COOLING COIL UNITS

A popular humidity-reducing method is to use a cooling coil to sub-cool the air and followed by reheat. In traditional cooling systems, dehumidification is achieved by cooling a moist air stream below its dew point, so that liquid water condenses out of the air. The approximate process path is illustrated in a psychrometric chart in Fig. 1. The process shown is for air being cooled and dehumidified from conditions of 95°F dry bulb (db), 75°F wet bulb (wb) to about 77°F db, 58 grains/lbm_{da}. Initially, the dry bulb temperature of the moist air decreases, while the moisture content remains constant, as shown in Fig. 1. The dry bulb temperature continues to decrease as moisture begins to condense out of the air onto the cooling coil. To deliver air at 77°F db, 58 grains/lbm_{da}, reheat must be used. The path of reheat process is also illustrated in Fig. 1. The resulting air state lies at the center of the ASHRAE summer comfort zone in Fig. 2. The American Society of Heating, Refrigerating, and Air-conditioning Engineers (ASHRAE) defines thermal comfort as ''that condition of mind in which satisfaction is expressed with the thermal environment.'' ASHRAE Standard 55 specifies conditions for which 80% of sedentary (or slightly active) persons find the environment thermally acceptable. In this example, the total net cooling load is 10.8 BTU/lbm_{da}, and, of this, 6.4 BTU/lbm_{da} or about 59% is latent load.

The dehumidification performance of a cooling coil system can be characterized in several ways. The most obvious indicator is the latent capacity, defined as the difference between the total and sensible capacities. The latent capacity increases with reduced airflow and higher entering wet-bulb temperature. However, the sensible capacity changes with these variables as well. As the operation of a DX system is almost always controlled by a dry bulb temperature thermostat, greater latent capacity alone does not necessarily mean lower humidity in a building.

In assessing the ability of an HVAC system to maintain acceptable humidity levels in the building, the more important performance parameter is the sensible heat ratio (SHR) of the equipment. The SHR is defined as the ratio of the sensible cooling load to the total cooling load. Improved latent performance is characterized by a lower SHR. Defining the relationships between SHR and other dehumidification indices is also convenient. In particular, the latent heat ratio (LHR) can be defined as the latent cooling load fraction, and the latent to sensible ratio (LSR) can be defined as the ratio of latent load to sensible load. These ratios appear as

$$\mathrm{SHR} = \frac{Q_{\mathrm{sensible}}}{Q_{\mathrm{sensible}} + Q_{\mathrm{latent}}} \tag{1}$$

$$\mathrm{LHR} = \frac{Q_{\mathrm{latent}}}{Q_{\mathrm{sensible}} + Q_{\mathrm{latent}}} = 1 - \mathrm{SHR} \tag{2}$$

$$\mathrm{LSR} = \frac{Q_{\mathrm{latent}}}{Q_{\mathrm{sensible}}} = \frac{1 - \mathrm{SHR}}{\mathrm{SHR}} \tag{3}$$

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007728

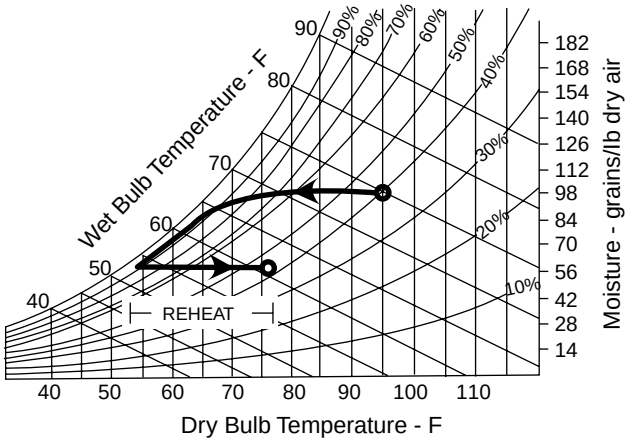

Fig. 1 Sub-cooling dehumidification process. (From Ref.[1].)

The SHR can also be related to the psychrometric properties of the entering and leaving air states.

$$\mathrm{SHR} = \frac{Q_{\mathrm{sensible}}}{Q_{\mathrm{sensible}} + Q_{\mathrm{latent}}} = \frac{c_p(T_{\mathrm{a,ent}} - T_{\mathrm{a,lvg}})}{h_{\mathrm{a,ent}} - h_{\mathrm{a,lvg}}} \quad (4)$$

where Q_{sensible} is the sensible cooling load, Q_{latent} the latent cooling load, c_p the specific heat of air, $T_{\mathrm{a,ent}}$ the entering air temperature, $T_{\mathrm{a,lvg}}$ the leaving air temperature, $h_{\mathrm{a,ent}}$ the entering air specific enthalpy, and $h_{\mathrm{a,lvg}}$ the leaving air specific enthalpy.

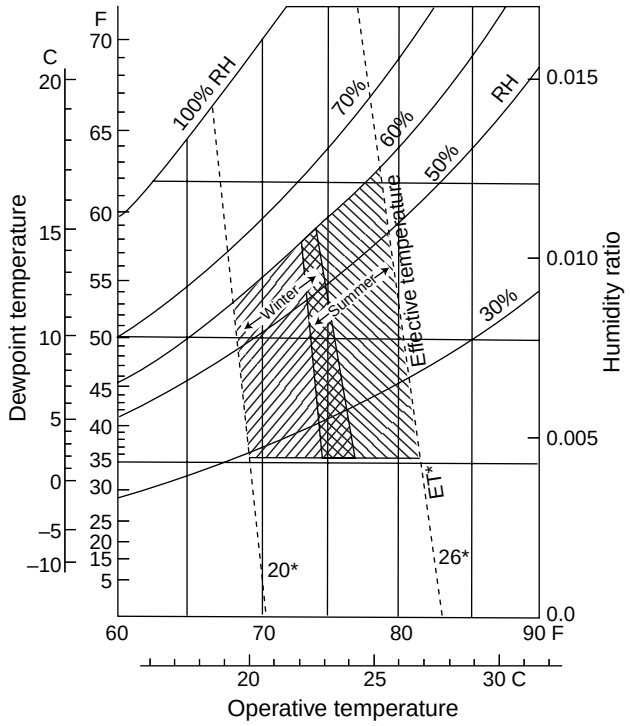

Fig. 2 ASHRAE comfort zones. (From Ref.[2].)

The relationships among the psychrometric states, loads, and sensible heat ratio are shown graphically in Fig. 3. For a given pair of entering and leaving air states, sensible, latent, and total loads are proportional to the differences in temperature, humidity ratio, and enthalpy, respectively, as shown in the figure. The SHR is defined by the slope of the line connecting the two points.

Brandemuehl[3] evaluated the ability of unitary equipment to maintain adequate space humidity levels. The evaluation involved the dehumidification requirements in different buildings and at different climates. He analyzed the building load characteristics to identify and describe key factors that affect humidity control in commercial building applications. The results indicated that ventilation loads dominated the dehumidification characteristics of most commercial buildings and dramatically affect the SHR of the system loads. He concluded that, in most cases, the dehumidification requirements were beyond the capability of conventional unitary HVAC equipment.[3]

In the conventional system, the same equipment is used for both sensible cooling and dehumidification. If both humidity control and temperature control are required, a provision for reheat of the sub-cooled air must be included. In the example in Fig. 1, the net cooling load is 10.8 $\mathrm{BTU/lbm_{da}}$, but the total load on the cooling coil is 16.1 $\mathrm{BTU/lbm_{da}}$ with the difference (5.3 $\mathrm{BTU/lbm_{da}}$) being added back during the reheat process. Thus, energy is used both for the excess sub-cooling and for the reheat.

Another disadvantage of the conventional approach is that the air leaving the evaporator coil is nearly saturated, with a relative humidity typically above 90%. This moist air travels through duct work until the air either is mixed with dryer air or reaches the reheat unit. The damp ducts, along with wet evaporator coils and standing water in a condensate collection pan (Fig. 4), foster problems with microbial growth and the associated problems of health and odor.

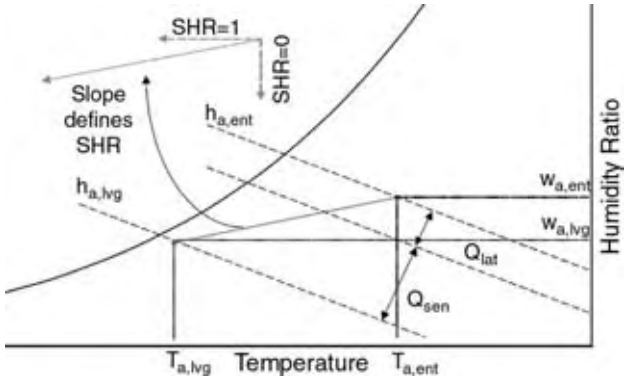

Fig. 3 Coil loads and sensible heat ratio on psychrometric chart.

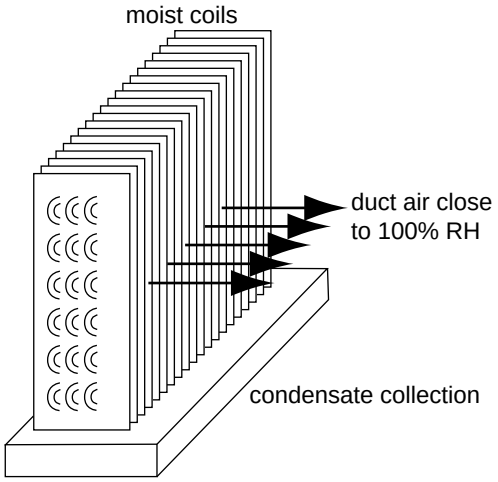

Fig. 4 Damp duct symptoms. (From Ref.[1].)

DESICCANT DEHUMIDIFICATION UNITS

Desiccant dehumidification systems remove moisture from the air by forcing the water vapor directly into a desiccant material. The moisture from the air is attracted to the desiccant because an area of low vapor pressure is created at the surface of the desiccant. The pressure exerted by the water in the air is higher, hence the water molecules move from the air to the desiccant and the air is dehumidified.

The functioning of a desiccant material might be compared to the action of a sponge in collecting a liquid. When the sponge is dry, it soaks up the liquid effectively. Once it becomes saturated, the sponge is taken to a different spot, the liquid is expelled by squeezing the sponge, and the dry sponge is ready to absorb more liquid. In a desiccant system, if the desiccant material is cool and dry, its surface vapor pressure is low and moisture is attracted and absorbed from the air, which has a high vapor pressure. After the desiccant material becomes wet and hot, it is moved to another air stream and the water vapor is expelled by raising the temperature (this step is called ''regeneration''). After regeneration, the desiccant material is ready to be brought back to absorb more water vapor. The entire process involves only water vapor—no liquid is ever condensed.

Desiccant dehumidification units are available with both solid and liquid desiccants. The difference between solid and liquid desiccants is their reaction to moisture. Some simply collect moisture like a sponge collects water. These desiccants are called adsorbents and are mostly solid materials. Silica gel is an example of a solid adsorbent. Other desiccants undergo a chemical or physical change as they collect moisture. These are called absorbents and are usually liquids or solids that become liquid as they absorb moisture. Lithium chloride collects water vapor by absorption. Sodium chloride, common table salt, is another example of an absorbent.

Solid desiccant dehumidification units contain desiccant-impregnated wheels. The solid wheel units come in two common configurations—single-wheel units and dual wheel units. Single-wheel units (sometimes called TWERS—total energy recovery system) are commonly used in conjunction with evaporative cooling systems (such as the one used in ice rinks). Dual wheel (sometimes referred to as DWERS—dual wheel energy recovery system) and liquid units are usually paired with cooling and heating coils for temperature control. Regardless of the type, desiccant units can provide increased energy savings for ventilation.

A variety of factors determine whether an adsorbent will be useful as desiccants. These factors include cost, long-term stability, moisture removal characteristics (rate, capacity, saturation conditions, and suitable temperatures), regeneration requirements (rate of moisture surrender as a function of temperature and humidity), availability, and manufacturing considerations.

Solid Adsorbents

Silica gels and zeolites are used in commercial desiccant equipment. Other solid desiccant materials include activated aluminas and activated bauxites. The choice of desiccant material for a particular application depends on factors such as the regeneration temperature, the level of dehumidification, and the operating temperature.

Solid desiccant materials are arranged in a variety of ways in desiccant dehumidification systems. A large desiccant surface area in contact with the air stream is desirable, and a way to bring regeneration air to the desiccant material is necessary.

The most common configuration for commercial space conditioning is the desiccant wheel shown in Fig. 5A. The desiccant wheel rotates continuously between the process and the regeneration air streams. The wheel is constructed by placing a thin layer of desiccant material on a plastic or metal support structure. The support structure, or core, is formed, so that the wheel consists of many small parallel channels coated with desiccant. Both ''corrugated'' and hexagonal (Fig. 5B) channel shapes are currently in use. The channels are small enough to ensure laminar flow through the wheel. Some kind of sliding seal must be used on the face of the wheel to separate the two streams. Typical rotation speeds are between 6 and 20 rotations per hour. Wheel diameters vary from 1 ft to over 12 ft. Because dust or other contaminants can interfere with the adsorption of water vapor and quickly degrade the system performance, air filters

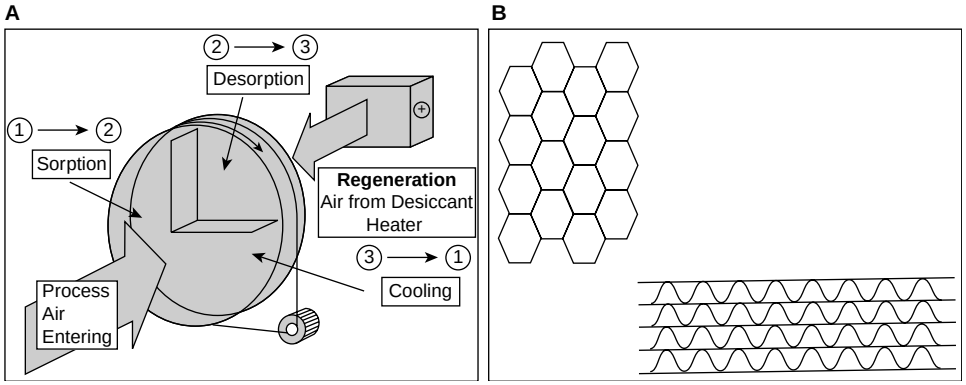

Fig. 5 (A) Desiccant wheel. (B) Corrugated and hexagonal channel shapes. (From Refs.[1,4].)

are an important component of solid desiccant systems. All commercial systems include filter and maintenance protocols for keeping the filters functioning properly.

Liquid Absorbents

Materials that function as liquid absorbents include ethylene glycols, sulfuric acid, and solutions of the halogen group such as lithium chloride, calcium chloride, and lithium bromide (ASHRAE[5]). A generic configuration for a liquid desiccant system is illustrated in Fig. 6. The process air is exposed, usually by spraying the solution through the air stream, to a concentrated desiccant solution in an absorber. As the solution absorbs water from the air stream, the concentration drops, and the weak solution is taken to a regenerator, where heat is used to drive off the water (which is carried away by a regeneration air stream) and the concentrated solution is returned to the absorber. Liquid desiccant systems provide the added advantage of removing many particulates from the air stream. Some liquid desiccants kill bacteria as well. Furthermore, liquid desiccant systems can be configured to operate with very low regeneration temperatures.

Regeneration

For solid or liquid systems, regeneration energy can be drawn from a variety of sources. Because of the relatively low temperature requirements of regeneration (<250°F), waste heat provided by combustion

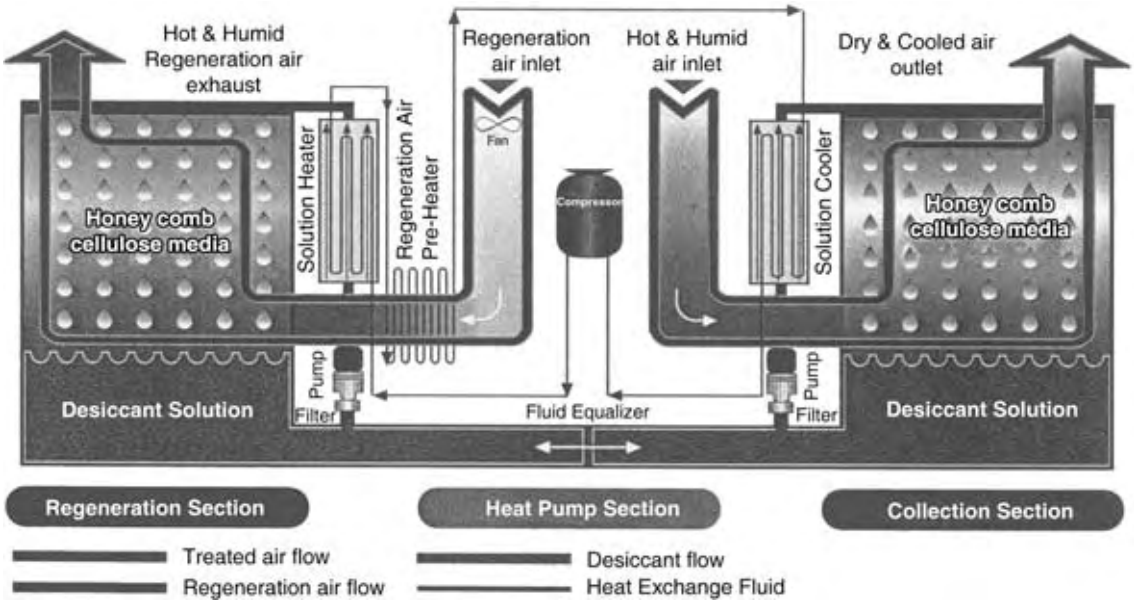

Fig. 6 Liquid desiccant unit schematic. (From Ref.[6].)

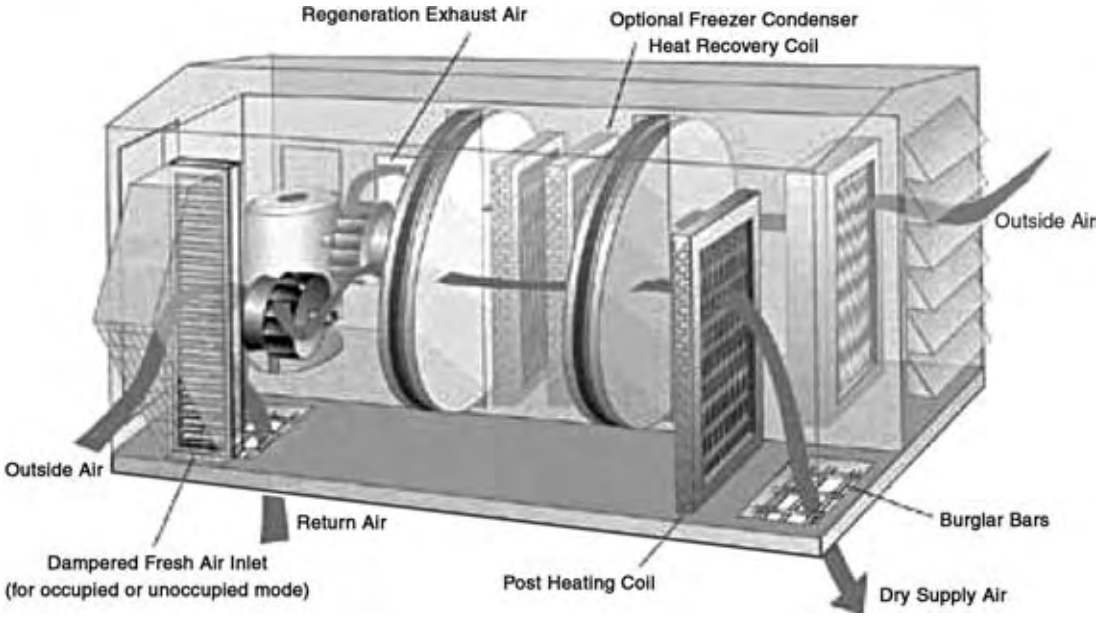

Fig. 7 Dual wheel desiccant schematic. (From Ref.[7].) *(View this art in color at www.dekker.com.)*

turbines, IC engines, and any of the fuel cell technologies is capable of supplying heat at regeneration temperatures.

Solid Desiccant System

The components of a generic solid desiccant dehumidification system are illustrated in Fig. 7. At a minimum, the system will include separated air streams of process and regeneration for the desiccant device and some kind of heat source to raise the temperature of the regeneration air.

The approximate path of the process air through a desiccant device is shown in Fig. 8 for the same inlet and outlet conditions as were shown for the sub-cooling system (Fig. 1). Note that, as implied by the path from point 1 to point 2 in Fig. 8, the desiccant process increases the dry bulb temperature of the process air. For solid desiccant materials, this increase is a result of the ''heat of adsorption'', which consists of the latent heat of vaporization of the adsorbed liquid plus an additional ''heat of wetting.'' The heat of wetting is the energy released during dehumidification, in excess of the latent heat of vaporization. The path from point 1 to point 2 is close to a line of constant enthalpy. After the dehumidification process, the process air must undergo a sensible cooling process to reach the end point.

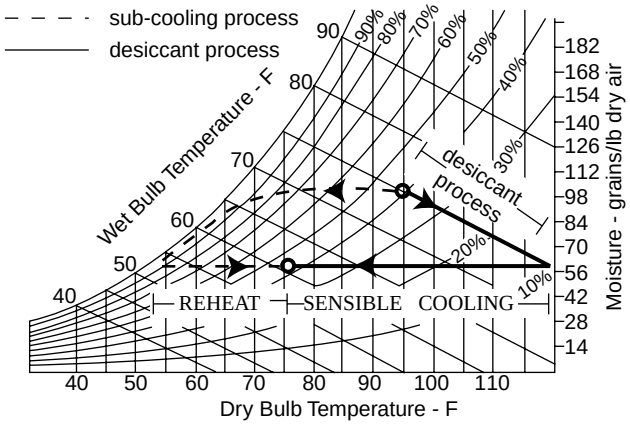

Fig. 8 Dry desiccant dehumidification process. (From Ref.[1].)

A wide variety of configurations of desiccant dehumidification system are available. The air inlet conditions and outlet requirements of process and regeneration call for different configurations depending the individual situations. For illustration purposes, two examples are presented in Figs. 9 and 10.

In Fig. 9, a configuration for a desiccant system that is designed for operation in a ventilation situation is illustrated; that is, 100% outside air is used to supply the conditioned space. The air for regeneration is taken from within the conditioned space and exhausted outside. The outside air starts at state 1 at approximately 95°F db, 75°F wb. From state 1 to state 2, the sensible temperature increases and the moisture content decreases as the outside air passes through a desiccant wheel. From state 2 to state 3, the hot air rejects some heat to the regeneration air stream via a heat exchanger. Finally, the air stream is cooled to the design supply condition by passing it through a conventional cooling coil (state 3 to state 4).

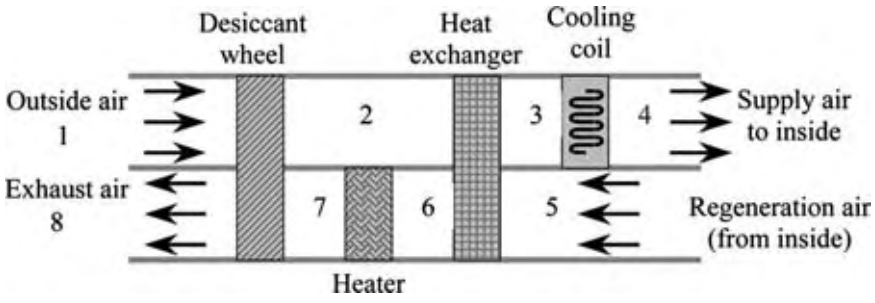

Fig. 9 Ventilated desiccant dehumidification system configuration. *(View this art in color at www.dekker.com.)*

The regeneration air stream starts at approximately 75°F db, 40% rh. From state 5 to state 6, this air stream acquires heat from the process air stream through a heat exchanger, and from state 6 to state 7, the regeneration stream is further heated to an appropriate temperature for desiccant regeneration. Finally, the regeneration air is cooled and humidified as it extracts moisture from the desiccant wheel (state 7 to state 8). At state 8, the regeneration stream is exhausted to the outside.

In Fig. 10, a re-circulating configuration is illustrated; 100% of the process air is drawn from the conditioned space (and all is returned to the conditioned space). The regeneration air is 100% from outside. The equipment arrangement is identical to that of the ventilation illustration in Fig. 9; only the air stream conditions are different.

Benefits and Cost Considerations

To effectively discuss the benefits and disadvantages of desiccant systems, the two common methods of installation must be understood. A ventilation installation is one in which the desiccant unit is completely independent of the air conditioning (A/C) coils. (In this discussion, both the cooling and the heating coils of conventional equipment are referred to as air conditioning coils). Such an installation allows outdoor air to be continuously supplied to the indoor space without requiring the fan of the main air conditioning system to operate simultaneously with the desiccant unit. Another advantage of this installation is that it allows for humidity control across several control zones in a building (or a group of buildings). Common applications for ventilation installations are in large office buildings and schools. A preconditioning installation is one in which the desiccant unit is connected to pretreat the outdoor air before it is treated by the main air conditioning unit. This type of installation requires the fan on the air conditioner to operate when the desiccant unit is operating. One advantage to a preconditioning installation is that it can eliminate the seasonal variations experienced by the A/C coil, which improves the energy efficiency of the coils (Fischer[8]). A typical range of outdoor air conditions throughout a year is shown in Fig. 11 as the teardrop shape filled with diagonal lines. The oval in the center of the seasonal variations is the typical range of air conditions that a desiccant unit supplies year around, when installed as a preconditioning system. Common applications for a preconditioning installation are in homes and small commercial buildings.

Regardless of the variation, desiccant units operate similarly. During the winter mode, the heat recovery (sensible) wheel of a dual wheel system does not rotate. Fig. 12 is an operational diagram, with the states indicated, of a desiccant system operating in ventilation mode; while both summer and winter modes of operation are shown in the figure, only the winter mode will be discussed (for a discussion of the summer ventilation mode of operation refer to Fischer[8]). On the process side, cold, dry air enters the desiccant wheel and is heated and humidified. The air then passes unchanged through the inactive cooling coil and the stationary sensible wheel. On the regeneration side,

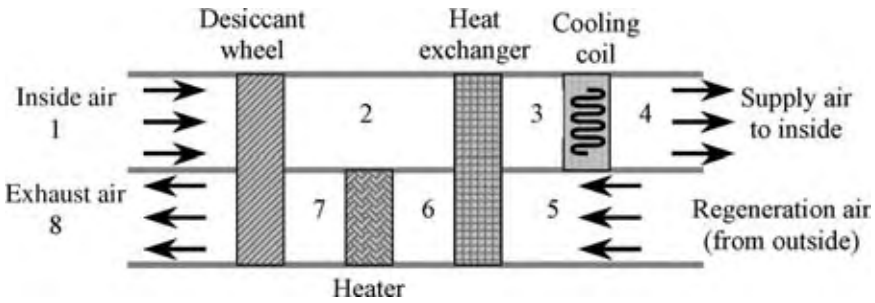

Fig. 10 Re-circulated desiccant dehumidification system configuration. *(View this art in color at www.dekker.com.)*

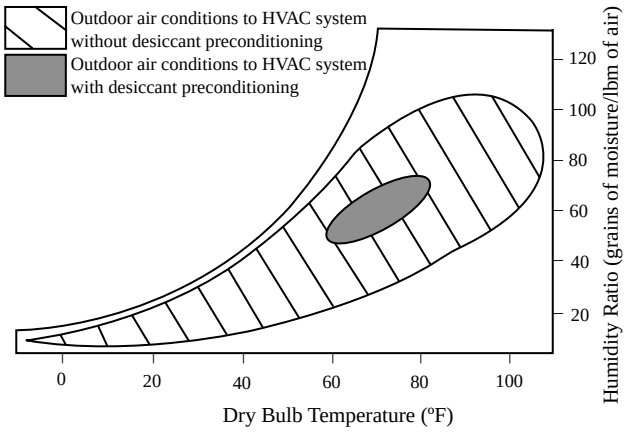

Fig. 11 Desiccant preconditioning target. (From Ref.[8].)

warm moist return air passes unchanged through the stationary sensible wheel and then passes through the desiccant wheel. The return air then exits the unit cooler and drier. In the example shown in Fig. 12, the supply air of 61.5°F and 31 grains is both cooler and less humid than the return air of 70°F and 38 grains. While the outdoor air has been dehumidified, the net effect on the indoor environment is that it has been dehumidified less than in conventional ventilation systems. Green,[9–11] Sale,[12] and Gelperin[13] recommend that the indoor environment be humidified during the winter. While the use of a desiccant unit to condition the ventilated fresh air reduces the humidity in the indoor space, it does not reduce the humidity nearly as much as ventilation alone.

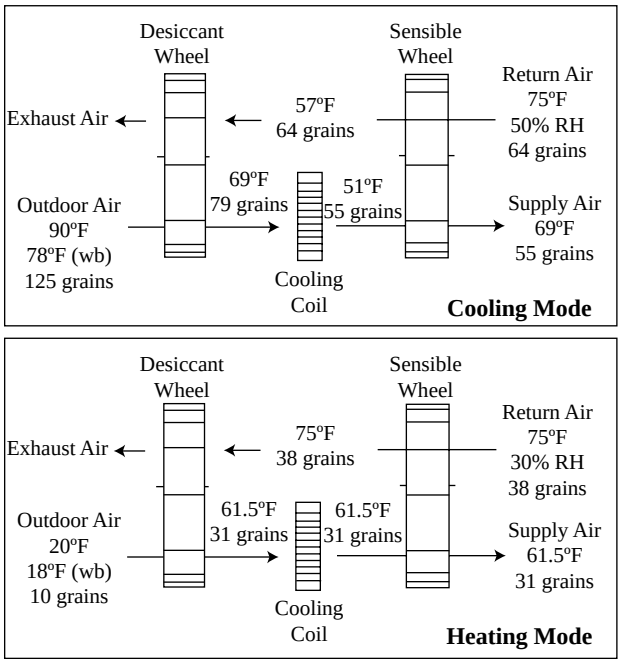

Fig. 12 Operating characteristics of a dual wheel desiccant unit. (From Ref.[8].)

Desiccant Dehumidification vs. Cooling Coil Dehumidification

Desiccant units have several advantages over cooling coil units. Downing and Bayer[14] conducted an investigation into a Georgia school with indoor air quality problems; the indoor air quality problems at the school were so bad that students walked out of class in protest and lawsuits were filed against the school system. As part of this investigation, data were collected for direct expansion cooling coils supplying 5 cfm/person continuously, direct expansion cooling coils supplying 5 cfm/person intermittently, and a dual wheel desiccant unit supplying 15 cfm/person; these data are shown in Fig. 13. As demonstrated in this figure, the direct expansion cooling coils could not maintain the indoor relative humidity low enough to prevent microbial problems. However, the dual wheel desiccant unit was able to maintain the humidity level low enough to help prevent microbial problems. Notice that at 5 cfm/student intermittently, the direct expansion unit operates below the maximum recommended relative humidity during the occupied hours; however, when the units are not run during the unoccupied hours, the relative humidity rises above the threshold. At 5 cfm/student continuously, the direct expansion unit cannot maintain an acceptable relative humidity; again there was a sharp increase in the relative humidity during the unoccupied hours when the direct expansion unit was shut down. The increase in the relative humidity when the direct expansion units were not operating was exacerbated by the evaporation of the condensed water in the cooling coil drain pan. Data for 15 cfm/student intermittently and continuously were taken; however, Downing and Bayer[14] did not present these data as the relative humidity for those cases was significantly higher than that for the 5 cfm/student continuously. When a dual wheel desiccant unit was installed and operated at 15 cfm/student continuously during both occupied and unoccupied hours, the relative humidity remained relatively constant. Fischer[8] does a complete economic analysis comparing desiccant units to direct expansion units providing 15 cfm/person continuously and concluded, as mentioned by Baughman and Arens[15] and Downing and Bayer,[14] that desiccant systems (unlike direct expansion cooling coils) do not require condensate drain pans, which can become a significant source of microbial growth.

The humidity-control capability of desiccant technology offers many potential cost savings when compared with conventional sub-cooling systems. The capital cost of a desiccant system is often more than that of an equivalent sub-cooling system because of extra equipment costs. Installed capital cost for active, solid desiccant systems range from $4 to $9

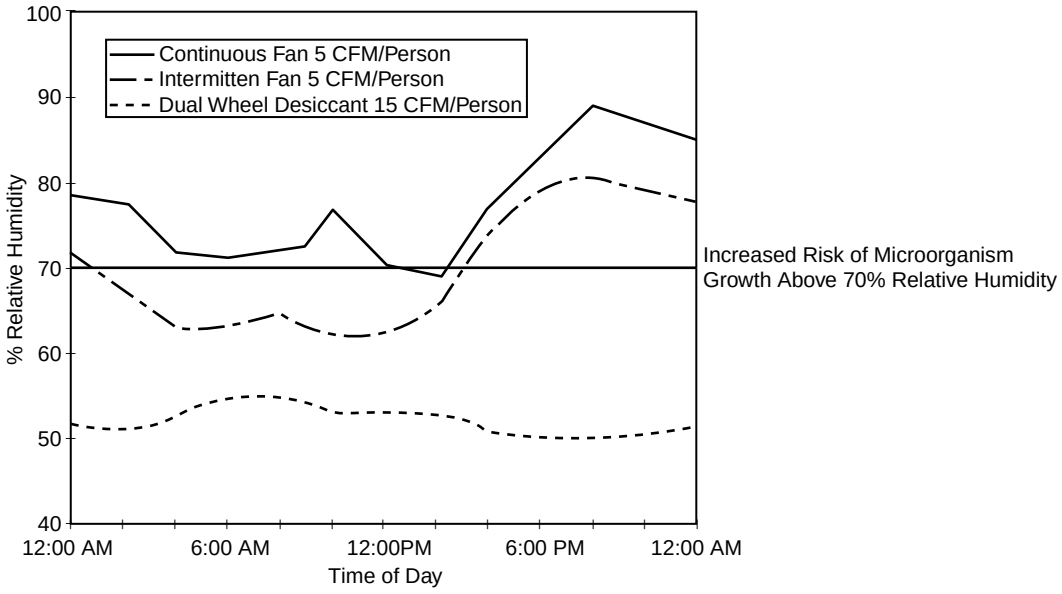

Fig. 13 Daily humidity level comparisons. (From Ref.[14].)

per cfm capacity for air handling, depending upon the total capacity and equipment enclosure requirement. The higher-end of the cost range applies to systems with <5000 cfm. Some desiccant systems, depending on the specific installation, may result in lower capital cost; however, the reduction of latent heating load will usually result in lower operating costs for desiccant systems. Harriman[16] discusses the installation of a desiccant dehumidification system in a medical research building where both capital costs and estimated operating costs were lower for the desiccant system.

Because the humidity and temperature can be controlled independently with a desiccant dehumidification and cooling system, the system performance is often more effective than that obtainable with conventional systems. Analysis of the SHR suggests the potential for saving energy cost that a desiccant system may have. An SHR close to unity implies that very little moisture is removed from the air, while a sensible heat ratio close to zero indicates that most of the load is latent cooling. Air-conditioned environments often have SHR values well below unity, which results in greater energy consumption for a sub-cooling system than that for a desiccant dehumidification and cooling system that meets the same zone temperature requirements.

Some potential cost savings vary with installation and are recognized based on the individual application. These cost savings are related to dehumidification and are implied by the process/product benefits outlined in Table 1. Other potential costs associated with poor humidity control should not be overlooked. Examples include retail establishments where customer discomfort or dissatisfaction because of unpleasant odors and merchandize appearance would be detrimental to business. For grocery stores, frost buildup in refrigerated display cases is unsightly, and its elimination requires expensive defrost cycles. Hospitals and nursing homes require careful attention to minimizing conditions favorable to microbial growth and propagation. Additionally, microbial growth can be hazardous to the health of children in school buildings as well as to the occupants of office and other commercial buildings. Ice rinks can reduce "fogging," condensation in the building, and can improve ice quality with lower humidity levels.

HYGROSCOPICALLY ACTIVE MATERIALS

Building materials can be divided into three categories—non-porous media, hygroscopic-porous media, and capillary-porous media. Arens and Baughman[17] define non-porous materials, such as plastic, glass, and sheet metal, as those that condense moisture on the surface of the material; hygroscopic-porous materials, such as wood, clay, and natural fibers, as those that have microscopic pores that reduce the vapor pressure at the surface and volume changes with the material moisture content; capillary-porous materials, such as brick, concrete, and gypsum board, as those that have visible pores and whose volumes are not affected by moisture levels. Initially, hygroscopic materials may appear to promote biological growth (especially natural fibers); however, wood-based products will adsorb/desorb the moisture in cellulose molecules which removes the water, and thus, not allowing it to be used for microorganism growth.[17]

Table 1 Process/product benefits because of dehumidification

Process	Product benefits
Lithium battery production	Prevent corrosion and improve production
Computer and electronic equipment production	Prevent condensation and corrosion on metal surfaces
Plastic molding	Improve product finish by preventing condensation on metal surfaces
Archives and museums	Increase longevity of books, artwork, and artifacts
Seeds and grain storage	Optimize seed moisture level and minimize microbial deterioration
Confectionary and pharmaceutical packaging	Keep products from deteriorating
Confectionary manufacturing	Improve product and appearance production

(From Ref.[1].)

Straube and deGraauw[18] provide an extensive review of a popular hygroscopically active material. Their research shows that cement-bonded wood fiber (CBWF) has ''an interesting and unique mix of vapor permeability and vapor storage capacity.'' Though CBWF had been known to provide a healthier indoor environment, it was Straube and deGraauw[18] who first attempted to learn why CBWF provides a healthier indoor environment. Their research also concludes that hygroscopically active materials may be able to help prevent mold and fungi problems during conditions of peak relative humidity by adsorbing some of the moisture from the ambient air. One study (West and Hansen[19]) found that hygroscopically active materials can influence the indoor relative humidity by as much as 15–20%. More research in this area is necessary before the widespread use of hygroscopically active materials can be recommended as a means to alleviate problems of indoor air quality. Baughman and Arens[15] report that wood paneling can ''adsorb/desorb large amounts of humidity on a diurnal cycle [over the course of a day] without surface condensation occurring.''

The use of hygroscopically active materials may help in controlling the space relative humidity during the peak humidity periods, which can be significantly high when using natural ventilation, mechanical ventilation, or direct expansion dehumidification units. Effects of hygroscopically active material could be even more significant in high-humidity rooms such as kitchens and bathrooms. Therefore, when no humidity control is present and in rooms that are usually humid, the use of hygroscopically active materials is recommended. However, there is little information, such as sorption rate and moisture capacity, available on most hygroscopic materials; therefore, this recommendation is made with the condition that only materials with known hygroscopic properties are used.

HUMIDITY CONTROL AND INDOOR AIR QUALITY

Humidity control may be accomplished by using cooling coil units, desiccant dehumidification units, and hygroscopically active materials. Effects of most indoor air pollutants are strongly influenced by the

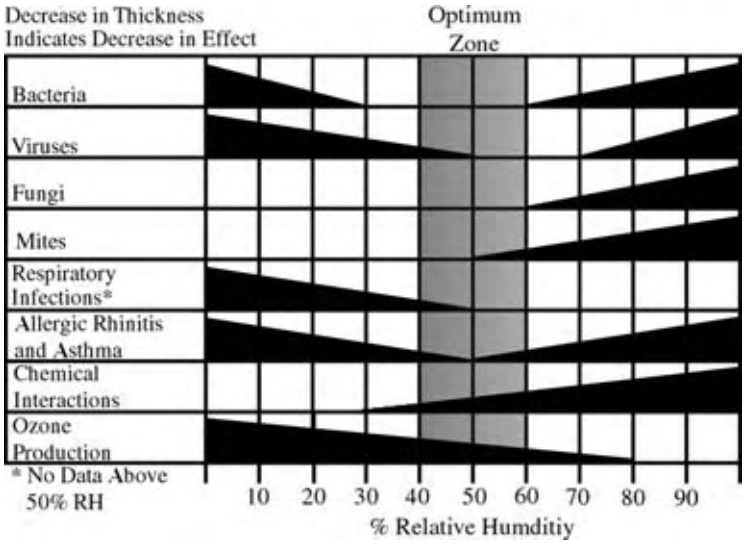

Fig. 14 Relative humidity effects on indoor air pollutants and human illnesses.

relative humidity. In Fig. 14, the effect of relative humidity on common indoor air pollutants and human ailments is illustrated. Here, the optimum relative humidity range is 40–60%. For this reason, common practice is to design humidification systems to maintain a 50% relative humidity; however, the needs of the space will determine the designed humidity set-point. The two most significant pollutants in the 40–50% relative humidity range are chemical interactions and ozone production.

CONCLUSIONS

Desiccant systems are the most convenient means to control the indoor relative humidity. As Downing and Bayer[14] have shown, desiccant systems can supply larger quantities of fresh air without introducing an unacceptably high relative humidity to the indoor environment. As desiccant systems remove the moisture from the process air stream through a mass transfer process, there is little chance for the system to promote microorganism growth. A major limiting factor in desiccant systems is the initial cost; however, the added benefits of the reduced health care costs because of better humidity (and microorganism) control (Fischer[8]). Furthermore, the initial cost of a desiccant unit to handle high ventilation rates is roughly equivalent to purchasing a direct expansion unit that can handle the same ventilation rates.[8]

Denitrogenation

Daeik Kim
Teh Fu Yen
University of Southern California, Los Angeles, California, U.S.A.

INTRODUCTION

Petroleum (rock-oil, derived from Latin *petra*, meaning rock or stone, and Latin *oleum*, meaning oil) occurs widely in the earth as a gas and a liquid.[1] Petroleum is a mixture of gas, liquid, and solid hydrocarbon-type chemical compounds that occur in sedimentary rock deposits throughout the world. In the crude state, petroleum has minimal value, but when refined, it provides high-value liquid fuels, solvents, lubricants, and many other products.

The fuels derived from petroleum contribute between one-third and one-half of the world's total supply of energy. They are used not only for transportation fuels (e.g., gasoline, diesel fuel, aviation fuel, and jet fuel), but also to heat buildings. Petroleum products are used to lubricate machines and a once-maligned byproduct, asphalt, is used to provide highway surface and roofing materials.

Petroleum is by far the most commonly used liquid fuel source. Nevertheless, dwindling supplies of this source make it essential that other sources of liquid fuels be found. Such sources are heavy oils, oil sand bitumens, coal, and oil shale. In fact, the occurrence of petroleum and its uses as sources of much-needed liquid fuels may be likened to the ''tip of the iceberg'' when compared to the resources of other fossil fuels. For instance, in the case of oil sand, the Alberta oil sand deposits contain approximately 1.6 billion barrels of oil,[2] which is the principle oil source in America. Thus, development of other fossil fuels will be expected to be the major energy recovery as petroleum stocks are depleted. Petroleum and other fuel sources contain nitrogen, sulfur, and metals in small amounts, as well as oil and gas. Those small amounts of compounds tend to degrade the quality of fuels as the final product. In this sense, desulfurization and demetallization technologies have been well developed and much investment was allowed as part of military and commercial projects, such as fuel cell and battle ship desulfurizer. Sulfur and metal removal have drawn more attention since these compounds are contained more in fuel sources than nitrogen. At the same time, sulfur in fuel leads directly to emission of SO_2 and sulfate particular matter (PM) which endanger public health and welfare. The regulation situation has become more stringent, requiring the use of low-sulfur fuel.[3] Nitrogen compounds contained in energy sources are equally problematic, even though its content is generally smaller than sulfur in fuel. Nitrogen compounds directly help produce NO_x and related air pollutions that are worse in urban areas, reacting with ozone in automobile emission and sunlight. Denitrogenation technology is required to decrease the nitrogen content in fuel, which will increase the opportunities for exploiting the energy sources that are presumed to be less valuable. This technology can even upgrade the value of current high-quality fuel products which still contain small amounts of nitrogen compounds, eventually resulting in reduction of air pollution.

NITROGEN AND DENITROGENATION

Nitrogen Compounds in the Environment and Petroleum

Nitrogen is a major element of nutrients for living organisms. It forms a very important component of the building blocks of protein in the living cell, which means that deoxyribonucleic acid (DNA) contains nitrogen. Microorganisms circulate nitrogen in the process of nitrification and denitrification. Finally, nitrogen fixation takes place in plants with the help of microorganisms which helps in maintaining a constant 79% nitrogen composition of air.

Natural gas, petroleum, tarsands, oil shale, and coal are called fossil fuels because of their presumed biogenic origin in buried decaying remains deposited in layers and geochemically transformed through heat and pressure over the course of time into their present form. For this reason, fossil fuels contain nitrogen compounds.

Many fuels and crude oils contain a certain amount of nitrogen in their compounds. For example, the nitrogen content of petroleum is generally within the range of 0.1–0.9%, although crude oils with no detectable nitrogen or even trace amounts are not uncommon.[4] In general, the ''heavier'' the oil, the higher is their nitrogen content. When comparing the amount of nitrogen in petroleum to all other fossil fuels of different locations, oil shale (Colorado) has 0.41%,

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120038486

oil shale (Alaska) has 0.30%, kerogene (Green River) has 2.13%, bitumen (Lower Freeport) has 1.42%, and asphaltene (Baxterville) has 0.80%.[5]

Different fossil fuels have different compositions. As mentioned, many nitrogen-containing organic species of biological origin are present in the precursors of fossil fuel deposits that have undergone very different geological transformations through biostratinomy (change after death) and taphonomy (fossilization). This difference not only shows the distinctive features in geochemical genesis and deposition histories of fossil sources, but also provides a new insight into the properties of pollutants and their physiological activities.

Nitrogen, oxygen, and sulfur are called heteroatoms (impurities) in fossil fuels. This trio comes in small amounts in fossil fuels, but they control the quality and treating the impurities improves the quality of fuels. Different fossil fuels with different geological features can have different major heteroatoms (impurities). For instance, the major heteroatom in crude petroleum is sulfur. Nitrogen is the major heteroatom in oil shale, as is oxygen in coal. Generally, oil shale shows higher nitrogen contents than does crude oil.

Why Do We Need Denitrogenation?

Chemically speaking, petroleum is an extremely complex mixture of hydrocarbon compounds, with a small amount of oxygen, nitrogen, sulfur, and metal impurities. These impurities result in the degradation of the quality of petroleum and lessen the production ability of available oil resources. Therefore, it is essential to lower the nitrogen content before any refinery processes are performed.

Nitrogen compounds in oil are converted by combustion or incineration to nitrogen oxides (NO_x), and hence to one of the main sources of acid rain and air pollution. The nitrogen compounds are also undesirable in the various refining processes because they deposit on to the catalyst, causing a loss in catalytic activity. Pyrrolic compounds, also nitrogen-containing (with concentrations as low as 0.01%), can cause both storage instability and the promotion of gum with sediment formation in fuels. The use of heavy oils as catalytic cracking feedstocks has accentuated the harmful effects of the nitrogen compounds, which are more prevalent in the higher boiling crude oils.[6]

Currently, denitrogenation technology for light oils is carried out industrially via the catalytic hydrodenitrogenation (HDN) process and simultaneous hydrodesulfurization (HDS).[7] The HDN of petroleum products is more difficult than the HDS. The production of light oil, which contains both very low nitrogen and sulfur, has a tendency to require inevitably severe operating conditions (high temperature and high pressure) and the use of particular active-catalysts, which induce high costs. Chemically assisted ultrasound process (CAUP) is relatively cost- and energy-effective since the CAUP method can produce localized high temperature and high pressure instantly at low energy consumption to break down the pollutants or target compounds.

Nitrogen Containing Model Compounds (Aniline; C_6H_7N, Indole; C_8H_7N, Carbazole; $C_{12}H_9N$)

Aniline, indole, and carbazole contain nitrogen bonding in their chemical structure. Tables 1–3 show where to these model compounds belong.

In the case of indole, alkaline hydrolysis and putrefaction of proteins result in its formation. This formation in the putrefaction of proteins is presumed to be result of decomposition of tryptophan. The formation of indole from albumin may be stopped by the addition of lactose, while other sugars have varying effects on its production. Indole frequently accompanies pus formation and is found in the human liver, pancreas, brain, and bile. Indole, accompanied by its β-methyl homolog, skatole, is found in the feces of humans and animals and in the contents of the intestines.[8]

Indole and homologs of indole have been found in coal and molasses tar. It is also present in ''practical'' α-methylnaphthalene. Its presence occurs by reaction with oxalyl chloride to give the acid chloride of 3-indoleglyoxylic acid. Indole can be prepared by the reduction of indoxyl by all of the following: sodium amalgam, zinc dust and alkali, catalytically, and dehydrogenation. In the preparation of indoxyl or indoxylic acid in the synthesis of indigo, a small amount of indole is obtained when the melt is overheated. Indole has been prepared in fair yields by adding sodium amalgam or zinc dust to the alkaline melt of indoxylic acid.[8]

Indole derivatives are found in many natural products. Indole has unpleasant (fecal) odors. It has

Table 1 Polycyclic aromatic hydrocarbon (PAH)

PASH (polycyclic aromatic sulfur hydrocarbon): benzothiophene and dibenzothiophene	PANH (polycyclic aromatic nitrogen hydrocarbon): indole, carbazole, quinoline and their alkylated derivatives

Table 2 Polycyclic aromatic hydrocarbons (PAHs)

Carbonaceous PAHs	Heteroatomic PAHs
Naphthalene, anthracene, pyrene, coronene	Hensofuran, benzothiophene, indole, carbazole benzoxazole, quinoline, isoquinoline, dibenzofuran

been found in *Robinia pseudacacia*, the jasmines, certain citrus plants, the perfume of the *Hevea braziliensis*, and in orange blossom.[8] Indole is also found in the wood of *Celtis reticulosa*. It is even found in Mexican mushroom, Epena snuff, Indian snuff, and the Isatis herb. The indole structures contribute hallucinatory and neurohumorous properties. Indole is usually obtained by repeated extraction of the blossoms with a suitable solvent and subsequent removal of the solvent by distillation.

Many different types of nitrogen-containing compounds have been shown in oil shale. Poulson and co-workers[9] reported that pyridines and pyrroles were major types of nitrogen compounds in shale oil. Cyclic amides and anilides were proposed as possible additional types of nitrogen compounds in shale oil. Van Meter and co-workers found benzonitriles in shale oil naphtha. Brown and co-workers identified alkylpyridines, cycloalkanopyridines, alkylanilines, quinolines, tetrahydroquinolines, and tetrahydroisoquinolines in

(From Ref.[15].)

hydrocracked shale oil naphata. However, major nitrogen compound types in petroleum crude oil have been characterized mainly into four classes—pyridines, diaza compounds, carbazoles, and amides. Some light oils contain considerable amounts of indole and aniline as well.

Petroleum and fuels can be categorized into two kinds, hydrocarbons and nonhydrocarbons. Nitrogen, sulfur, and oxygen belong to the nonhydrocarbon category, which is very recalcitrant and degrades the quality of fuels.

Polycyclic aromatic compounds (PAC) are a significant environmental chemical group, with an associated health effect. PACs includes PAH (polycyclic aromatic hydrocarbon), PASH (polycyclic aromatic sulfur hydrocarbon), and PANH (polycyclic aromatic nitrogen hydrocarbon). The main PAHs are naphthalene, fluorene, phenanthrene, and their alkylated homologs; PASHs are benzothiophene and dibenzothiophene; PANHs are indole, carbazole, quinoline, and their alkylated derivatives[10] (see Table 1).

Polycyclic aromatic hydrocarbons (PAHs) are categorized into carbonaceous PAHs(naphthalene, anthracene, pyrene, and coronene) and heteroatomic PAHs (benzofuran, benzothiophene, indole, benzoxazole, quinoline, isoquinoline, dibenzofuran, and carbazole)[10] (see Table 2).

Nitrogen species are also divided through acidic extraction into basic species (such as aniline, quinoline, benzoquinoline, and their derivatives) and nonbasic species (such as indole, carbazole, and their derivatives)[8] (see Table 3).

Denitrogenation Technology

Microbial degradation[11]

Microbial degradation of nitrogen compounds from fossil fuels was one type of method to remove nitrogen. An example of this is the biodegradation of the nitrogen-containing compound, quinoline, in crude oil. For example, 2 mg/L of carbazole (which accounts for 80% of nitrogen compound), and 500 mg/L of carbazole (which accounts for 24% of nitrogen compound), were removed after 15 days. Microbial degradation however has some drawbacks, such as (1) it is a very slow method; (2) there are difficulties in manipulating the bacterial growth; (3) it needs the skill of a professional operator; and (4) it cannot handle high concentrations of pollutants.

Pyrolysis[12]

Pyrolysis (coal) is another method that is old but still widely used. Pyrolysis oil derived from oil shale was hydrotreated in a stirred reactor at 400 C for 12 hr. The catalysts are nickel- and cobalt-molybdenum types. The results showed that the nitrogen and sulfur contents of the oils were significantly decreased after hydrotreatment and were further decreased with increasing pressure of hydrogen. However, this method requires very high temperature and pressure, which means high costs.

Ferric chloride-clay complexation method[13]

Raw shale oil is allowed to process through $FeCl_3$-clay chromatography. $FeCl_3$-clay is prepared by contacting the attapulgus (Engelhard Minerals and Chemicals) with a methanolic ferric chloride solution (saturated $FeCl_3 \cdot 6H_2O$ in methanol) for 1 hr. $FeCl_3$-clay is filtered, washed, and extracted with pentane for 48 hr in a Soxhlet extractor to remove retained, nonadsorbed, iron salts and then dried under nitrogen. This method is similar to the ion exchange. The data showed that in shale oil 65% of total nitrogen, 56% of total oxygen, and 27% of total sulfur were removed by the $FeCl_3$-clay technique. This method is nondestructive because pollutants stay in another form of chemicals.

Hydrotreating reactions[14]

Denitrogenation reactivities of nitrogen species in gas oils were followed in the hydrotreating reactions at 340°C under 5 MPa of H_2 to quantify their respective reactivities by gas chromatography-atomic emission detection (GC-AED).

The reactivity orders are found as: indole > methylated aniline > methylated indole > quinoline > benzoquinoline > methylated benzoquinoline > carbazole > methylated carbazoles.

Solid acid denitrogenation[15]

A new method to remove the nitrogen compounds of lubricating base oils was suggested. A solid acid was employed as an effective reagent to remove the basic and nonbasic nitrogen compounds. However, the sulfur compound is relatively difficult to remove. Clay treating after the solid acid denitrogenation process can apparently improve the oxidation stability of denitrogenated base oils.

Ultraviolet irradiation and liquid–liquid extraction[7]

Denitrogenation for light oils is based on a combination of ultraviolet (UV) irradiation and liquid–liquid extraction. Two extraction systems, one oil/water and the other oil/acetonitrile, were used for the denitrogenation of three separate light oils of differing

nitrogen and hydrocarbon composition. Photodecomposition of carbazole was found to be suppressed by the presence of double-ring aromatic hydrocarbons. This adverse effect can be reduced by the addition of hydrogen peroxide to the water phase. In the presence of 30% H_2O_2 and 36 hr of photoirradiation, the nitrogen content of light oils was decreased to less than 20% of feed value. In the oil/acetonitrile system, the nitrogen-containing compounds in the light oils were extracted into the acetonitrile phase and were photodecomposed effectively, even in the presence of double-ring aromatics. Then, with 10 hr of photoirradiation, the nitrogen content of the light oils was decreased successfully to less than 3% of initial concentration. This method is time-consuming and is not cost-effective and therefore cannot treat high concentrations of pollutants.

Alkylation and a subsequent precipitation method using alkylating agents (CH_3I and $AgBF_4$)[16]

Nitrogen and sulfur are methylated by the addition of the alkylating agents under moderate conditions and are removed successfully as the precipitates of the corresponding *S*-methylsufonium and *N,N*-dimethlycarbasolium tetrafluoroborates. By these means, the sulfur and nitrogen concentration of vacuum gas oil were reduced simultaneously to less than 0.1 and 7.0% of initial concentration with a 20-fold molar excess of CH_3I and a 10-fold molar excess of $AgBF_4$. Analytic methods are by means of field ionization-mass spectrometry (FI-MS) and gas chromatography-atomic emission detection (GC-AED). This is a nondestruction method.

Chemically assisted ultrasound process

CAUP is an ultrasonic reaction that produces a considerable amount of energy and pressure, which causes large numbers of bubbles or cavitations. With this energy, the bounding of a pollutant can be broken. Most of conventional methods necessarily accompany high energy and pressure all the time, which is expensive. Ultrasound is an amazing source of energy and pressure with relatively low electricity. The mechanism of ultrasound can be summarized in three phenomena:[17–19] (1) solvent compression and rarefaction (rapid movement of fluids); (2) cavitation [high temperature: 20,000°F, high pressure: 75,000 psig, collision time: 1.25 (10^{-5} sec)]; and (3) microstream with little heating (great volume of vibrational energy confined to a small volume of reaction).

In summary, the target compound is dissolved in a solvent. Surfactant entails one phase of emulsion by changing surface properties of target compound and solvent while stirring, then ultrasonic reactions attack the loose bonding of target compound through a high degree of energy and pressure. The bond scission reaction occurs between N–H and C–H bonding. The concentration of the target compound is then noticeably decreased. Fig. 1 shows the mechanism of CAUP.

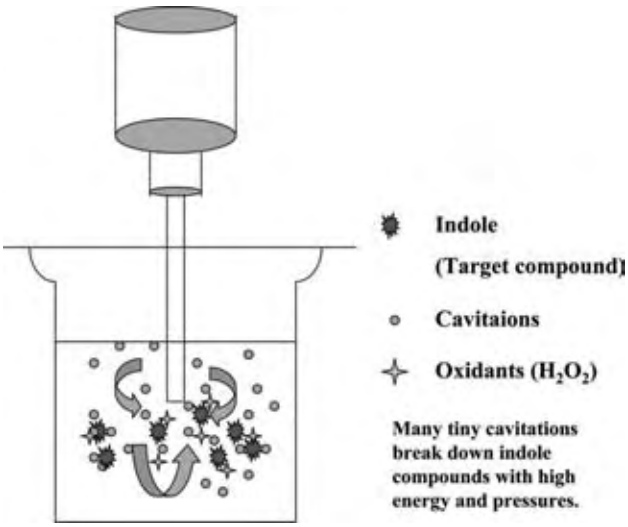

Fig. 1 Diagram showing ultrasonic reaction. *(View this art in color at www.dekker.com.)*

CONCLUSIONS

The trend in fossil fuels shows that heavy bitumen and oil shale consumption will increase over the next century because high quality oil resources are limited. This also means there is no need to expect high quality fuel production only from petroleum or natural gas. Low value energy sources will be commercially viable only if denitrogenation technology is allowed to reduce the nitrogen content. Many profitable resources such as heavy bitumen and oil shale have commanded less attention due to their low commercial value, although the exploration of oil shale for production has become an important energy program. The U.S. reserves the largest amount of oil shale in the world, but can only produce high quality oil as long as the technology is available.

Technology tends to control the industry. Denitrogenation technology is equally important as desulfurization and demetallization when it comes to upgrading low value energy resources. The theory and technology of denitrogenation will have a great impact on commercial applications in industry and scientific areas.

Design of Extrusion Dies

INTRODUCTION

The goal of this chapter is to introduce the reader to the importance of extrusion die design as well as the complexities inherent in the task. Extrusion is of vital importance to all plastics processing. In addition to providing raw stock such as sheet for thermoforming and pellets for injection molding and other extrusion processing, numerous end-use products are made with extrusion such as film, tubing, and a variety of profiles. Although the types of extruded products made can differ dramatically in shape, there are a set of common rules that govern basic die design. For example, it is important to streamline the flow from the inlet to the exit, and as a practical measure, to fine-tune the flow balance and product dimensions, flow adjustment devices could be included in the die design.

Several unique products are made by extrusion and the dies needed to make these products are classified as: 1) sheet dies; 2) flat-film and blown-film dies; 3) pipe and tubing dies; 4) profile extrusion dies; and 5) co-extrusion dies. Furthermore, each product type has unique hardware downstream of the die to shape and cool the extruded melt. To aid the reader, detailed illustrations of the various die designs and the complementary downstream cooling and shaping hardware are shown.

Predicting the required die profile to achieve the desired product dimensions is a very complex task and requires detailed knowledge of material characteristics and flow and heat transfer phenomena, and extensive experience with extrusion processing. Extrusion die design is still more an art than a science, even though the latter is becoming more and more relevant for design optimization because of recent advancement in the powerful computation and modeling of complex flow and heat transfer processes, before, through, and after the die.

DESIGN FUNDAMENTALS

Extrusion is a continuous process where solid polymeric materials, either pellets or powders, are sheared and heated as they are conveyed through either a single- or a twin-screw extruder (as described elsewhere) to become a pressurized melt. The pressurized melt flows through a properly shaped orifice, or extrusion die, and then is pulled (with a little pressure) as it is cooled and shaped to a final product called the extrudate. The proper design of an extrusion die is extremely important to achieve the desired shape and accurate dimensions of the extruded product. The function of an extrusion die is to shape the molten plastic exiting an extruder into the desired cross section depending on the product being made. The die provides a passage between the circular exit of the extrusion barrel and the more complex and often much thinner and wider die exit. A schematic of a common die, called a sheet die, is shown in Fig. 1A to illustrate this point. The extrusion process creates products of uniform cross section in a continuous fashion. An ideal passage will:[1,2]

- Balance the melt flow by providing a more uniform exit velocity across the entire die exit.
- Achieve this flow balance with a minimal pressure drop.
- Streamline the flow to avoid abrupt changes in the flow passage that may cause stagnation areas. Stagnated flow may lead to thermal degradation of the plastic melt as the melt is exposed to high heats for long periods.

As a practical measure, flow control devices should be incorporated into the die design to permit fine-tuning of the die passage shape to ensure a proper flow balance. In addition, the design of extrusion dies is complicated by two unique material properties of molten plastics:[3]

- Melts exhibit shear thinning behavior (become less viscous) as they are sheared.
- Melts exhibit viscoelastic behavior, which influences the ''die swell'' on exiting the die.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120039324

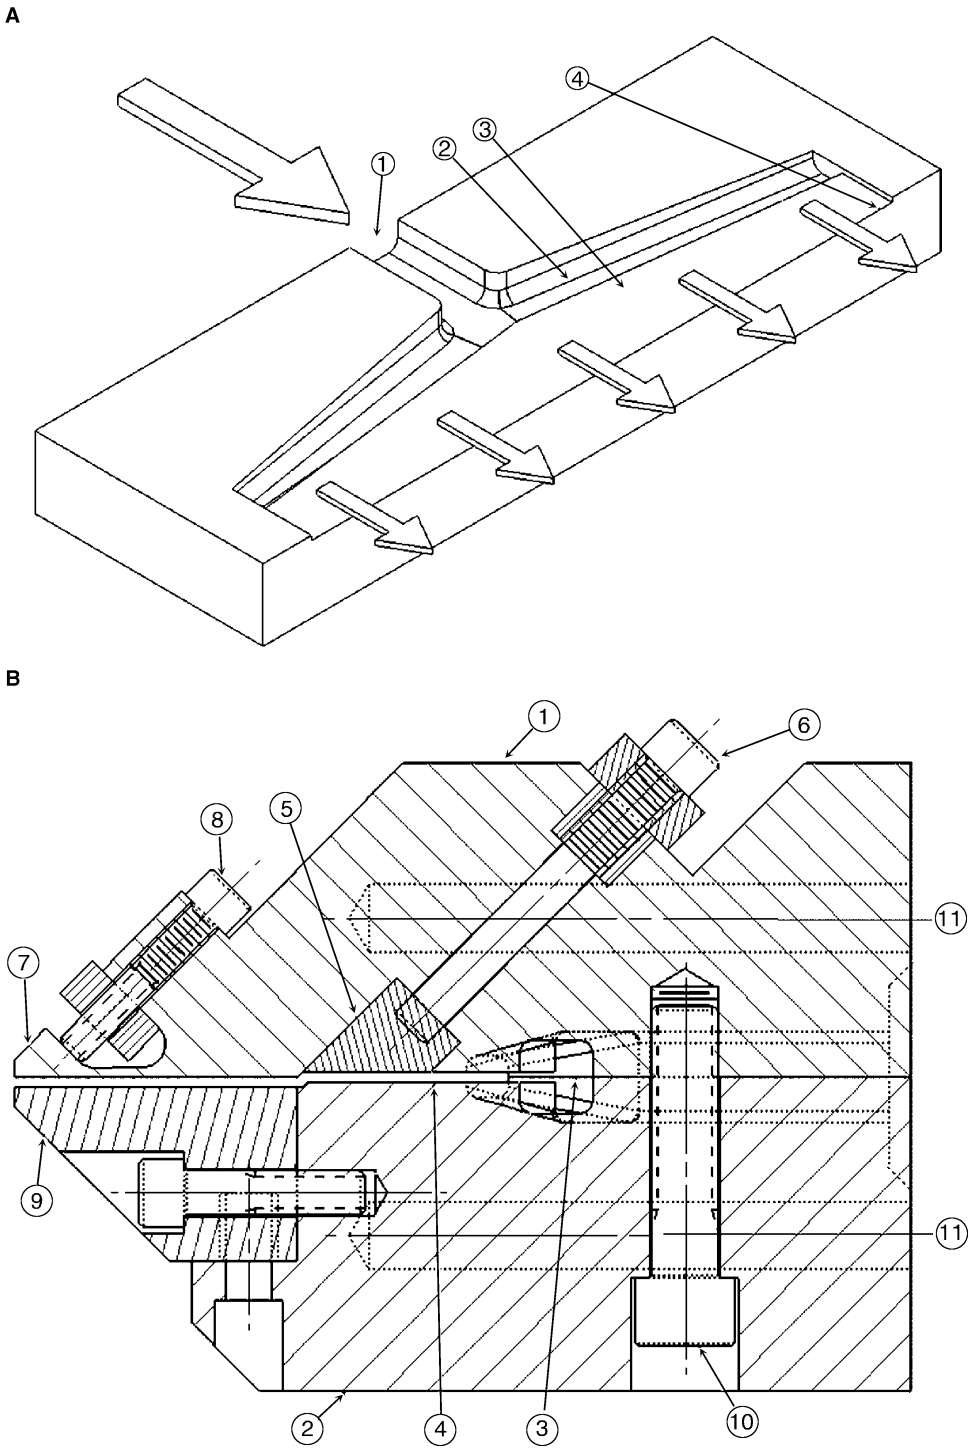

Fig. 1 Coat hanger-type sheet die concept (A): (1) central inlet port; (2) manifold (distributes melt); (3) island (along with manifold, provides uniform pressure drop from inlet to die lip; (4) die lip (die exit forms a wide slit); and schematic of sheet die (B): (1) upper die plate; (2) lower die plate; (3) manifold; (4) island; (5) choker bar; (6) choker bar adjustment bolt; (7) flex die lip; (8) flex lip adjustment bolt; (9) lower lip; (10) die bolt; (11) heater cartridge.

The shear thinning causes the volumetric flow to be very sensitive to slight changes in die geometry. For example, the flow for a typical polymer melt through a slit will vary with the cubic thickness of the gap. Thus, a small change in the die gap along the contour of the die exit may cause considerable change of the melt flow. The term ''die swell'' refers to the enlargement in the direction orthogonal to the flow direction.

Swelling after exiting the die lip is due to two distinct phenomena:[4,5]

- Velocity relaxation (unification) of the melt flow.
- Viscoelastic relaxation of the strained polymer molecules.

Velocity relaxation occurs because the melt is no longer under shear from the no-slip walls of the extrusion die. The melt assumes a uniform bulk velocity that causes the high-speed areas to slow down and the areas previously retarded from the wall to increase their speed. The net result is enlarging (swelling) of the melt cross-section bulk as it exits the die, while the stagnant outside region and, especially, the corners are stretched and shrunk. Newtonian and non-Newtonian fluids exhibit die swell owing to velocity relaxation. The swelling due to viscoelastic memory is a characteristic of polymeric fluids and occurs because the polymer molecules are stretched in the flow direction while passing through the high-shear area before the die exit. On exiting, the molecules recoil and shorten in the flow direction. The result is an expansion in the direction orthogonal to the flow, a swelling of the diameter of a round strand on exiting the die, for example. The amount of viscoelastic swelling is a combination of the material properties of the polymer as well as process conditions such as melt temperature, shear rate, and residence time under high shear, especially near the die exit.[6]

The design of extrusion dies today is facilitated by computer-based simulation tools. The flow of non-Newtonian fluids through complex passages is routinely performed by computational fluid dynamics (CFD) programs.[7–10] Factors such as shear thinning are readily accounted in die design. The viscoelastic behavior can also be modeled today, although this simulation requires extensive material testing to obtain the required material parameters for accurate simulation results. This is discussed in more detail later in this entry.

Extrusion dies vary in shape and complexity to meet the demands of the product being manufactured. There are five basic shapes of products made with extrusion dies, as illustrated in Table 1.[11,12] Film and sheet dies are called slit dies as the basic shape of the die exit is a slit. Film is also made with annular dies as in the case of blown film. Strand dies make simple geometric shapes, such as circles, squares, or triangles. Pipe and tubing dies are called annular dies as the melt exits the die in the shape of an annulus. The inner wall of the annulus is supported with slight air pressure during extrusion. Open profile dies make irregular geometric shapes, such as ''L'' profiles or ''U'' profiles, and combinations of these. Hollow profile dies make irregular profiles that have at least one area that is completely surrounded by material. Examples of hollow profiles can be simple, such as concentric squares to make a box beam, or a very complex window profile.

Each extruded product relies on a die to shape the moving melt followed by shaping and cooling devices downstream to form the extrudate into the final desired shape and size. A more complete treatment of these devices, which are typically water-cooled metallic

Table 1 Typical extruded product shapes

	Hollow chamber	Tubes	$d < 1.0$ in.	Pipes	$d > 1.0$ in.	

devices that contact the extrudate melt, is presented later in the section ''Extrudate Cooling and Sizing Hardware.''

SHEET DIES

The most common extrusion die for sheet products is the coat hanger-type manifold die as shown schematically in Fig. 1A and as a section view in Fig. 1B. The key elements of Fig. 1A are:

- Central inlet port: connects to the extruder barrel.
- Manifold: provides a streamlined channel to evenly distribute the melt to the island.
- Island: with the manifold serves to create an equal pressure drop from the die inlet to all points across the die exit.
- Die lip: wide slit across the die that provides the final sizing of the melt.

Commercial sheet dies typically employ four features to control the flow to the die lip. These are the combined shape of the manifold and the island as well as the following three features shown in Fig. 1B:

- Choker bar: adjustable along with the width of the die and serves to tune the flow balance across the width of the die.
- Lower lip: sets the nominal sheet thickness.
- Flex-lip: adjustable along the width of the die and provides the final tuning to create uniform flow across the die.

In addition, sheet dies have die bolts that hold the upper and lower die plates together. The die plates are normally heated with cartridge heaters spaced along the width of the die. This type of die is typically made for a specific type of polymer to account for the shear thinning behavior of that polymer.[11] Consequently, the flow distribution in the die will change with melt viscosity, i.e., when the power law viscosity index of the resin changes. As the polymer grades change, flow adjustments can be made at the choker bar and at the flex lip, which both span the width of the die and can be adjusted at numerous points along the width. Clam shelling, or die deflection, is another cause of nonuniform flow across the die.[13,14] The higher pressures along the centerline of the die coupled with the lack of bolting to keep the die plates together cause the centerline of the die gap to widen. Clam shelling can increase as the throughput of the die increases because of higher die pressures. Thus, the flow balance across the die will be sensitive to production rates. Innovations in automatic flow adjustments have been made with designs like the Auto-Flex sheet die where the die lip gap at the flex lip is automatically adjusted by changing the length of the flex lip adjustment bolts.[15,16] The temperature-controlled bolts change length in response to cross-machine scanning of the sheet thickness.

FLAT FILM AND BLOWN FILM DIES

Dies used to make film less than 0.01 in. thick include flat, slit-shaped dies called T-dies and annular dies for blown film (Figs. 2 and 3). The design of the T-die is similar to the coat hanger-type die with the exception that the manifold and the land length are constant along with the width of the die. Consequently, the use of T-dies is often limited to coating applications with low-viscosity resins that resist thermal degradation, as the ends of the manifold in the T-die create stagnation pockets.[13] A common application for a film die is to coat a substrate like paper.

Blown film dies are the most common way of making commercial films. Because the blown film is so thin, weld lines are not tolerated, and the melt is typically introduced at the bottom of a spiral mandrel through a ring-shaped distribution system, as shown in Fig. 3. A series of spiral channels, cut into the mandrel-like multiple threads, smear the melt as it flows toward the die exit. This mixing action ensures that the melt is homogenous on exiting the die. Unlike other extrusion processes, blown film is sized and quenched from melt to solid film without contacting metallic cooling elements. The interior of the melt tube is pressurized with approximately 2 in. of water pressure. This pressure causes the tube to suddenly expand into a bubble as it exits the die. The tube forms a bubble because it is pinched overhead with nip rolls, which retain the air pressure. During the process of expanding, the melt tube undergoes an order of magnitude reduction in thickness and thus cools rapidly. This quenching moment occurs at the frost line of the bubble. The melt quenching occurs with a combination of external cooling air and internal bubble cooling air, as shown in Fig. 3. After the film passes through the nip rolls, it passes through a series of guide rollers to be wound up on to a roll.

PIPE AND TUBING DIES

Both pipe and tubing are made in dies with an annular die exit. A pipe product is defined as being greater than 1 in. in outer diameter and a tube less than 1 in. Dies for these products are made in two styles: 1) in-line dies (also called spider dies) shown in Fig. 4A and

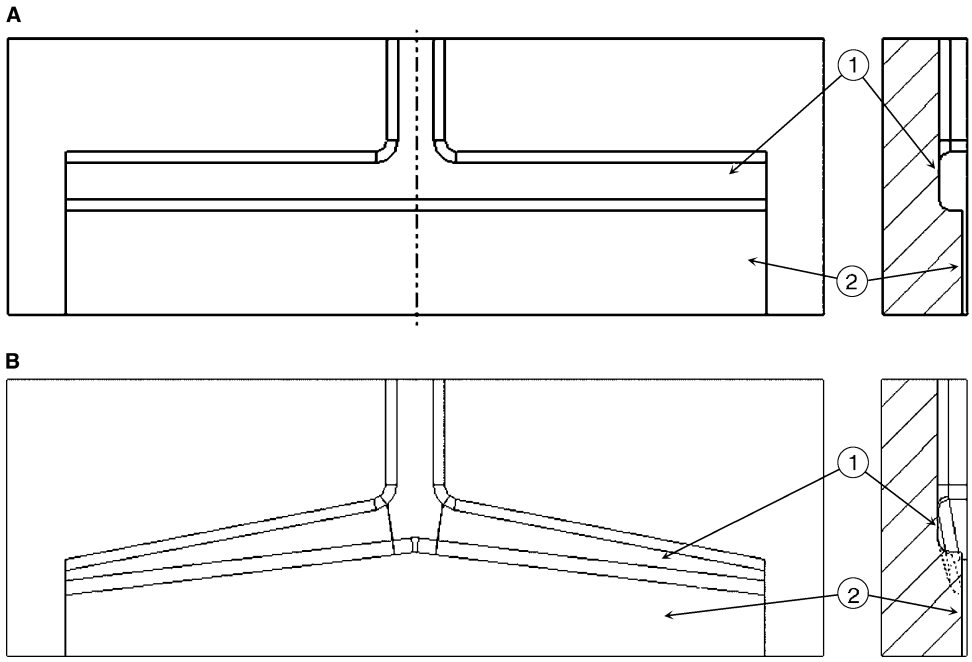

Fig. 2 Comparing designs of T-type die (A) [(1) constant cross-section manifold; (2) constant land length] to coat hanger-type die (B) [(1) manifold cross-section decreases as distance from centerline increases; (2) land length becomes shorter farther from the centerline of the die].

2) cross-head dies shown in Fig. 4B. The key elements of an in-line die are:

- Housing: mounts onto the end of the extruder, provides a circular passage through which the melt flows; it supports the mandrel and retaining ring.
- Mandrel (Torpedo): suspended in the center of the circular passage in the die body with metal bridges called spiders (typically three are used). One spider allows for passage of air into the center of the torpedo, is streamlined to avoid flow stagnation, and supports the die pin.
- Die pin: mates with the torpedo to provide streamlined sizing to the final inner diameter of the melt tube leaving the die; it has an air hole running through it to allow air to pass through the die body to the interior of the melt tube. A slight positive air pressure may be used to keep the inner diameter of the tubular extrudate from collapsing on exiting the die.
- Die land: forms the outer diameter of the tubular extrudate, held in place with a retaining ring and position adjusted with centering bolts. The die land can be changed to create a tube of a different diameter or wall thickness while keeping the original die pin.
- Retaining plate: secures the alignment of the die land with the die pin, bolted to the die body.
- Heater band: closely fitted to the housing (and for larger pipes to the exposed portion of the die pin) to ensure that the die is held at a temperature close to the required temperature of the melt.
- Flange for extruder attachment: tapered flange to permit alignment and attachment to extruder with split locking collars.

The in-line die is the least costly for manufacture of the two designs but can create defects called weld lines in the product. Weld lines occur because the melt is split and rejoined as it passes over the spider legs. A cross-head die can overcome this problem by eliminating the spiders. The melt enters the side of the die and turns 90° as it flows through a coat hanger-type passage that is wrapped around the mandrel. Key elements of a cross-head die that are different from an in-line tubing die are (see Fig. 4B):

- Core tube: mandrel with coat hanger-type passage that splits the flow and uniformly distributes melt along the annulus between the die pin and the die land.
- Side feed: melt enters from the side of the die and flows around the mandrel.
- Air supply: in-line with the die pin support.

Another application for the cross-head-style tubing die is wire coating. The following adjustments are made to a cross-head tubing die to perform wire coating:

- First, instead of passing air through the core tube, a bare conductor wire is pulled through the die entering the core tube inlet and exiting the die pin.

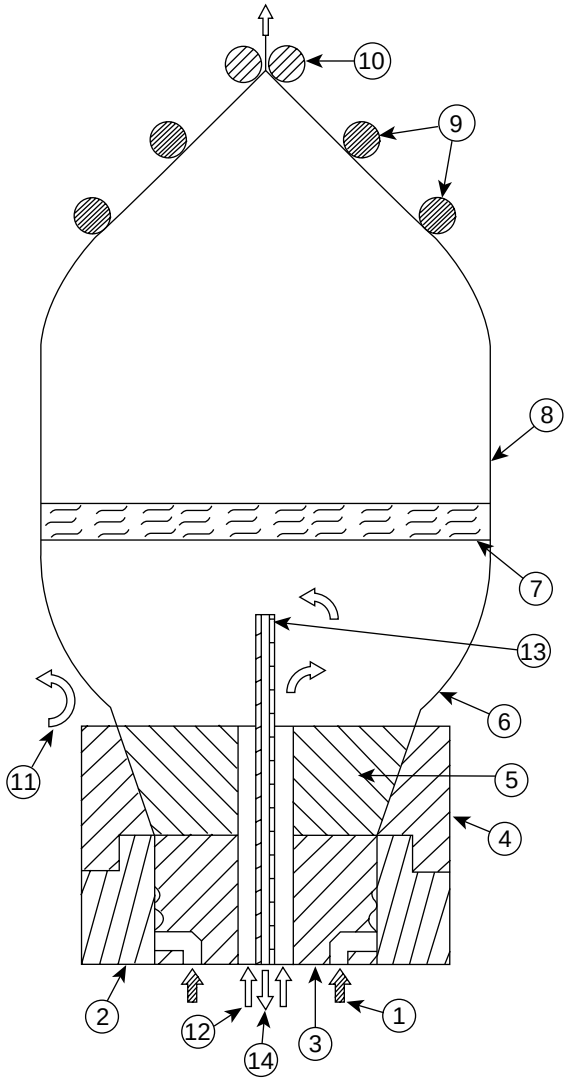

Fig. 3 Schematic of spiral mandrel blown film die operation: (1) ring-shaped melt distribution; (2) die body; (3) spiral flow mandrel; (4) sizing ring; (5) spreader; (6) film bubble; (7) frost line; (8) solidified film; (9) bubble collapsing rollers; (10) nip rollers; (11) external bubble cooling air; (12) internal bubble cooling air inlet; (13) internal bubble cooling pipe; and (14) heated internal bubble air return.

- Second, the length of the die pin is shortened to cause the wire to contact the melt tube before it exits the die land.

PROFILE EXTRUSION DIES

Profile extrusions are the most difficult to make because changes in take-up speed or screw rotational speed alone are not enough to compensate for deficient product dimensions. In the case of sheet and film, if the edges of the sheet are not at the target thickness, they can be trimmed off and sent back to the extruder to be reprocessed. Profile extrudates are significantly affected by nonuniform die swell unlike sheet and tube products. In the case of profiles with corners and other irregularities, like a square profile, the die exit needed to achieve a square profile is not square owing to the influence of die swell. Fig. 5 illustrates a die exit required to achieve a square extrudate. Note that the corners have an acute cusp shape and the side walls are not flat. A melt exiting this required but nonorthogonal shape will swell into a desired, orthogonal square shape. The design of nonorthogonal die exit required to achieve orthogonal profiles is addressed later in this entry in the section Modern Design Simulation and Computational Tools.

Open profile dies are typically shapes, such as ''U-shaped'' or ''L-shaped'' channels, that are not axisymmetric, unlike tube shapes. Consequently, open profiles are more prone to cooling unevenly and thus may generate residual stresses in the solidified (frozen) extrudate that cause the product to bow. A critical design rule for open profiles is to maintain a uniform wall thickness throughout the product cross section. Examples of poor and better profile designs are shown in Fig. 6 with the poorly designed sections shown on the left-hand side and the improved designs on the right-hand side. The difficulty with the original designs of both profiles A and B is the nonuniform wall thickness. The thinner sections will solidify first with the thicker sections still remaining molten in some core area. The result will be additional thermal shrinkage in the thicker regions and thus warpage of the final product. Product A will warp downward and product B will warp toward the right. These warping problems can be alleviated by making the entire cross section with more uniform thickness. Then, the entire cross section will solidify more uniformly and a little residual stress will be trapped in the solid extrudate. Design A illustrates a case where a hollow profile is used to solve the warpage problem whereas design B illustrates the use of an open profile to replace the thick region. The revised product designs of A and B will require more expense to fabricate the dies for these products as a set of mandrels must be made to form the hollow chambers. However, there are key benefits derived by making these changes:

- Better-quality products due to more uniform cooling and shrinkage: straighter products.
- Less material use by removing thick, unnecessary regions: savings of material costs.
- Faster cooling rates due to less hot plastic to cool: higher production rates.

Profile dies are commonly made with a series of plates that are stacked together to form a complex

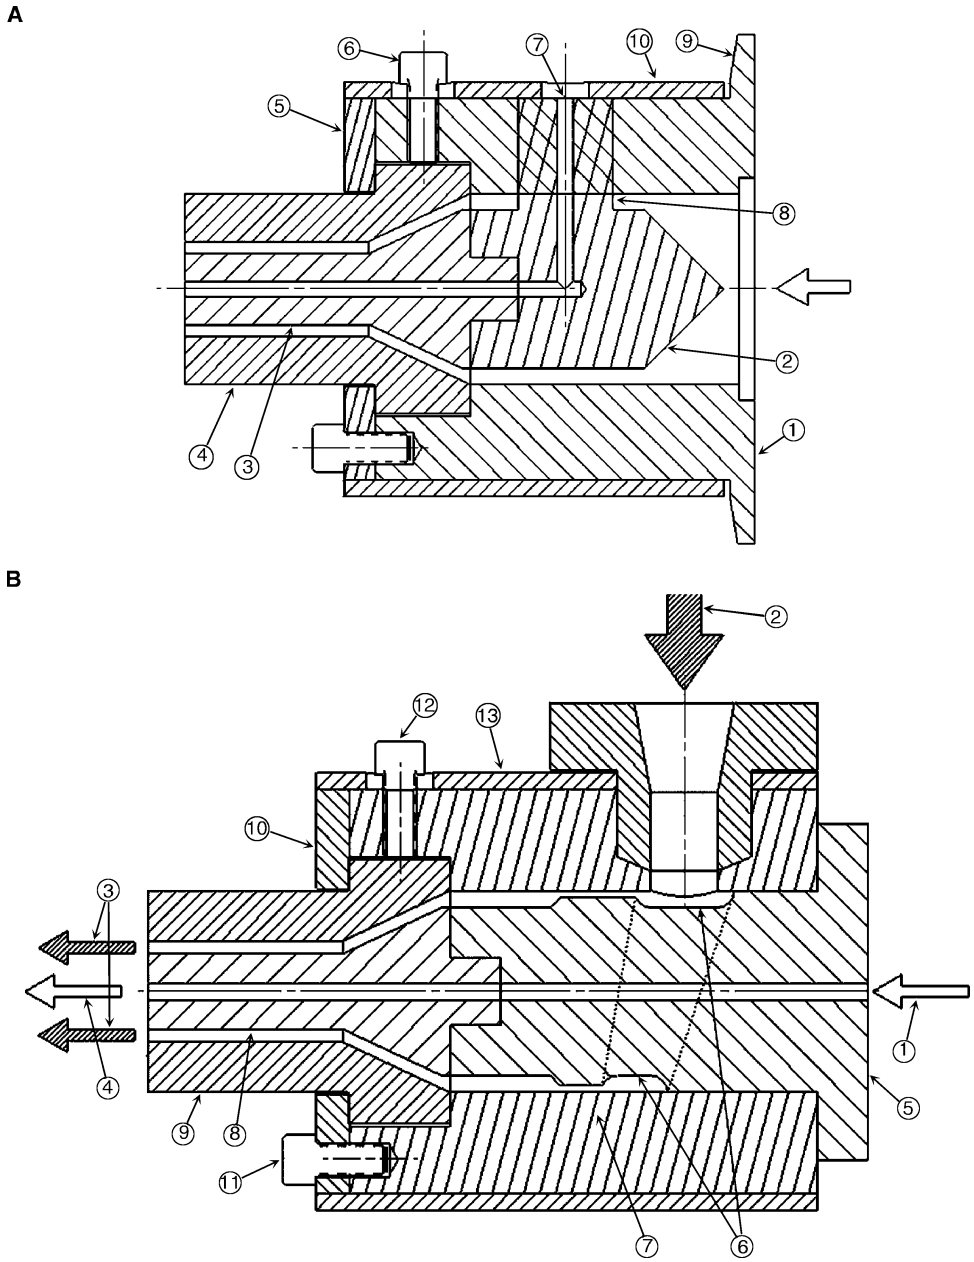

Fig. 4 Schematic of in-line tubing die (A): (1) housing; (2) mandrel (torpedo); (3) die pin (interchangeable); (4) die land (interchangeable); (5) retaining plate; (6) die centering bolt; (7) air hole; (8) mandrel support (spider leg); (9) die flange (mount to extruder with split clamp); (10) heater band; and cross-head tubing (or wire coating) die (B): (1) air or wire conductor inlet; (2) melt inflow (side inlet); (3) melt exit (annulus); (4) air or wire conductor exit; (5) core tube; (6) flow splitter; (7) housing; (8) die pin; (9) die land; (10) retaining plate; (11) retaining ring bolt; (12) die centering bolt; (13) heater band.

passage from the circular exit of the extruder to the required profile die exit. A stacked plate design makes for easier manufacture and permits adjustments to parts of the die assembly as needed during extrusion trials to fine-tune the die flow. An example of a stack plate die that makes a U-shaped profile is shown in Fig. 7. This figure illustrates an exploded view of a stack plate die, a cross-sectional view of the assembled die, and a detail of the die exit compared to the target profile. Stacked plate profile dies typically have these elements:

- Adapter plate: forms transition from circular extruder exit to approximate profile shape.
- Transition plate: forms streamlined transition from adapter plate exit to preland plate inlet.

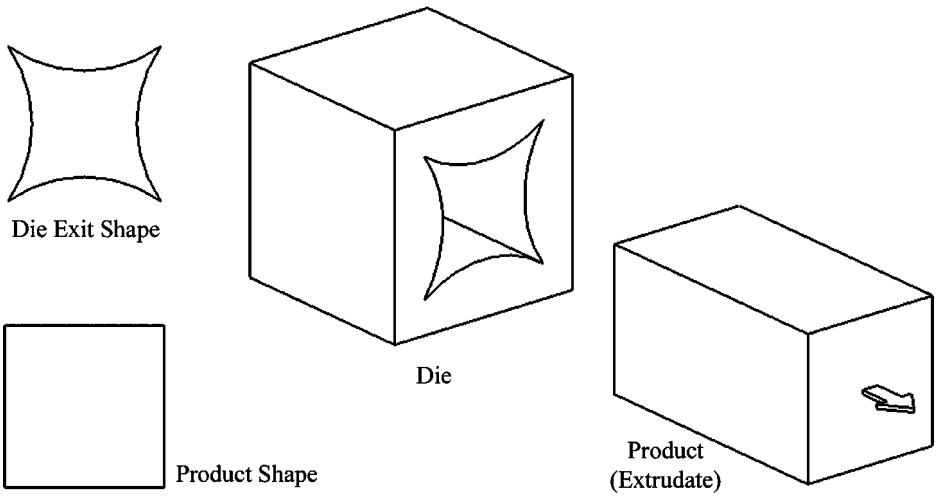

Fig. 5 Irregular die shapes required for regular extrudates.

- Preland plate: imparts significant flow adjustment by reducing thickness in high-flow areas and increasing thickness in low-flow areas anticipated downstream in the die land to make flow more uniform.
- Die land plate: provides a uniform cross-section passage that is typically 10 times longer than the thickness of the extrudate to relax the viscoelastic stresses in the melt before leaving the die (reduces die swell) and forms the shape of the extrudate leaving the die. The die land profile has the required shape to compensate for extrudate deformation after the die (die swell and drawdown) and yield the desired shape downstream.

The die exit profile shown in Fig. 7 creates an extrudate that is a U-shaped profile with three sides of uniform thickness and perpendicular walls to the bottom surface. The irregular shape of the die exit was generated with the aid of CFD as outlined in the section Modern Design Simulation and Computational Tools later in this entry.

COEXTRUSION DIES

Another important product made with extrusion dies is the creation of multilayered materials. Multilayered sheet and film materials have two applications:

- Making more economical material by sandwiching a less costly core material between two more expensive materials.

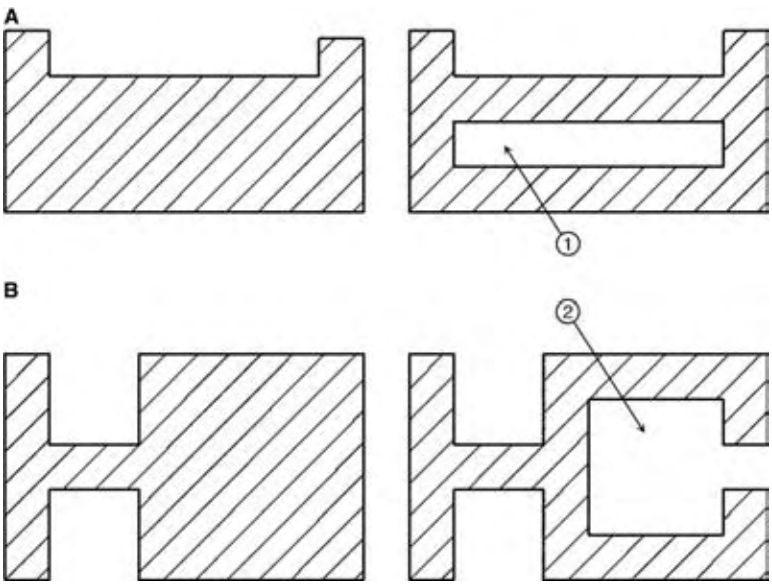

Fig. 6 Examples of poor (on left) and improved extrusion product designs (on right) to achieve uniform product thickness: (1) profile (A) made into a hollow profile and (2) profile (B) made into an open profile.

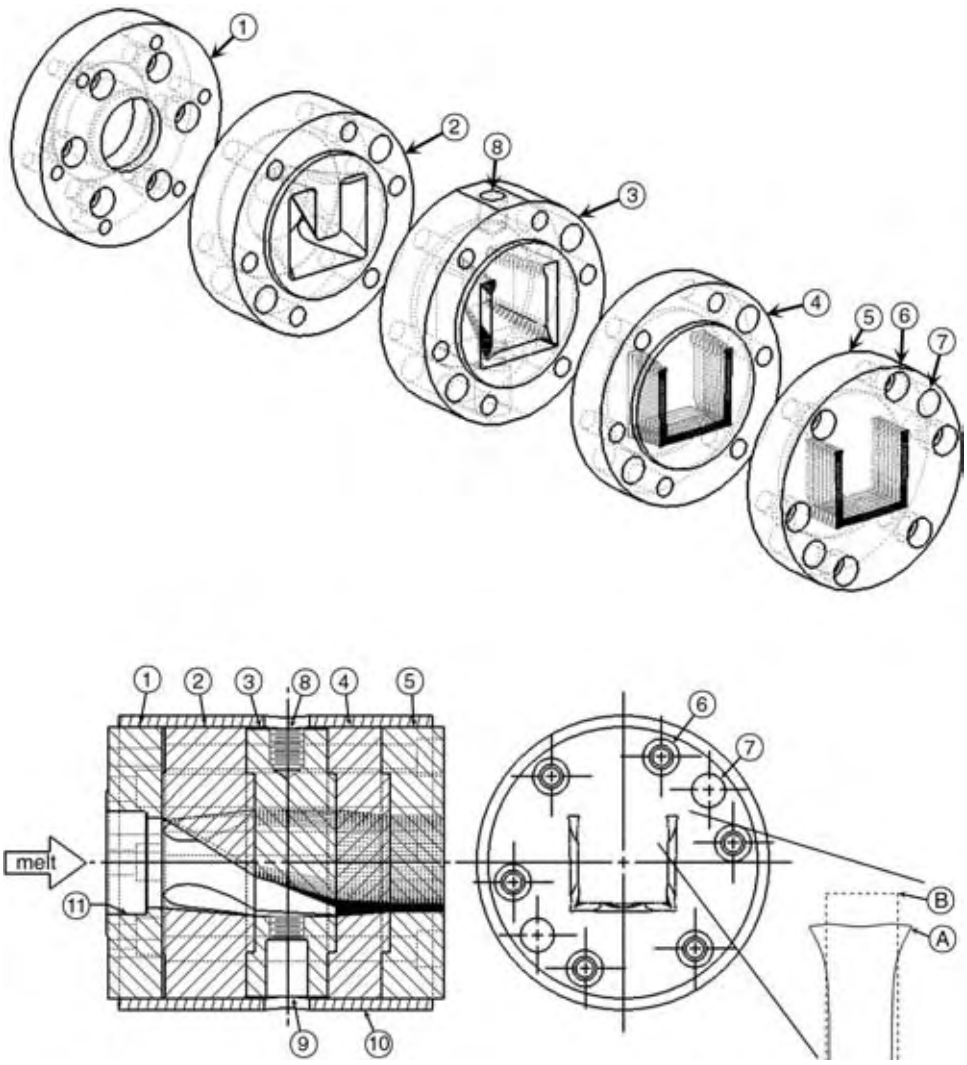

Fig. 7 U-Profile stack die: exploded view (top); section view (lower left); and end view (lower right): (1) extruder mounting plate; (2) die adapter plate; (3) transition plate; (4) preland plate; (5) die land plate; (6) die bolt hole; (7) alignment dowel pin hole; (8) thermocouple well; (9) pressure transducer port; (10) heater band; (11) breaker plate recess. Detail (lower right): (A) die exit profile and (B) product profile.

- Creating a composite material with improved properties by combining two or more materials that each posses a desirable property.

Applications of coextruded material include:

- Sheet stock made with an acrylic topcoat over acrylonitrile–butadiene–styrene (ABS). The acrylic provides UV resistance and gloss while the ABS provides impact resistance.
- Blown film with special barrier properties: one layer limits oxygen migration through the film and another provides protection from UV radiation.

There are two common methods of achieving co-extruded materials: feed block manifolds and multimanifolds within dies.[17] Two, three, or more melt streams may be combined with co-extrusion dies. The key elements of a feed block manifold as shown in Fig. 8A are:

- Inlet ports for the upper layer, middle layer, and lower layer.
- Streamlined melt lamination area that channels separate flow streams into one laminated melt stream inside feed block.
- Adapter plate between the feed block and the sheet die.
- Sheet die, which is identical to a monolayer die. The laminated melt stream enters the center of the die and spreads out along the manifold flowing out of the die exit as a distinct multilayer extrudate.

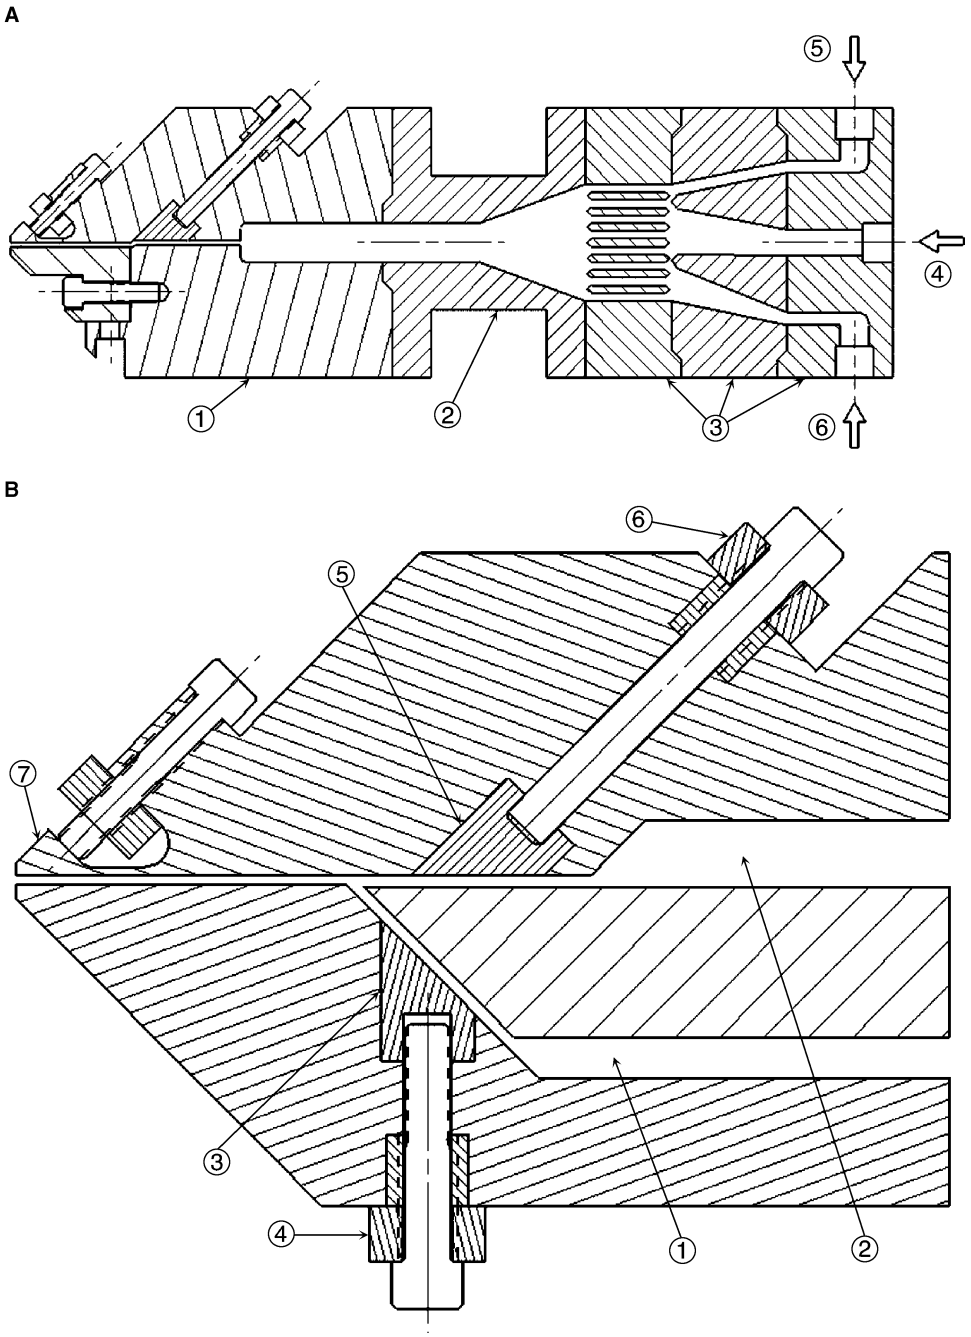

Fig. 8 Coextrusion feed block manifold and sheet die (A): (1) sheet die with flow restriction; (2) adapter plate; (3) feed block asembly; (4) core material layer inlet; (5) upper material layer inlet; (6) lower material layer inlet; and coextrusion multimanifold sheet die (B): (1) lower melt channel; (2) upper melt channel; (3) lower choker bar; (4) lower choker bar adjustment bolt; (5) upper choker bar; (6) upper choker bar adjustment bolt; (7) flex lip.

An alternative to the feed block design is a multimanifold die as depicted in Fig. 8B. The key elements of this design are:

- It is similar to a monolayer extrusion die, except that there is more than one feed channel.
- Each melt channel has its own choker bar for flow control.
- Melt streams converge inside the die near the die exit and emerge as a distinct multilayer extrudate.

The feed block technique is cheaper to implement than the multimanifold approach, but because the melt streams travel some distance before reaching the die exit, irregular flow patterns can develop at the interface of the different melt streams.[18–20] This is especially

true when attempting to coextrude melts of significantly differing viscosities. Lower-viscosity melt tends to encapsulate the more viscous melt. The alternative method is to keep the melt streams separated until just before the die exit as is done with the multimanifold design. Multimanifold designs permit coextrusion of plastic melts having significantly differing viscosities. With any coextrusion process, however, there must exist basic chemical compatibility between the neighboring melt streams to ensure good cohesion between the layers.

EXTRUDATE COOLING AND SIZING HARDWARE

With the exception of blown film and strand profiles, all extrudates require cooling and/or sizing by some metallic element. Table 2 summarizes the type of cooling and sizing hardware used for the various extrusion products.[21] In the case of sheet extrusion, the cooling is achieved with a chill roll stack, schematically illustrated in Fig. 9. The chill rolls are typically highly polished chrome-plated rollers that impart the surface gloss on sheet products and cool the extrudate while pulling the melt away from the die with a constant take-up speed. The average sheet thickness is achieved by the combination of extrusion screw rotational speeds and take-up speed adjustments. If the line speed taking the extrudate melt away from the die is greater than the average die exit speed, the thickness of the sheet decreases. This is called drawdown.

In the case of pipe and tubing products, the nominal outer and inner diameters of the extrudate are made by selecting the appropriate size of the die pin and die land. The final outer dimension of tubing products is achieved with sizing rings that are typically placed in the vacuum water bath, shown schematically in Fig. 10. The outer diameter of the tube is set with the sizing ring as the vacuum, which combined with a slight positive pressure inside the tube, forces the extrudate against the inner race of the ring. The desired inner diameter of the tube is achieved by adjusting the take-up speed of the extrudate relative to the average die exit speed. If the take-up speed is greater than the average die exit speed, the cross-sectional area decreases. Because the outer diameter of the tube is set with a sizing ring, the inner diameter will increase. Thus, the wall thickness of a tube is controlled this way.

The sizing and cooling of profiles have special requirements because of their complex shape.[21,22] These devices are called calibrators and are often as complicated as the die. To maintain the shape of a profile, vacuum is applied while simultaneously cooling the extrudate. Some calibrators, called wet vacuum calibrators, alternately inject water between the extrudate and the calibrator to lubricate and augment the cooling. A schematic of the dry vacuum calibrator setup used to size and cool the U-shaped profile is shown in Fig. 11. Fig. 11B illustrates a partially disassembled vacuum calibrator to reveal the following details: the vacuum channels and the cooling lines that simultaneously hold the moving extrudate in the desired shape while cooling it. Vacuum calibrators for profiles are typically made of stainless steel to withstand the abrasive action of extrudates while in contact with the calibrator during the cooling process. For example, the U-profile shown in Fig. 11 will tend to shrink onto the core feature of the lower calibrator and pull away from the upper calibrator surfaces. This complicates the design of the calibrator as the extrudate will conform to the ideal calibrator shape as it deforms. The cooling of the extrudate also complicates the simulation and design of the calibrator as discussed in the next section.

Table 2 Cooling and sizing devices for various extruded products

Product type	Cooling and sizing device
Film and sheet	Chill roll
Blown film	External and internal bubble air
Profiles—strand	Water tank
Profiles—open and hollow chamber	Vacuum calibrators and water tank
Tubing and pipes	Sizing rings and vacuum water tank

MODERN DESIGN SIMULATION AND COMPUTATIONAL TOOLS

The development of powerful computing hardware and proficient numerical techniques makes it possible now to simulate, analyze, and optimize three-dimensional extrusion processes with complex geometries, including nonlinear and viscoelastic polymer behavior. Numerical simulation has the potential to uncover important interior details of the extrusion process, such as velocity, shear stress, pressure, and temperature fields in the region of interest, which is not possible to do experimentally. A critical challenge for simulation methods is the ability to accurately represent the complex viscoelastic polymer material behavior that is dependent on process parameters, like shearing flow rate and temperature. Another challenge is to accurately model the complex geometry and the boundary conditions of extrusion dies and calibrators, especially for profile extrusions.

Experts in the polymer processing field have cited that the increasing complexity of product designs, coupled

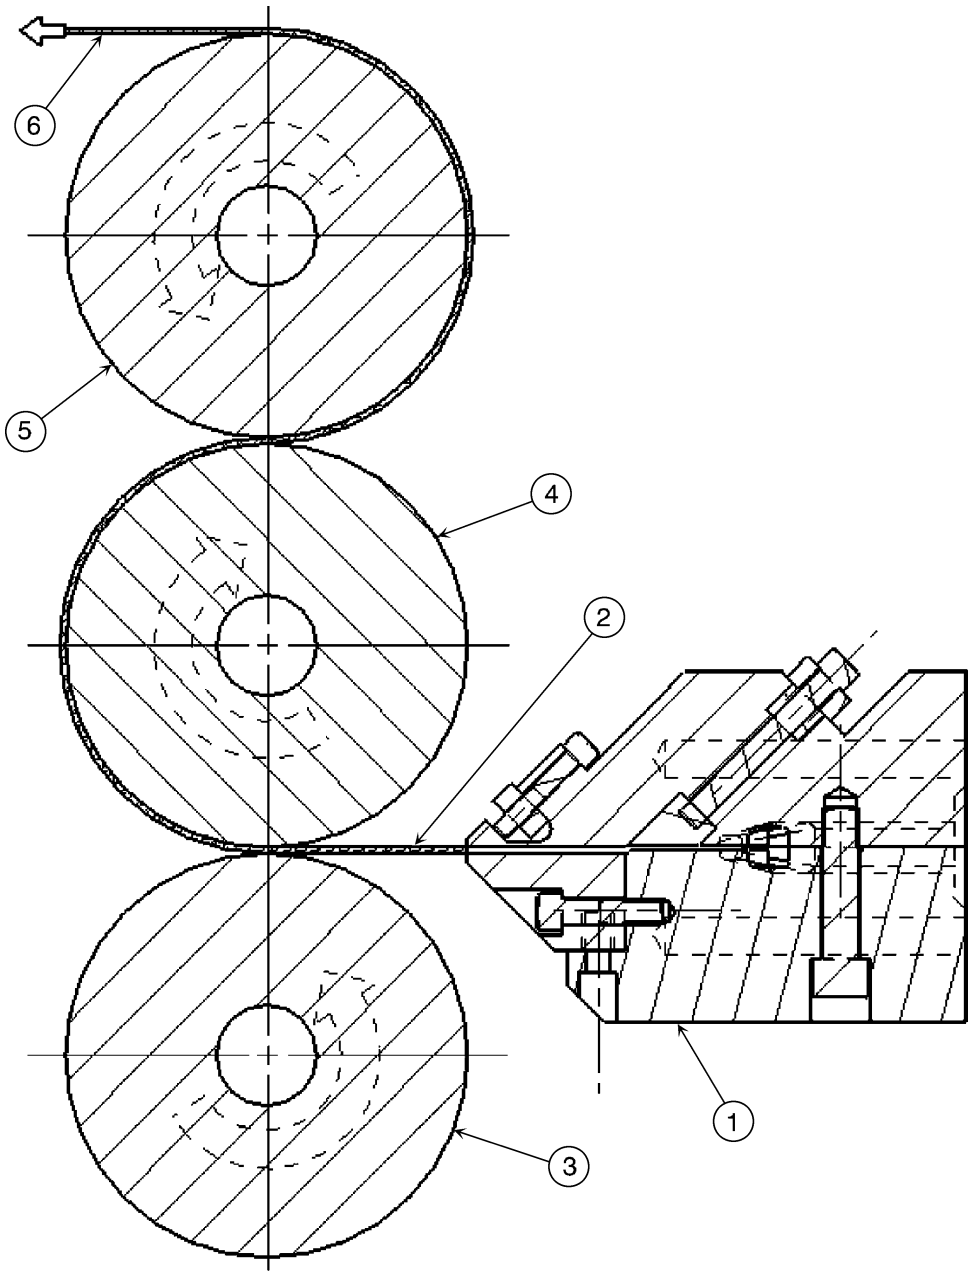

Fig. 9 Chill roll stack for sheet extrusion: (1) sheet die with flow restrictor; (2) molten sheet extrudate; (3) lower chill roll (all chill rolls temperature controlled); (4) middle chill roll (imparts gloss/surface texture to sheet); (5) upper chill roll; and (6) solidified sheet.

with the shorter development times, and a shortage of qualified engineers fuel the need for more process simulation in industry.[23] As already stated, several commercial polymer flow simulation programs are used for profile die design.[7–10] However, because the cooling rate of the extruded product determines the speed of the extrusion line, optimal design of a calibrator is also critical to productive operations. In addition, the design of the calibrator has an influence on the straightness of the final product because of uneven cooling results in unfavorable thermal deformations and warped products.[24]

Analytical solutions have been developed to aid the design of calibrators for simple shapes, such as sheets and pipes.[22] More complex shapes, such as window profiles, require the use of numerical finite element methods that can model arbitrary shapes.[25]

Computational Fluid Dynamics Simulation of Polymer Flow for Die Design

The design process begins with a target product shape. The objective of the simulation is to determine

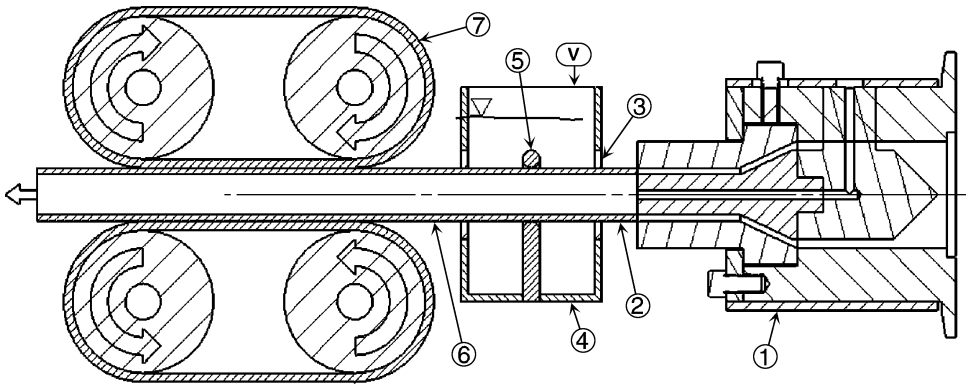

Fig. 10 Tubing vacuum water-bath calibration and take-off: (1) tubing/pipe die; (2) molten tube extrudate; (3) baffle; (4) vacuum water tank; (5) sizing ring; (6) solidified tube; and (7) puller.

the required die passage that results in a balanced mass flow exiting the die and an extrudate shape downstream of the die that matches the target profile.

A commercial polymer flow simulation program was used to simulate the three-dimensional die flow and heat transfer through the U-profile die, shown in Fig. 12.[7,26] Because the last two die plates have the greatest influence on the extrudate profile shape, only these two plates are designed with flow simulation. Simulation requires the following inputs:[7]

1. Geometric model of the die passage
   a. Two-dimensional profile of the inlet plane of the passage
   b. Two-dimensional profile of the target extrudate shape.

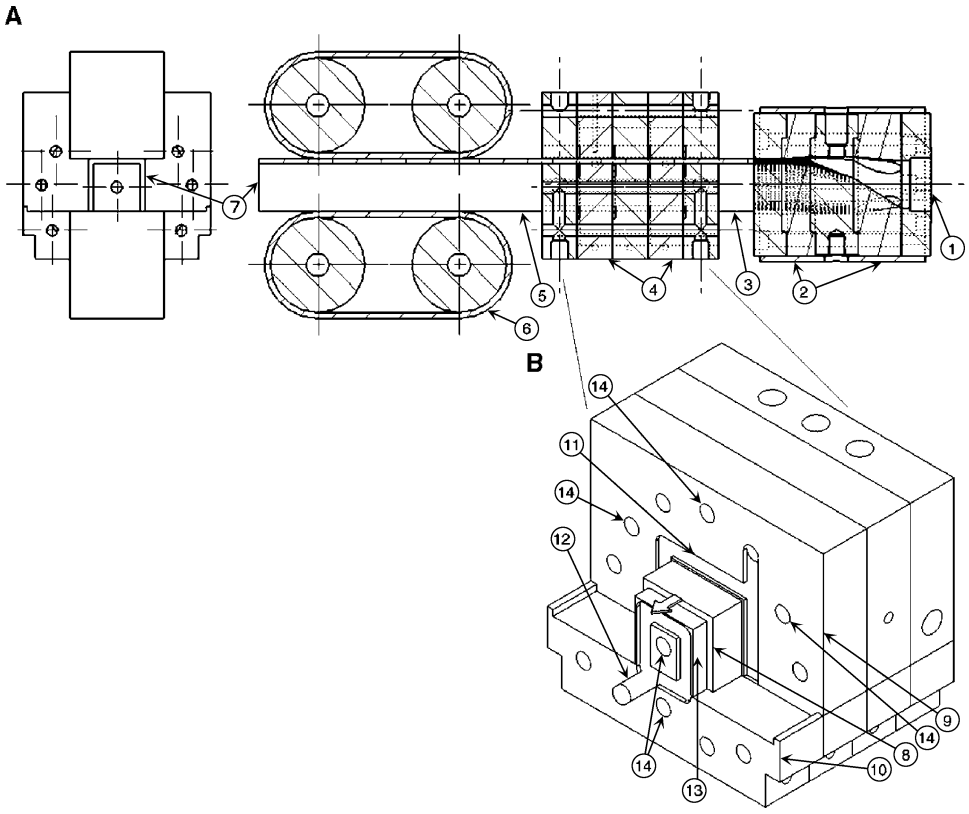

Fig. 11 Profile vacuum calibration and take-off. (A) Section view of calibration process: (1) melt enters profile die; (2) profile die stack; (3) molten profile extrudate; (4) calibrator (cools, shapes, and sizes extrudate); (5) solidified plastic; (6) puller; (7) orientation of profile. (B) Partially disassembled calibrator: (8) profile passing through calibrator; (9) upper calibrator stack; (10) lower calibrator stack; (11) upper vacuum channel; (12) lower vacuum channel; (13) core feature of lower calibrator; (14) cooling line.

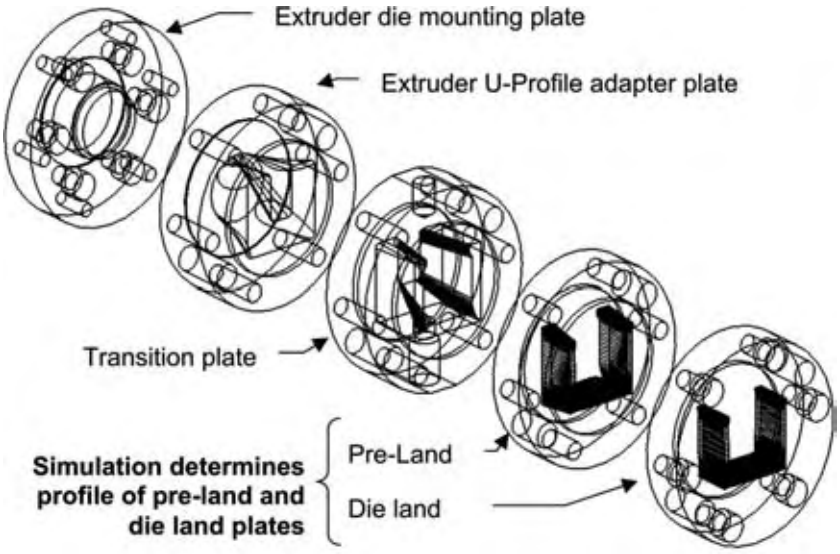

Fig. 12 U-Profile die plates designed with CFD simulation.

c. Specification of the preland length, the die land length (note that die land has a constant cross-sectional profile), and the free surface flow length after the die exit.
2. Thermomechanical properties of the polymer melt: density, heat capacity, and thermal conductivity.
3. Rheological properties of the polymer melt: non-Newtonian viscosity as a function of shear rate and temperature and/or viscoelastic material characteristics.
4. Process conditions: inlet melt temperature, mass flow rate into the die passage (or pressure at the inlet), die wall temperature, and take-up speed of the extrudate downstream from the die.

The computational domain resembles the real three-dimensional die geometry and a free surface flow after the die, where velocity redistribution (equalization) and stress relaxation take place in a short distance downstream from the die exit (Fig. 13A). Because of the symmetry of the die design, only half of the die passage is modeled (Fig. 13B). A finite element model of the die passage and the free surface region consists of 16,592 hexahedral elements and 19,530 nodes, as detailed elsewhere.[26] The computational domain must have appropriate boundary conditions to represent the realistic conditions present as the melt passes through the die and exits into a free surface flow (Fig. 13C). The used commercial CFD program implements an ''inverse extrusion'' solution algorithm, which computes the shape of the die exit (die land profile) required to achieve the target profile dimensions at the exit of the free surface domain.[7] The program solves for the shape of the die land that will achieve the target profile after die swell occurs.[7,26]

Cooling Simulation and Calibrator Design

For optimal design of the profile extrusion calibrators, cooling bath, and other cooling accessories, a comprehensive knowledge about the extrudate heat transfer process (cooling) is necessary. The biggest challenge in modeling of profile extrudate cooling is to specify properly the boundary conditions in every local part of the cooling equipment. It is possible to approximate heat transfer coefficients or determine the values experimentally.[27,28] It may be very difficult to estimate the heat transfer coefficient in a vacuum calibrator because it is not possible to predict, without experimental verification, where the polymer has a good contact with the cooling wall and what is the influence of a thin layer of cooling water being sucked in from the cooling bath. However, even estimated values can be used to get a good overall picture of the process, as the polymer materials have a fairly low thermal conductivity. This means that the obtained results are not exact, but they can be very useful for design. Therefore, the modeling and simulation of extrudate cooling is a useful tool for studying the profile extrusion cooling process, as well as for design improvement of the calibrators and other cooling equipment. Other researchers also indicated that calibration design can be done to estimate the cooling performance.[29,30] An illustration of the type of information that can be obtained by simulating the cooling of the extrudate is shown by cooling simulation of a U-profile extrudate using a commercial simulation program and

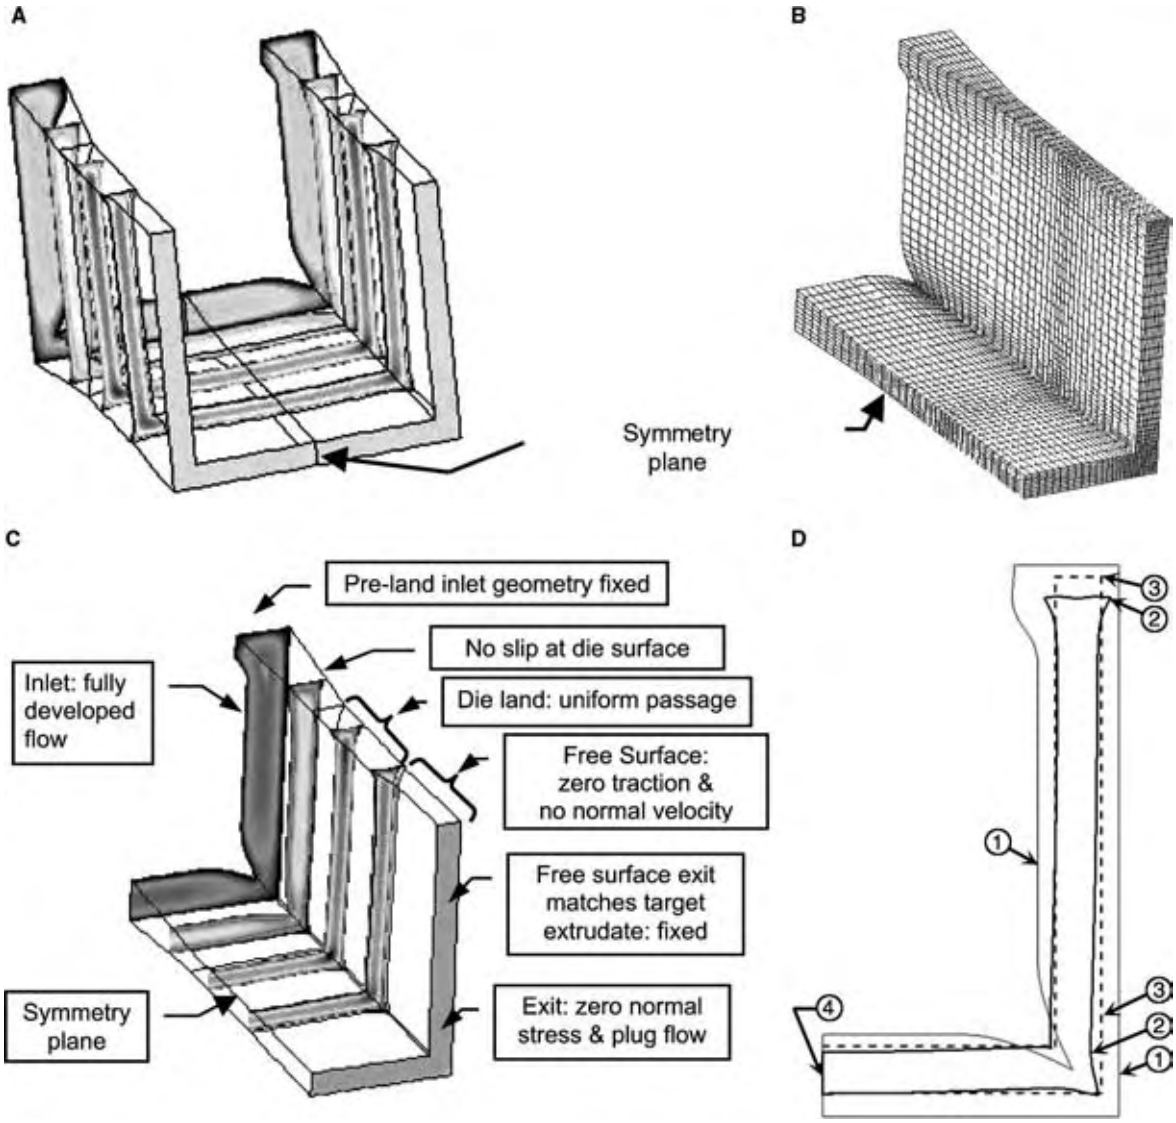

Fig. 13 Computational model for U-Profile die design: (A) preland, die land, and free surface as computational domain; (B) finite element mesh (symmetry exploited to reduce computational requirements); (C) boundary conditions for simulation of polymer flow through die and extrudate free surface; and (D) relevant profiles: (1) preland inlet; (2) die land (uniform along flow length); (3) final free surface (target extrudate profile); and (4) symmetry plane.

experimentally determined heat transfer coefficients in a vacuum calibrator.[26]

CONCLUSIONS AND DESIGN RECOMMENDATIONS

As stated above, extrusion die design is a complex task because the extrudate product dimensions depend not only on the die design (die shape), but also on the polymer properties and extrusion process parameters. The following are general recommendations for extrusion die design:

- Achieve a balanced melt flow exiting the die.
- Minimize the pressure drop required to achieve a balanced flow to permit the maximum mass flow rate with the smallest-sized extruder required.
- Provide flow control devices in the die to optimize the flow distribution.
- Streamline the die flow passage to avoid flow stagnation areas. Such areas facilitate degradation of the polymer melt due to prolonged exposure at elevated temperatures.
- Use modular design with stacked plates for manufacturability, convenient assembly, and disassembly, as well as convenient modifications and cleaning.
- Die land length should be at least 10 times the product thickness (or gap) to facilitate the polymer melt stress relaxation within the die.

- Avoid thick and nonuniform extrudate wall thickness to achieve better flow balance control in the die, minimize material use, reduce cooling times, and minimize postextrusion warping of the product.
- Avoid or minimize hollow profiles as they increase die fabrication costs and complicate the cooling process of the extrudate.

Except for circular dies, it is virtually impossible to design a die geometry to achieve a quality extrudate product for a wide range of polymers and extrusion process conditions. That is why a good die design must incorporate appropriate adjustment features to be set (or tuned) during the extrusion process to compensate for the deficiency of the final product, i.e., the cooled extrudate. For a fixed die geometry, adjustment of the deficient profile may be achieved by changing extrusion process parameters, like temperature, flow rate, cooling rate, and/or take-up speed. However, it is important to optimize the die design to make the necessary adjustments practically possible. This is why polymer extrusion die design has most often relied on experience, empirical data, and expensive trial and error adjustments to design and optimize a die and complementary process parameters. However, by integrating computational simulation with empirical data and by improving the extrusion monitoring instrumentation the die design process can be improved. A better die design method yields improved product quality and a reduction in the time to design and optimize the extrusion process, resulting in lower costs. It is important to state again that computational simulation and empirical extrusion engineering are synergistic in nature. They have their exclusive strengths and weaknesses that cannot replace each other, but, if properly integrated, may significantly improve extrusion die design.

Desulfurization

Chunshan Song
Uday T. Turaga

Clean Fuels and Catalysis Program, The Energy Institute, and Department of Energy and Geo-Environmental Engineering, The Pennsylvania State University, University Park, Pennsylvania, U.S.A.

INTRODUCTION

Desulfurization of hydrocarbon streams is an important process used in a petroleum refinery to reduce the sulfur concentration in fuels such as gasoline, jet fuel, kerosene, diesel, and heating oil so that the resulting fuels meet environmental protection standards.[1–7] Hydrotreating is one of the most popular and widely practiced desulfurization processes and refers to the catalytic removal of sulfur [hydrodesulfurization (HDS)], nitrogen [hydrodenitrogenation (HDN)], oxygen [hydrodeoxygenation (HDO)], and metals [hydrodemetallation (HDM)] from petroleum distillates in the presence of hydrogen. Hydrotreating first appeared in petroleum refineries as a finishing process in the 1930s.[2] Hydrotreating operates at conditions milder than those typically used in fluidized catalytic cracking (FCC) or hydrocracking. Typical hydrotreating process conditions vary with feedstock and are summarized in Table 1.

In the past two decades petroleum refining has changed extensively and the fortunes of hydrotreating, in particular, have witnessed a sea change. Hydrotreaters now occupy a central role in modern refineries and more than 50% of all refinery streams now pass through hydrotreaters for conversion, finishing, and pretreatment purposes.[2] Hydrodesulfurization is the largest application of catalytic technology in terms of the volume of material processed.[8] On the basis of usage volume, HDS catalysts are ranked third behind catalysts used for automobile emission control and FCC.[8]

Commercial hydrotreating catalysts are, typically, sulfides of Mo or tungsten (W) supported on γ-Al_2O_3 and promoted by either Co or Ni. Nickel, known for its high hydrogenation activities, is preferred as a promoter when feedstocks containing high amounts of nitrogen and aromatics need to be processed. Table 2 provides the compositional range and physical properties of typical hydrotreating catalysts in the oxidic phase.

GROWING DEMAND FOR DESULFURIZATION

The challenge of fulfilling the world's growing transportation energy needs is no longer a simple issue of producing enough liquid hydrocarbon fuels. This challenge is instead accentuated by a complex interplay of environmental and operational issues. Environmental issues include societal demands that liquid hydrocarbon fuels be clean and less polluting. The emergence of new refining processes and the increasing use of new forms of energy production, e.g., fuel cells, exemplify operational issues. Together, these trends are driving the need for deep desulfurization of diesel and jet fuels.

As an example of the kind of regulations that are being specified and contemplated for hydrocarbon fuels, Table 3 lists the compositional and performance properties for diesel. The United States Environmental Protection Agency (USEPA) has mandated that diesel—whose automotive use is now growing at a pace faster than that of gasoline—have no more than 15 parts per million by weight (ppmw) of sulfur by 2006.[9,10] This represents a 97% reduction in the allowable sulfur concentration in diesel from 500 to 15 wppm. The United States now allows up to 3000 wppm of sulfur in jet fuel.[11] With the European Union now demanding no more than 1000 wppm of sulfur in jet fuel, a reduction in the permissible sulfur content of U.S. jet fuel can be expected.[12] New gasoline sulfur regulations will require most refiners to meet a 30 ppmw sulfur average with an 80 ppmw cap for both conventional and reformulated gasoline by January 1, 2006.

Initially, fuel sulfur was regulated to reduce emissions of the oxides of sulfur, which contribute to acid rain, ozone, and smog. The recent and stricter round of sulfur specifications, however, are an effort to reduce automobile emissions of the oxides of nitrogen (NO_x) and particulate matter (PM). For example, the 15 ppmw diesel sulfur limit follows from the USEPA's parallel program of rule making that seeks to reduce automobile NO_x and PM emissions by 95% and 90%, respectively, by 2007. Automobile manufacturers are demanding ultra-low-sulfur fuels because only then would their advanced, sulfur-sensitive after-treatment technologies achieve such drastic reductions in NO_x and PM emissions.[13,14]

Sulfur specifications are the more visible drivers for desulfurization research. Fig. 1 presents a qualitative

relationship between the type and size of sulfur molecules in various distillate fuel fractions and their relative reactivities.[5] Various refinery streams are used to produce three major types of transportation fuels, gasoline, jet fuels, and diesel fuels, that differ in composition and properties. Other fuel specifications are equally important, albeit less visible, reasons for continued research and development in desulfurization. For example, European countries typically require diesel fuel with sulfur less than 50 wppm, cetane number of 48–51, and density less than 0.825 g/cm^3. These fuel specifications are more stringent than those enforced in the United States (see Table 3). To be active in the European diesel fuels market—larger than that in the United States—oil refiners will have to produce ultraclean, high-quality, premium diesel fuel through sophisticated refining processes such as the selective ring opening (SRO) of naphthenes.[15]

Ring opening is commonly observed in the hydrocracking process where one or more carbon–carbon (C–C) bonds are broken. Selective ring opening, in contrast, breaks only one C–C bond open, thus preventing extensive reduction in molecular weight.[16] This process, shown for a model diaromatic molecule in Fig. 2, leads to extensive improvement in the quality of diesel fuel by increasing cetane number and decreasing fuel density simultaneously.[16]

Hydrodesulfurization is important for the SRO process because the most effective SRO catalysts are based on noble metals such as iridium, which are highly sensitive to sulfur. Therefore, all SRO feedstocks will have to be extensively desulfurized and hydrogenated before being sent to an SRO reactor. Selective ring opening, while fulfilling important nonsulfur fuel specifications, is an emerging refining process that symbolizes a compelling operational issue that could require more active HDS catalysts.

In recent times, there has been tremendous interest in fuel cells. This interest is set to intensify with the U.S. government's new Freedom Cooperative Automotive Research (Freedom CAR) program that seeks to develop cars based on hydrogen-powered fuel cells.[17] Enough hydrogen to satisfy a fuel cell-based transportation system will have to be produced by processing hydrocarbon fuels through reforming and related processes all of which are sensitive to sulfur. While most fuel cells are also sulfur sensitive, some are intolerant to as little as 0.1 wppm sulfur, e.g., polymer electrolyte membrane fuel cell (PEMFC).[7] As the sulfur compounds in liquid hydrocarbon fuels and the H_2S produced from these sulfur compounds in the hydrocarbon reforming process are poisonous to both the catalysts in hydrocarbon fuel processor and the electrode catalysts in fuel cell stack, the sulfur content in the liquid hydrocarbon fuels has to be reduced to a very low level [<10 ppmw for solid oxide fuel cell and <0.1 ppmw for PEMFC].[7] Consequently, desulfurization will continue to be one of the most important processes in oil refineries.

Table 2 Composition and properties of typical hydrotreating catalysts

Composition and properties[a]	Range	Typical values
Active phase precursors (wt%)

SULFUR COMPOSITION OF KEY HYDROCARBON FUEL

The major organic sulfur compounds in petroleum fractions are thiols (mercaptans), sulfides, disulfides, thiophenes, benzothiophenes (BTs), dibenzothiophenes (DBTs), naphthothiophenes (NTs), benzonaphthothiophenes (BNTs), phenanthro[4,5-b,c,d]thiophenes (PTs), and their alkyl-substituted derivates, as shown in Table 4. There are three major types of transportation fuels, gasoline, diesel, and jet fuels, which differ in composition and properties (Fig. 1, Table 4). The major sulfur compounds existing in commercial gasoline are thiophene, 2-methylthiophene, 3-methylthiophene, dimethylthiophenes, and benzothiophenes, indicating that most sulfur compounds with higher HDS reactivity, including thiols, disulfides, and sulfides, have been removed from the commercial gasoline in conventional petroleum refining processes such as FCC. The major sulfur compounds in the jet fuels such as, JP-8 are dimethylbenzothiophenes and trimethylbenzothiophenes. Most of them have two methyl groups at the 2- and 3-positions, respectively, implying that these alkyl benzothiophenes are more difficult to be removed than others. The sulfur compounds in commercial diesel fuel include alkyl benzothiophenes and alkyl dibenzothiophenes. Of these compounds, alkyl dibenzothiophenes with alkyl groups at the 4- and/or 6-positions are the most difficult to remove by conventional HDS processes.

REACTIVITY AND REACTION MECHANISM OF VARIOUS SULFUR COMPOUNDS

The major fundamental approaches of the numerous theoretical and experimental studies conducted on desulfurization since the 1980s can be grouped into four general areas: 1) determining reaction kinetics and inhibition, over existing and new catalysts; 2) catalyst characterization using spectroscopy; 3) studying coordination chemistry of organometallic complexes; and 4) employing molecular simulation and computational analysis.

The kinetics and poisoning investigations indicate that the sulfur compounds present in hydrocarbon fuels usually show different reactivities and mechanisms for undergoing desulfurization. The HDS reactivity of various sulfur compounds decreases in the order of disulfides > sulfides, thiols > thiophenes > BTs, NTs > BNTs, DBTs without any alkyl group at the 4- and/or 6-position > DBTs with one or two alkyl group(s) at the 4- and/or 6-position(s). For the sulfur compounds without a conjugation structure between the lone pairs on S atom and the π-electrons on the aromatic ring, including disulfides, sulfides, thiols, and tetrahydrothiophene, HDS occurs directly through the hydrogenolysis pathway:

$$R\text{–}S\text{–}H + H_2 \longrightarrow R\text{–}H + H_2S$$
$$R\text{–}S\text{–}R' + 2H_2 \longrightarrow R\text{–}H + H_2S + R'\text{–}H$$
$$R\text{–}S\text{–}S\text{–}R' + 3H_2 \longrightarrow R\text{–}H + 2H_2S + R'\text{–}H$$

These sulfur compounds exhibit higher HDS reactivity than that of thiophenic compounds, because they have higher electron density on the S atom and a weaker C–S bond. For the thiophenic compounds, in which the lone pairs on the S atom conjugate with the π-electrons on the ring, including thiophenes, BTs, DBTs, NTs, PTs, and BNTs, HDS over the commercial catalysts usually proceeds through two pathways, the hydrogenation pathway (hydrogenation followed by hydrogenolysis) and the direct hydrogenolysis pathway (direct elimination of S atom via C–S bond cleavage), as shown below.

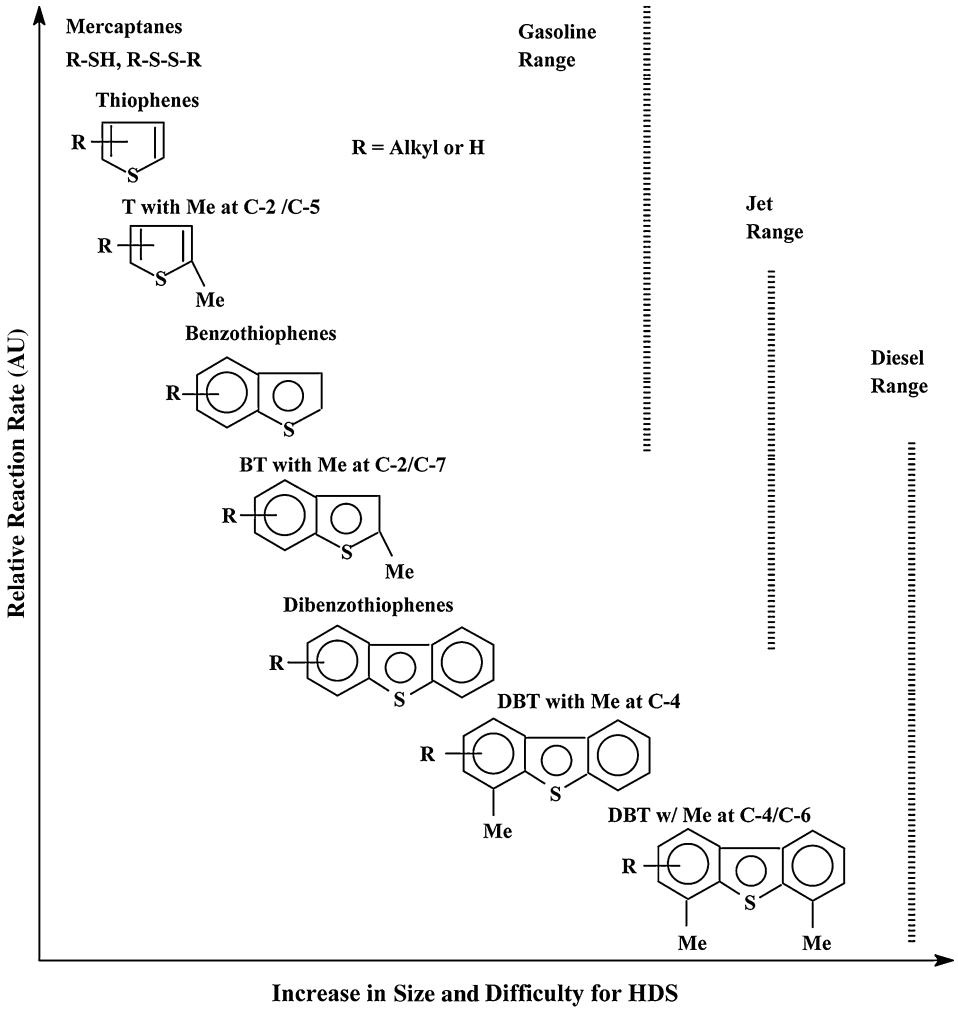

Fig. 1 Reactivity of various organic sulfur compounds in HDS vs. their ring sizes and positions of alkyl substitutions on the ring.

The HDS reactivity of the thiophenic compounds is dominantly dependent on both the electron structure and the steric hindrance of alkyl groups. For thiophene and BT, the total HDS reactivity is greater than that of DBT by about an order of magnitude because there is higher π-electron density at the C(2)–C(3) and C(4)–C(5) bonds in thiophene and at the C(2)–C(3) bond in BT, leading to their greater HDS reactivity through the hydrogenation pathway.[18] The π-electron distribution on dibenzothiophene is more uniform, as on a benzene ring, resulting in its lower hydrogenation reactivity. Thus, HDS of DBT over commercial Co–Mo catalysts proceeds dominantly through the hydrogenolysis pathway (see Scheme 1). However, if one or two alkyl groups are attached at the 4- or/and 6-positions of DBT, the hydrogenolysis pathway will be hindered strongly and the hydrogenation pathway becomes dominant.[3] In this case, the HDS reactivity will

decrease significantly. These sulfur compounds are called as the refractory sulfur compounds.

Some coexisting compounds in petroleum fractions and in the products during the HDS process exhibit a strong effect on HDS. H_2S was found to be one of the main inhibitors of the hydrogenolysis pathway, while polyaromatic compounds were found to be the main inhibitors of the hydrogenation pathway.[3] Basic nitrogen compounds affect both the hydrogenolysis pathway and the hydrogenation pathway. Some excellent reviews of this aspect of HDS research are available in the literature.[1–6]

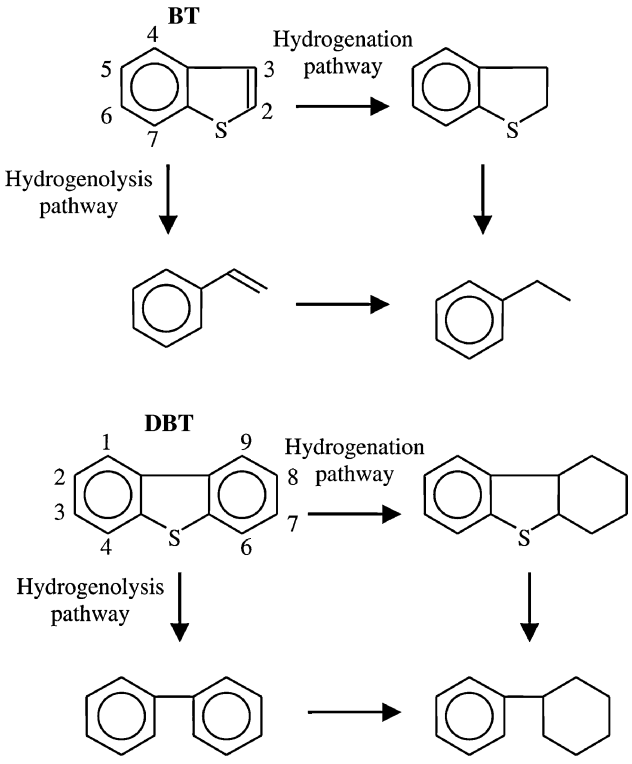
CHALLENGES IN ULTRADEEP DESULFURIZATION PROCESSES

Reactivity of Sulfur Compounds

Recently, investigations demonstrated that sulfur compounds remaining in diesel fuels at sulfur level lower than 500 ppm are dominantly the DBTs with alkyl substituents at the 4- and/or 6-position, and are lower in HDS reactivity.[3–6] These species are termed refractory sulfur compounds. Both steric hindrance and electronic factor are responsible for the observed low reactivity of 4- and 6-substituted DBTs.[19]

Based on HDS reactivity of sulfur compounds in a gas oil, the sulfur compounds can be classified into four groups according to their HDS reactivities that were described by the pseudo-first-order rate constants.[20] The first group is dominantly alkyl BTs; the second, DBT and alkyl DBTs without alkyl substituents at the 4- and 6-positions; the third, alkyl DBTs with only one alkyl substituent at either the 4- or the 6-position; the fourth, alkyl substituents at the 4- and 6-positions. The sulfur distribution in the four groups in the gas oil is 39, 20, 26, and 15 wt%, respectively, and the relative rate constant of HDS for each of the four groups is 36, 8, 3, and 1, respectively.[20] Fig. 3 shows the relative reactor volume requirements for various degrees of sulfur removal by conventional single-stage HDS of diesel fuel.[6] According to this result, when the total sulfur content is reduced to 500 ppmw, the sulfur compounds remaining in the hydrotreated oil are the third and fourth group sulfur compounds. When the total sulfur content is reduced to 30 ppmw, the sulfur compounds remaining in the hydrotreated oil are only the fourth group sulfur compounds, indicating that the lower is the sulfur concentration the lower is the HDS reactivity of the remainder sulfur compounds.

For desulfurization of sulfur species in gasoline, it is not difficult to remove the sulfur compounds in the



Scheme 1 Mechanistic pathways (hydrogenolysis and hydrogenation) for the desulfurization of refractory polyaromatic sulfur compounds.

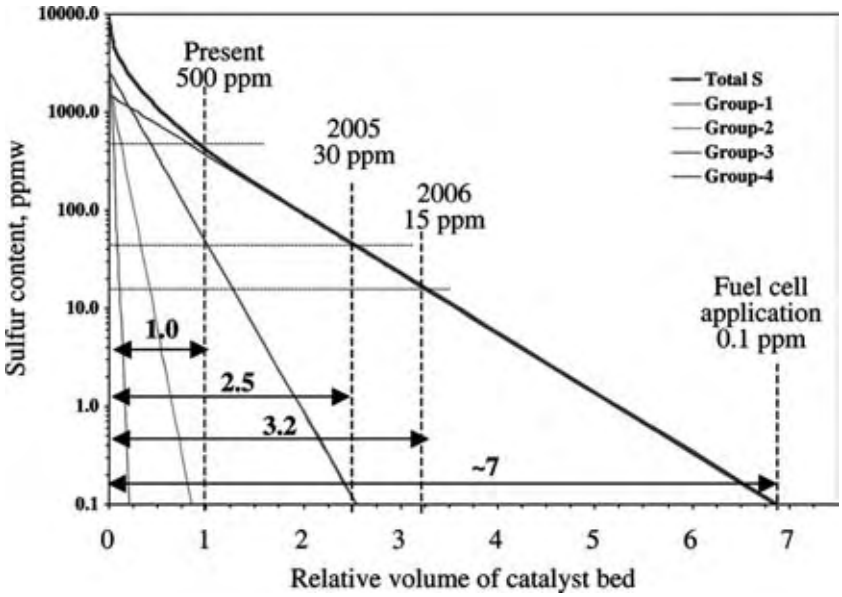


Fig. 3 Simulated HDS of diesel to meet 15 and 0.1 ppm levels on the basis of a conventional single-stage reactor, assuming 1.0 wt% S in the feed. HDS kinetic model: $C_{S,total} = C_{S1o}\,e^{-k1t} + C_{S2o}\,e^{-k2t} + C_{S3o}\,e^{-k3t} + C_{S4o}\,e^{-k4t}$. *(View this art in color at www.dekker.com.)*

naphtha range by current catalytic HDS processes. For the U.S. refineries, most of the sulfur in the gasoline pool is found in FCC naphtha. The challenge in deep desulfurization of FCC naphtha is selective conversion of sulfur compounds without saturation of olefinic compounds, which account for about 15–25 wt% in FCC naphtha and contribute to octane number enhancement. High hydrogen consumption in ultradeep HDS of FCC naphtha is another issue that needs to be considered. For straight-run kerosene, which is used for making jet fuels, the sulfur removal by HDS is more difficult than that from naphtha but less difficult compared to that from gas oil.

Inhibiting Effects of Fuel Components

A major challenge in the ultradeep desulfurization of hydrocarbon fuels is the inhibiting effects of fuel components (e.g., nitrogen compounds) and reaction products (e.g., hydrogen sulfide). While this area has been studied in catalysis literature, it is expected to gain increased attention because of the severity of the new sulfur specifications.[1]

The difference in the catalytic activity between model compounds and real feedstocks is the most visible evidence for the influence of feedstock components on HDS catalysts. Some researchers have shown that an increase of 30–50°C in temperature is required for a commercial catalyst to achieve the same conversions of DBT, 4-MDBT, and 4,6-DMDBT in light gas oil as compared to the model compounds when dissolved in a hydrocarbon solvent.[1,8] Inhibition of HDS activity occurs predominantly through one of the following compounds:

1. Aromatic hydrocarbons
2. Nitrogen-containing compounds
3. Hydrogen sulfide
4. Ammonia, saturated hydrocarbons (solvents), and water.

The influence of these inhibitors is known to increase in the following order:[21] saturated hydrocarbons, monoaromatics < condensed aromatics, oxygen compounds, hydrogen sulfide < organic sulfur compounds < basic nitrogen compounds. Three of these inhibitor classes are discussed here.

Aromatic compounds

Naphthalene and its derivatives are one of the more dominant aromatics present in various diesel and jet fuel feedstocks. Therefore, several investigators have reported the influence of naphthalene on HDS of model compounds. One of the first reports was by Lo who found naphthalene to weakly inhibit the conversion and selectivity of the HDS of DBT.[22] Similarly, LaVopa and Satterfield found little effect of naphthalene and phenanthrene on the HDS of thiophene.[23] Other researchers have, however, found naphthalene to be a stronger inhibitor of HDS activity.[4] Nagai and Kabe, in fact, found naphthalene to significantly reduce catalyst selectivity for the hydrogenation pathway.[24] Isoda et al., on the basis of similar selectivity inhibition, concluded that naphthalene severely inhibits the hydrogenation active sites in a

conventional HDS catalyst.[25] While the inhibition of HDS by naphthalene and other aromatic hydrocarbons is significant, Girgis and Gates believe that it is weaker than inhibition caused by nitrogen-containing heterocyclic compounds.[1]

Nitrogen-containing compounds

Among nonsulfur diesel fuel components, nitrogen-containing organic compounds have received significant attention because of their lower reactivity as compared to that of polyaromatic sulfur compounds (PASCs).[8] Therefore, at very low sulfur levels, refractory nitrogen compounds could significantly influence the deep HDS of PASCs. Atmospheric gas oil, which is frequently used as a diesel feedstock, typically contains nitrogen compounds 70% of which are nonbasic (e.g., carbazole type) while the rest are basic (e.g., quinoline type). Light cycle oil (LCO), a feedstock used for diesel and thermally stable naphthenic jet fuels, contains much higher nitrogen, predominantly nonbasic in nature.[8,11] Diesel and some jet fuel feedstocks, therefore, have enough nitrogen species to significantly influence deep HDS.

Several researchers have clearly established the inhibiting effect of basic nitrogen compounds on the HDS of thiophene and DBT.[4] A much smaller body of work has dealt with the effect of nonbasic nitrogen on HDS and the results seem to be inconclusive. For example, La Vopa and Satterfield and, more recently, Furimsky and Massoth have reported on the inhibiting effects of carbazole and indole, respectively, for the HDS of DBT.[23,26] Similarly, others found the inhibiting effects of carbazole and indole comparable to that of basic nitrogen compounds such as quinoline.[4] However, a very recent study found carbazoles having little negative effect on the HDS of DBT and substituted DBTs found in their blend of gas oil and LCO.[4] They, however, determined carbazoles and substituted carbazoles as the least reactive nitrogen compounds.

In addition to ambiguity on the effect of basic and nonbasic nitrogen, little is known about the exact mechanism of nitrogen poisoning. Kwak et al. found interesting influences of carbazole and quinoline on the HDS of DBT, 4-MDBT, and 4,6-DMDBT over a Co–Mo/γ-Al_2O_3 catalyst.[4] While both nitrogen compounds inhibited conversion of all three PASCs, the HDS of DBT was only mildly poisoned till at least 500 ppm of the nitrogen compound was present in the feedstock. More profoundly, the nitrogen compounds inhibited different types of sites on the catalyst. For example, the HDS of DBT occurred less through the hydrogenation route when poisoned with nitrogen compounds. Nagai and Kabe also obtained similar results with the HDS of DBT on a sulfided Mo/γ-Al_2O_3 catalyst.[4] In the case of the substituted DBTs, however, Kwak et al. noticed that conversion was achieved mainly through the hydrogenation pathway, i.e., the hydrogenolysis route was inhibited.[4]

Hydrogen sulfide

Several researchers have experimentally demonstrated the inhibiting influence of hydrogen sulfide (H_2S) on HDS.[1,4] This inhibiting influence is expected from simple and kinetic and equilibrium considerations. Refiners take great care to keep H_2S in commercial hydrotreaters at an optimum level. For example, hydrogen—used in excess in a hydrotreater—is recirculated after scrubbing out the H_2S by-product carefully. The recycle stream needs to contain an optimum level of H_2S to keep the catalyst as a sulfide and thus maintain its activity and selectivity. Sie has described other process options to minimize inhibition effects by H_2S, e.g., countercurrent flow reactors and monolithic catalyst systems.[27]

Hydrogen sulfide also inhibits HDS activity by modifying the catalyst surface. For example, high concentrations of H_2S are known to increase the density of Bronsted acid sites on a commercial catalyst.[2] Several researchers have found H_2S to poison mainly hydrogenolysis sites on a sulfided Co–Mo/γ-Al_2O_3 catalyst.[2]

Therefore, the petroleum refining industry faces a major challenge to meet the new stricter sulfur specifications and the need for fuel cell applications in the early 21st century when the quality of the crude oils continue to decline in terms of increased sulfur content and decreased API gravity.

APPROACHES TO ULTRADEEP DESULFURIZATION PROCESS

Ultradeep desulfurization approaches include: 1) improving catalytic activity by new catalyst formulation for HDS of 4,6-DMDBT; 2) tailoring reaction and process conditions; 3) designing new reactor configurations; and 4) developing new processes. One or more approaches may be employed by a refinery to meet the challenges of producing ultraclean fuels at an affordable cost.

Improving Catalytic Activity by New Catalyst Formulations

Design approaches for improving catalytic activity for ultradeep HDS focus on how to remove 4,6-DMDBT

more effectively, by modifying catalyst formulations to 1) enhance hydrogenation of the aromatic ring in 4,6-DMDBT by increasing the hydrogenating ability of the catalyst; 2) incorporate acidic feature in the catalyst to induce isomerization of methyl groups away from the 4- and 6-positions; and 3) remove inhibiting substances (such as H_2S). The catalytic material formulations may be improved for better activity by using different supports (carbon, TiO_2, TiO_2–Al_2O_3, HY, MCM-41, etc.) for conventional alumina-supported Co–Mo, Ni–Mo, and Ni–W catalysts; increasing the loading level of active metal (Mo, W, etc.); adding one more base metal (e.g., Ni to Co–Mo or Co to Ni–Mo); and incorporating a noble metal (Pt, Pd, Ru, etc.). Catalyst companies such as Akzo Nobel, Criterion, and Haldor Topsoe have developed more active catalysts for deep HDS.

One catalyst development approach, the inclusion of acidic functionality in HDS catalysts, is discussed briefly here as a case study. Turaga and Song hypothesized that molybdenum sulfide (MoS_2) supported on mesoporous molecular sieve MCM-41 and promoted by cobalt would have superior activity for deep HDS because of MCM-41's 1) high surface area and uniform mesopores and 2) superior acidity as compared to conventional supports such as γ-alumina (γ-Al_2O_3).[28] They synthesized and screened a series of mesoporous aluminosilicate MCM-41 molecular sieves with different silica/alumina (SiO_2/Al_2O_3) ratios (the framework SiO_2/Al_2O_3 ratio determines support acidity) as catalyst supports for varying loadings of cobalt oxide (CoO) and molybdenum oxide (MoO_3).

The activity of the MCM-41-supported catalysts was found to depend on the CoO–MoO_3 loading. At CoO–MoO_3 loadings typical of commercially available HDS catalysts, MCM-41-supported catalysts were only slightly better. At higher loadings—27.0% (by weight) MoO_3 and 5.8% CoO—MCM-41-supported catalysts were twice more active than the commercial catalyst. This difference in activities is related to the degree of MoS_2 stacking as suggested by temperature-programmed reduction and X-ray photoelectron spectroscopy. Additional characterization studies, furthermore, suggest the presence of a different and more active catalytic phase on MCM-41-supported catalysts.

A remarkable increase in the conversion of 4,6-DMDBT was observed over MCM-41-supported catalysts with decreasing SiO_2/Al_2O_3 ratio (or increasing acidity). More significantly, the SiO_2/Al_2O_3 ratio of MCM-41 has a profound effect on product distribution and catalyst selectivity. Irrespective of CoO–MoO_3 loading, catalysts using MCM-41 with a SiO_2/Al_2O_3 ratio of 50 convert more of 4,6-DMDBT through the highly desirable hydrogenolysis pathway. In comparison, the γ-Al_2O_3-supported commercial catalyst relies on the hydrogenation pathway for catalytic conversion. The acidity of these catalysts was measured using temperature-programmed desorption of *n*-butylamine and aluminum magic angle spinning nuclear magnetic resonance and correlated to their selectivities for hydrogenolysis and hydrocracking.

Tailoring Reaction and Process Conditions

Tailoring process conditions aims at achieving deeper HDS with a given catalyst in an existing reactor without changing the processing scheme, with no or minimum capital investment. The parameters include those that can be tuned without any new capital investment (space velocity, temperature, pressure) and those that may involve some relatively minor change in processing scheme or some capital investment (expansion in catalyst volume or density, H_2S scrubber from recycle gas, improved vapor–liquid distributor). First, space velocity can be decreased to increase the reactant-catalyst contact time. More refractory sulfur compounds would require lower space velocity for achieving deeper HDS. Second, temperature can be increased, which increases the rate of HDS. Higher temperature facilitates more of the high activation energy reactions. Third, hydrogen pressure can be increased. Fourth, improvements can be made in vapor–liquid–solid contact, which effectively increases the surface area of the catalyst. Fifth, the concentration of hydrogen sulfide in the recycle stream can be removed by scrubbing. Because H_2S is an inhibitor to HDS, its buildup in high-pressure reactions through continuous recycling can become significant. Recent work on decreasing the concentration of hydrogen sulfide in gas phase has been discussed by Sie.[27] Finally, more volume of catalyst can be used, through either catalyst bed volume expansion or more dense packing.

Designing New Reactor Configurations

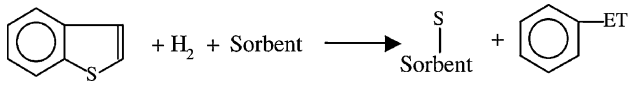
Industrial reactor configuration for deep HDS of gas oils in terms of reaction order, and the effects of the H_2S produced have been discussed by Sie.[27] The reactor design and configuration involve both single-stage and two-stage desulfurization processes. Desulfurization processes in use today in the United States generally have only one reactor, because of the need to only desulfurize diesel fuel to 500 ppmw or lower. Hydrogen sulfide strongly suppresses the activity of the catalyst for converting the refractory sulfur compounds, which should occur in the major downstream part of a cocurrent trickle-bed reactor during deep desulfurization.

The normally applied cocurrent trickle-bed single reactor is, therefore, not the optimal technology for deep desulfurization. A second reactor can be used, particularly to meet the lower sulfur levels. Both desulfurization and hydrogenation in the second reactor can be improved by removing H_2S and NH_3 from the exit gas of the first reactor before entering the second reactor. This last technical change is to install a complete second stage to the existing one-stage hydrotreater. This second stage would consist of a second reactor, and a high-pressure hydrogen sulfide scrubber between the first and the second reactor. Assuming use of the most active catalysts available in both reactors, UOP projects that converting from a one-stage to a two-stage hydrotreater could produce 5 ppm sulfur relative to the current level of 500 ppm today.[29]

A new way of reactor design is to have two or more catalyst beds, which are normally placed in separate reactors, within a single reactor shell and have both cocurrent and countercurrent flows. This new design was pioneered by ABB Lummus and Criterion, as represented by their SynSat process.[30] Traditional reactors are cocurrent in nature. The hydrogen is mixed with the distillate at the entrance to the reactor and the mixture flows through the reactor. The advantage of cocurrent design is practical; it eases the control of gas–liquid mixing and contact with the catalyst. The disadvantage is that the concentration of H_2 is the highest in the front of the reactor and lowest at the outlet. The opposite is true for the concentration of H_2S. The novel solution to this problem is to design a countercurrent reactor, where the fresh H_2 is introduced from the bottom of the reactor and the liquid distillate from the top. Here, the hydrogen concentration is highest (and the hydrogen sulfide concentration is lowest) where the reactor is trying to desulfurize the most difficult (sterically hindered) compounds. The difficulty of countercurrent designs in the case of distillate hydrotreating is vapor–liquid contact and the prevention of liquid flooding and hot spots within the reactor. The SynAlliance (consisting of ABB Lummus, Criterion Catalyst Corp., and Shell Oil Co.) patented a countercurrent reactor design called SynTechnology. With this technology, in a single reactor design, the initial portion of the reactor will follow a cocurrent design, while the last portion of the reactor will be countercurrent.[30]

Developing New Processes

Among the new process concepts, design approaches for ultradeep desulfurization focus on several different areas.[1] Some researchers are looking at adsorption and sulfur atom extraction–removing sulfur by using reduced metals to react with sulfur to form metal sulfides at elevated temperatures under H_2 atmosphere without hydrogenation of aromatics. For instance, Phillips Petroleum (now Conoco Phillips) studied its refineries and concluded the use of hydrotreating technologies to reach ultralow sulfur levels in gasoline to be a cost-prohibitive option. It developed a new process, S Zorb Sulfur Removal Technology for gasoline and diesel, in which the sulfur atom in the sulfur-containing compounds adsorbs onto a sorbent and reacts with the sorbent (see Scheme 2) at elevated temperatures under low H_2 pressure.[31] On another front, researchers at Pennsylvania State University are investigating selective adsorption for removal of sulfur compounds (PSU-SARS) in which sulfur is removed under ambient or mild conditions without using hydrogen by selective interaction with sulfur compounds in the presence of aromatic hydrocarbons.[6,7,32] Researchers at University of Michigan are using pi-complexation for adsorption of sulfur compounds.[33] In other studies, sulfur compounds are oxidized by liquid-phase oxidation reactions with or without ultrasonic radiation, followed by separation of the oxidized sulfur compounds.[34] Finally, biodesulfurization is a process that removes sulfur from fossil fuels using bacteria via microbial desulfurization. Several recent reviews outline the progress in the study of microbial desulfurization from the basic and practical point of view.[35,36]



Scheme 2 Basic principle of the S Zorb Sulfur Removal Technology process developed by Phillips Petroleum for sulfur removal from liquid fuel at elevated temperatures under low H_2 pressure.

CONCLUSIONS

Heightened concerns for cleaner air and increasingly more stringent regulations on sulfur contents in transportation fuels will make desulfurization more and more important. The sulfur problem is becoming more serious in general, particularly for diesel fuels, as the regulated sulfur content is getting an order of magnitude lower, while the sulfur content of crude oils refined in the United States is becoming higher. The chemistries of gasoline and diesel fuel processing have evolved significantly around the central issue of how to produce cleaner fuels in a more efficient, environment friendly, and affordable fashion. New design approaches are necessary for making affordable ultraclean fuels.

INTRODUCTION

The subject of this entry relates to the manufacture of linear alkylbenzene (LAB), commercially known as detergent alkylate. It is one of the primary surfactant raw materials for the production of household, laundry, dishwashing, and other surfactants.

The alkylation is the substitution of a hydrogen atom bonded to the carbon atom of an aromatic ring by an alkyl group. The alkylations of paraffins, nitrogen, oxygen, and sulfur are described in separate entries. Most of the industrially important alkyl aromatics used for petrochemical intermediates are produced by alkylating benzene with mono-olefins, e.g., ethylene, propylene, and olefins with 10–18 carbons. The liquid anhydrous hydrofluoric acid (HF) was the most commonly used catalyst until the mid-1990s. Environmental concerns associated with mineral acid catalysts have encouraged process changes and the development of solid-bed alkylation processes. This entry summarizes the process steps used produce LAB via both HF and solid-bed alkylation technologies, including economic comparison of both the processes.

HISTORICAL BACKGROUND

The synthetic detergents industry originated in the 1940s, when it was found that a new anionic surfactant type—alkylbenzene sulfonate—had detergent characteristics superior to those of natural soaps. The first surfactant of this kind was sodium dodecylbenzene sulfonate (SDBS). This material was produced by the Friedel–Crafts alkylation reaction of benzene with propylene tetramer (a mixture of C_{12} olefin isomers), followed by sulfonation with oleum or sulfur trioxide and then neutralization, usually with sodium hydroxide. The alkylation was typically performed using homogenous acid catalysts, such as HF or sulfuric acid.

Because of its low, stable price and its effectiveness in a wide range of detergent formulations, SDBS rapidly displaced natural soaps in household clothes washing and dishwashing applications. It became the standard synthetic surfactant for the detergent industry.

In the early 1960s, it became obvious that dodecylbenzene-based detergents were contributing to the pollution of lakes and streams. The reason for this was the poor biodegradability of the highly branched propylene tetramer aliphatic chain. This caused detergents discharged from water treatment plants to maintain their surfactant properties and form relatively stable foams.[1–3]

In the mid-1960s, commercial processes were developed for the production of linear paraffins. These could be used as feedstock to produce linear alkylbenzene sulfonates (LAS), a biodegradable alternative to SDBS.[4,5] The majority of synthetic detergent plants built after the 1970s were for the production of LABs rather than DDB. Reformulation with LAS started the phaseout of DDB, and by the end of the 1990s, most DDB plants were no longer in operation or had been converted to production of LAB.

In the 1980s and 1990s concern over environmental and safety issues associated with the use of HF in alkylation plants increased. This pressure resulted in the development of solid-bed alkylation technology for the production of LAB. The majority of LAB plants built since 1995 utilize solid catalyst technology.

The worldwide annual production of LAB increased from 1.1 million tons in 1980 to 1.8 million metric tons in 1990 and 2.4 million tons in 2000.[6] Linear alkylbenzene sulfonates continue to be one of the most efficient and cost-effective surfactants in the detergent industry.

PRODUCTION OF BRANCHED DODECYLBENZENE

Branched dodecylbenzene is produced by alkylation of polymer tetramer and benzene. The polymer tetramer feedstock is produced in a propylene oligomerization plant using a process such as the UOP catalytic condensation process. Benzene feedstock is typically produced by solvent extraction of reformate or pygas by means of an aromatics extraction process. There is no detailed discussion of DDB production in this entry, as the production of SDBS has been almost entirely phased out. A complete discussion is presented in Ref.[7].

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120016170

PRODUCTION OF LAB

Manufacturing Routes

There are several routes for the production of LAB. In most cases, a linear paraffin feedstock is used to produce olefins for alkylation. The paraffin feedstock is typically a mixture of linear paraffins in the range of C_{10}–C_{14}. The paraffins are derived from kerosene by means of adsorptive separation.

Other sources of olefins, such as α-olefins, can also be used to produce LAB. In most cases, these are only used as a supplemental feedstock to alkylation units, as a means of boosting LAB production. Typically, economics preclude the use of purchased olefins as the sole feedstock for the production of LAB. Benzene is another feedstock required for the alkylation of olefins to produce alkylbenzenes.

The most common route to LAB involves HF alkylation to produce LAB from linear mono-olefins and benzene. In this route, linear mono-olefins are produced by catalytic dehydrogenation of linear paraffins. The mono-olefins may then be enriched, by selective hydrogenation of diolefins (formed because of the side reactions in the dehydrogenation step). In the final step, olefins and benzene are fed to the alkylation unit to produce LAB. There are over 30 operating plants worldwide producing LAB by this manufacturing route.

The current state-of-the-art technology for LAB production uses a solid acid catalyst instead of HF. As with HF alkylation, this route uses catalytic paraffin dehydrogenation to produce mono-olefins, and selective hydrogenation to revert diolefins back to mono-olefins. An added step of aromatics removal is used to increase LAB yields in the alkylation step. As of 2003, there are three operating plants producing LAB using this manufacturing route, with several more in the design stage.

A less common route uses an aluminum chloride ($AlCl_3$) alkylation to produce LAB. This route typically uses a linear olefin feedstock produced by either catalytic dehydrogenation or paraffin chlorination/dehydrochlorination. A variation of the aluminum chloride route uses a chlorination step to convert paraffins to monochloroparaffins as an intermediate, which is then fed directly to an $AlCl_3$ unit to form LAB.[8,9] Considerable amounts of indane and tetralin derivatives are formed as by-products from this technology.[10] Aluminum chloride routes were in common use during 1960s and 1970s. However, because of corrosion, higher maintenance, and inferior product quality, the aluminum chloride plants have been mostly phased out and only a few industrial plants continue to use this technology to produce LAB.

Paraffin dehydrogenation followed by alkylation accounts for about 90% of the current world production. Most of the units built prior to the 1990s employ a homogenous HF acid catalyst system and the units built post-1990 employ heterogenous solid acid catalyst systems. As such, detailed discussion in this entry will be focused on these two manufacturing routes with particular emphasis on the heterogenous catalyst system.

Yields and Economics

Typical yields for complexes using HF and solid-bed alkylation routes are shown in Table 1. This table illustrates that the yields for the two routes are similar. For constant production of LAB, paraffin use is approximately equal for both the routes. The ''HAB'' by-product stream consists of heavy alkylate (discussed in more detail in later sections). The HAB by-product is formed in both routes and depending on the properties, may be used in applications, such as heat transfer fluids, or as enhanced oil recovery surfactants in a sulfonated form. Both routes also produce some light products in the form of off-gas and cracked product from the dehydrogenation unit. The solid-bed alkylation route also produces an aromatic by-product stream (PEP™ Extract in Table 1), which consists of aromatics produced in the dehydrogenation unit. While aromatics removal is possible for the HF route, it is typically not practiced. Instead, the HF route has an acid regenerator bottoms stream, which consists of by-products extracted from purification of the HF acid. Both of these by-products are typically recovered for fuel value. In the table Case-1 represents an LAB complex that includes the Pacol™, DeFine™, PEP, and Detal™ processes all licensed by UOP LLC and hereafter referred to as ''Pacol/DeFine/PEP/Detal complex.'' Case-2 represents the Pacol, DeFine, and UOP HF detergent alkylation processes, all licensed by UOP LLC and hereafter referred to as ''Pacol/DeFine/HF Alky complex.''[a]

Typical economics for a modern LAB complex are shown in Table 2.

Linear Alkylbenzene Product Properties

Table 3 compares LAB product properties for the HF, $AlCl_3$, and Detal catalyst systems. Bromine index and sulfonatability are the key measures of product quality, as they affect final product value. High-bromine index LAB also will produce a more colored sulfonate. Tetralin content can be important, as it relates to the ultimate biodegradation of the product and sulfonability.

[a]UOP™, Pacol™, DeFine™, and Detal™ are trademarks and/or service marks of UOP LLC.

Table 1 Yields for LAB complex. Case 1: Solid-bed alkylation; Case 2: HF alkylation

	Units	Case 1 Pacol/DeFine/ PEP/Detal	Case 2 Pacol/DeFine/ HF Alky
Raw materials			
Normal paraffins	MT	78.2	77.8
Benzene	MT	33.2	33.0
Total raw materials	MT	111.4	110.8
Products			
LAB	MT	100.0	100.0
HAB	MT	4.4	4.5
Benzene drag	MT	—	—
PEP extract	MT	2.4	—
Acid Regen Btms (polymer)	MT	—	1.6
Net separator off-gas	MT	1.5	1.6
Stripper Ovhd (Liq + Vap)	MT	3.1	3.1
Total products	MT	111.4	110.8

A significant reduction in tetralin content was brought about by the conversion of diolefins to mono-olefins prior to alkylation. Product linearity is a parameter related to the rate of biodegradation of the ultimate LAS product. The 2-phenyl content of the LAB has an impact on product solubility with a maximum solubility at approximately 30%. As can be seen in Table 3, the Detal LAB has the same or better linearity, improved sulfonate color, and lower tetralin content compared to the LAB produced in either the $AlCl_3$ or the HF alkylation process. It also has higher 2-phenylalkane content, which gives improved solubility in many detergent formulations. The cloud point of a liquid-detergent formulation prepared with LAS derived from Detal LAB is lower than that of the same formulation produced from HF LAB over a wide range of surfactant concentrations.[11] All of these properties demonstrate that the current Detal technology produces a superior product to the HF technology or the older $AlCl_3$ technology.

DISCUSSION OF MANUFACTURING ROUTE

Fig. 1 shows a block flow diagram for the processing flow scheme of a LAB complex. The first step in the complex is the dehydrogenation of paraffins to produce mono-olefins. This is typically done in a Pacol process. Owing to equilibrium limitations, conversion levels in Pacol units are typically 10–15%. This necessitates a large recycle paraffin stream from the alkylation unit. The net products from the Pacol unit are hydrogen, a small amount of light ends (from cracking side reaction), and the paraffin/olefin mixture, which becomes the feed to the DeFine unit. In this unit, diolefins produced in the Pacol process are hydrogenated to mono-olefins or paraffins. The DeFine unit requires a small hydrogen stream to give appropriate conversion/selectivity. The mono-olefin-containing product from the DeFine unit then goes to the PEP unit for removal of aromatics by-products. Aromatics are produced in small quantities in the Pacol unit, and their removal increases product yields in the alkylation unit. As such, one of the side products from the PEP unit is an aromatic by-product stream. Last, the treated product from the PEP unit is routed to the alkylation unit. This can be done with a UOP HF detergent alkylate unit or a Detal solid-bed alkylation unit. Here, the olefins are

Table 3 Typical LAB properties

Properties	$AlCl_3$ detergent alkylate	HF detergent alkylate	Detal detergent alkylate

Molecular weight	235–260	235–260	235–260

alkylated with benzene to make LAB. A side product from both units is a heavy alkylate stream. An additional side product only from HF units is the acid regenerator column bottoms stream. This stream contains mostly aromatics and heavy alkylate, and is a result of purification of the HF acid phase from the alkylation reaction.

Paraffin Dehydrogenation—Chemistry and Reaction Conditions of the Pacol Unit

The paraffin dehydrogenation reaction scheme is shown in Fig. 2. Paraffins are dehydrogenated to form mono-olefins with the double bond distributed according to thermodynamics (less than 10% in the α position). The extent of the reaction is largely controlled by thermodynamic equilibrium, and typical paraffin conversion levels are limited to 10–15%. The reaction is typically carried out at low pressure to enhance the equilibrium in favor of olefin production.

Dehydrogenation is carried out over a noble metal catalyst in the vapor phase and in the presence of hydrogen at temperatures of greater than 400°C. To minimize coking on the catalyst and improve the catalyst stability some hydrogen is introduced with the feed. In addition to the olefins, hydrogen is the second main product that is recovered and a portion of it is recycled. Because of the high activity relative to equilibrium conversion, a high space velocity is used.

Some undesirable side reactions can also occur. Mono-olefins can be further dehydrogenated to give diolefins, which in turn can be dehydrogenated further to, ultimately, give aromatics. The aromatic compounds are typically disubstituted cyclics with molecular weight similar to the starting paraffins.

Paraffins can also be isomerized to isoparaffins, which in turn are dehydrogenated to *iso*-olefins, branched diolefins, and aromatics (the last two are not shown in Fig. 2). Some cracking of both paraffins and olefins occurs, to give light ends (C_9 and lighter). It is desirable to maximize the yield to mono-olefins while reducing the yield to diolefins, aromatics, and light ends.

Selective Hydrogenation—Chemistry and Reaction Conditions of the DeFine Unit

The reaction of diolefins in the alkylation unit results in the formation of undesirable products: diphenyl alkanes, polymers, and indane/tetralins (Fig. 3). The first two result in yield loss, while the third lowers product quality. Selective hydrogenation can be used to convert diolefins to mono-olefins. The UOP DeFine process was commercialized for this purpose in 1986.[12,13] Use of the DeFine process in LAB production results in approximately 50% reduction in the formation of heavy alkylate and approximately 5% increase in LAB yield. The reaction takes place over

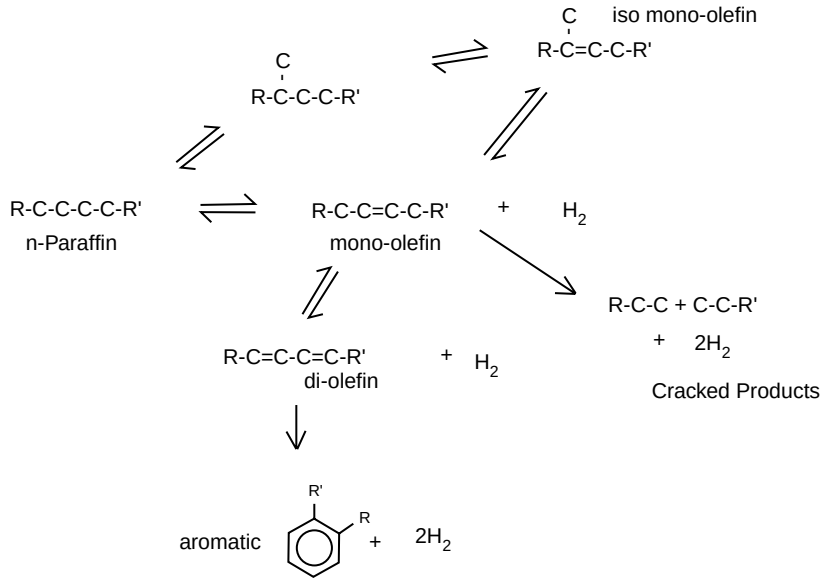

Fig. 2 Pacol reaction scheme. *(View this art in color at www.dekker.com.)*

a catalyst, in the liquid phase, at temperatures from 150°C to 250°C.

Aromatics Removal—PEP Chemistry and Conditions

In the Pacol unit, aromatics produced via dehydrocyclization reaction are of the same carbon range (C_{10}–C_{13}) as the small quantity of alkylaromatics that are present in the feed paraffin. Aromatics are undesirable for several reasons:

- Olefins will alkylate with the aromatic by-product in the alkylation unit forming a heavy alkylate (C_{10}–C_{13} plus C_{10}–C_{13} making C_{20}–C_{26} range heavy alkylate, see Fig. 4).
- Conversion of alkylaromatics in the alkylation unit is low—only 15%.
- This results in a buildup of alkylaromatics in the recycle paraffin stream. This lowers the production capacity of the LAB unit.

The UOP PEP unit is present in all Detal-based complexes to remove alkylaromatics. Aromatic removal is accomplished by molecular sieve adsorption, and exploits differences in adsorption affinity between aromatics and other molecules in the Pacolate. The PEP units consist of several adsorbent chambers

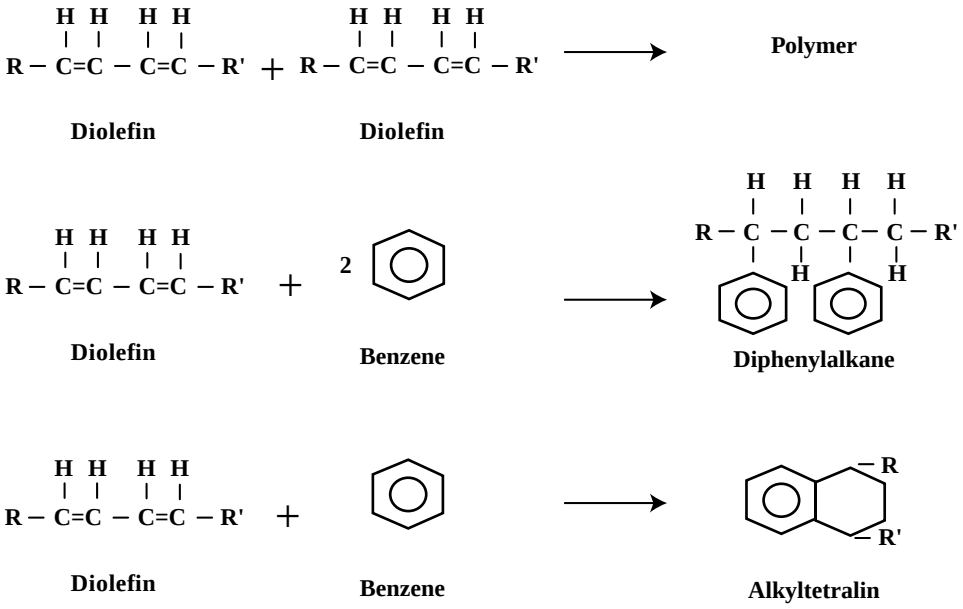

Fig. 3 Undesirable diolefin reactions in alkylation unit. *(View this art in color at www.dekker.com.)*

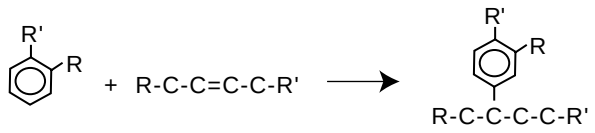

Fig. 4 Undesirable aromatics reactions in alkylation unit. *(View this art in color at www.dekker.com.)*

as shown in Fig. 5. A desorbent displaces the adsorbed aromatics from the molecular sieve. These aromatics are then separated from the desorbent and purge material by fractionation.

Alkylation—Chemistry

As shown in Fig. 6, the primary detergent alkylation reaction is the alkylation of benzene with the straight chain mono-olefins to yield LAB.

This reaction is acid catalyzed and can be generalized as occurring in two steps. The first step is the formation of a carbonium ion or polarized complex. The second step is the electrophilic attachment of the aromatic to the carbonium ion resulting in the LAB molecule.[14] This is accomplished using traditional protonic acid catalysts (H_2SO_4, HF, and phosphoric acid), Friedel–Crafts-type catalysts ($AlCl_3$ and boron fluoride), or any solid acid catalyst having a comparable acid strength. In either case (whether heterogenous or homogenous catalyst), the catalyst must demonstrate sustained activity, selectivity, and stability over long periods of operation.

During alkylation, some undesirable side reactions occur. A couple of these side reactions are outlined in Fig. 7. These secondary reactions include alkylation of olefin with LAB to form dialkylbenzenes, and the reaction of two olefins to form a dimer.

Other undesired reaction can occur between diolefins and benzene (see DeFine section) and Pacol aromatics and benzene (see PEP section).

In addition to the alkylation activity, all acid catalysts possess the ability to shift the olefinic double bond position along the chain. Researchers have shown that the position of the phenyl group in the final product is specific to the catalyst system used.[15,16] Table 4 summarizes some of this work for the reaction of 1-dodecene (112-41-4) with benzene.

HF ALKYLATION—UOP DETERGENT ALKYLATE PROCESS

Processing Conditions

The HF alkylation process is the dominant route for LAB production utilized by the plants built before 1995.[17] The olefin feed to a conventional HF alkylation unit is typically derived from the Pacol process. Olefin feed is combined with an excess of benzene before the addition of the HF acid. Diluting the olefin in benzene followed by intense mixing helps minimize the formation of by-products, such as dialkylbenzene. The typical operating temperature for the HF alkylation reaction is 30–40°C. Operating pressure is sufficient

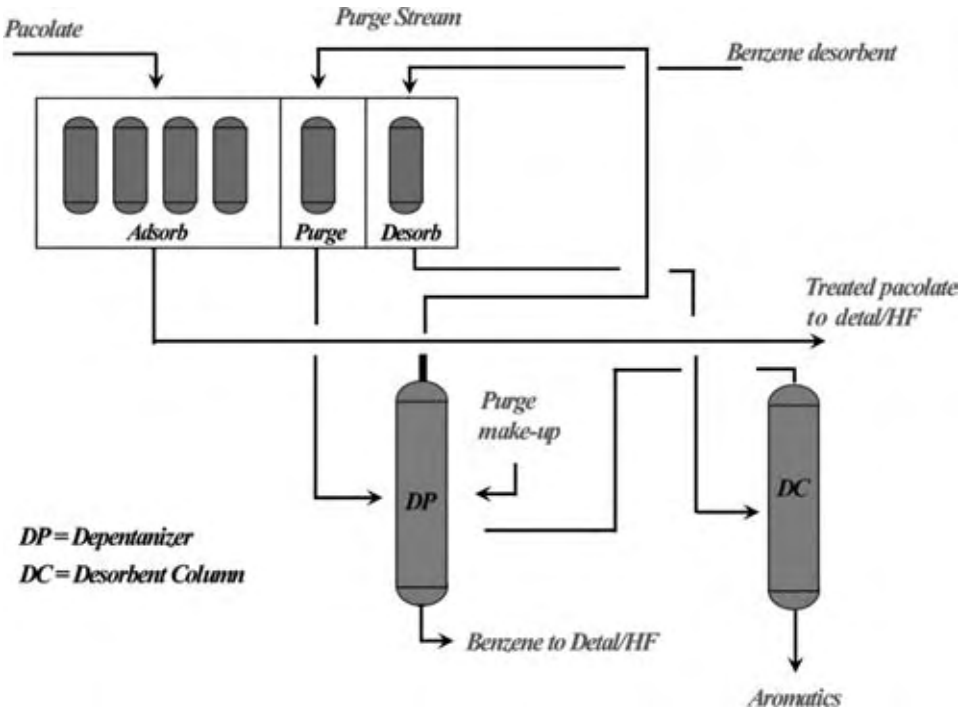

Fig. 5 PEP unit flow scheme. *(View this art in color at www.dekker.com.)*

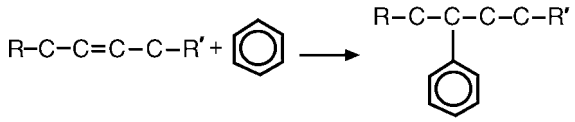

Fig. 6 Formation of LAB from mono-olefins and benzene. *(View this art in color at www.dekker.com.)*

to ensure that the HF acid remains in the liquid phase. A simplified flow diagram for a typical UOP detergent alkylate process is shown in Fig. 8. The olefin feed is combined with makeup and recycled benzene and cooled prior to mixing with HF acid. The reaction section consists of either one or two mixer reactors and acid settlers. A portion of the HF phase from the settler is sent to the HF regenerator, where heavy by-products are removed to maintain the required purity of the HF acid. The balance of the HF phase or circulating acid is returned to the inlet of the HF reactor to mix with the feed prior to entering the reactor. The hydrocarbon phase from the acid settler proceeds to the fractionation section, where the remaining HF catalyst, excess benzene, unreacted *n*-paraffins, heavy alkylate, and the LAB product are separated by fractionation. In these sequential fractionation steps, the recovered HF acid and benzene are recycled to the alkylation reactor. The unreacted *n*-paraffins are passed through an alumina treater to remove combined fluorides and are then recycled back to the dehydrogenation unit. Not shown in Fig. 8 is the HF acid handling and neutralization section. The HF acid from the HF regenerator–HF stripper overhead is recycled to the alkylation reactor, and then, after separation in the settler it is pumped to the alkylation reactor. The HF acid from the first-stage settler is pumped as feed to the HF regenerator.

Olefins react to a small extent with HF to form alkylfluorides that are separated in the paraffin column with the recycle paraffins (Fig. 9). Alumina treaters help to eliminate both combined fluorides and free HF acid from the recycle paraffins.

Metallurgy

Since its introduction during the early 1940s, the HF alkylation process has gone through many changes.

Table 4 Isomer distribution, wt%, of dodecylbenzene from 1-dodecene and benzene

	HF	SiO_2–Al_2O_3	HY–Zeolite
2-Phenyl	16.7	33.4	29.5
3-Phenyl	16.4	21.9	20.2
4-Phenyl	17.5	14.8	17.1
5-Phenyl	24.1	15.6	16.9
6-Phenyl	25.3	14.2	16.3

Its first application was in the production of aviation gasoline, followed by motor fuel blending components, and then extension to the detergent alkylation field.

At low water contents, HF has a very low corrosion rate on mild carbon steel, but as the water content rises above 5%, the corrosion rate rapidly increases. Corrosion is anticipated wherever there is a possibility of acid or acid–hydrocarbon mixtures in contact with water. Copper, silver, and platinum are resistant to corrosion from all concentrations of HF, with the exception that copper and silver are attacked in the presence of sulfur compounds and oxygen. Lead is useful only if the water content is above 35%. Finally, stainless steel has poorer corrosion resistance to HF than carbon steel.

There are four rules for long and successful operation of HF alkylation process units: good engineering design, appropriate materials of construction, diligence in keeping equipment and feedstocks dry, and careful adherence to routine prescribed maintenance practices.

Use of carbon steel may be acceptable where water concentration is assured to be below 5% with varying corrosion allowances for major vessels and piping. However, the HF acid regeneration and the neutralization sections require monel or monel cladded vessels and all monel piping. All instruments in HF or hydrocarbons that contain any amount of HF or may have a possibility of getting some HF acid contamination must have monel parts. Monel is generally specified for the moving parts, for the trim of pumps, in thermowells, in select instrument parts, and as trim on most valves. Monel cladding is necessary for the acid regenerator, a small column, and the piping around the acid regenerator. Kel-F™ and Teflon™ are used largely as

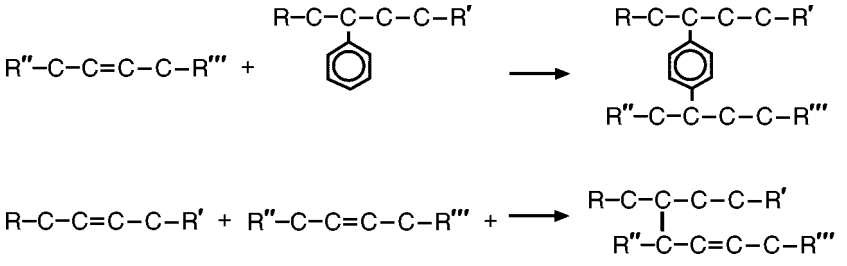

Fig. 7 Alkylation section side reactions. *(View this art in color at www.dekker.com.)*

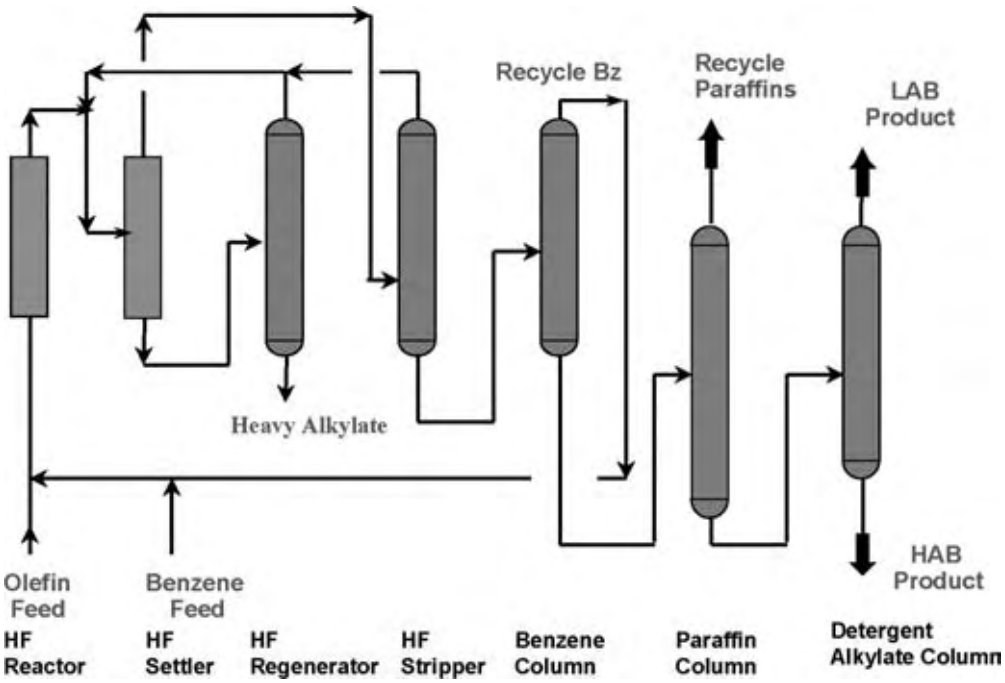

Fig. 8 UOP detergent alkylate process flow scheme. *(View this art in color at www.dekker.com.)*

sealing materials and for certain instrument parts, as well as for packing and trim in some valves.[b]

The hazards of HF acid in HF alkylation have been identified and managed for many years. Plant design, operating practices, and safety equipment are combined to cope with potential risks. Several references deal with safe maintenance and operation.[18–20] Although most of these references are directed toward the HF alkylation process for motor fuel production, general safety rules of handling HF and HF-containing equipment also apply to the detergent alkylation process.

Waste Management

In the UOP detergent HF alkylation process the engineering and design standards have been developed and improved over the years to obtain a process that will operate efficiently and economically. In normal operation, the waste streams from these process units consist of a small water stream from the Pacol stripper overhead and the HF regenerator bottoms.

There may also be certain other undesirable materials in addition to the normal process flow that could be discharged from the unit. These undesirable materials could potentially cause concern if steps were not taken in the waste management process and product treating areas to transform them into either inert or harmless substances.

One common step is to divide the gaseous and liquid waste streams into two separate waste streams, acidic and nonacidic, handled separately. Nonacidic gaseous waste streams from units, such as the dehydrogenation unit, or the acid-free section of the detergent alkylation unit, typically are combined and sent directly to a nonacid flare system where they are disposed of by burning.

Acidic gaseous streams from the detergent alkylation units usually are combined and sent to a relief gas scrubber where HF acid is removed by countercurrent gas–liquid contacting using circulating limewater solution:

$$Ca(OH)_2 + 2HF \rightarrow CaF_2 + 2H_2O$$

Calcium fluoride, being insoluble in water, deposits as sludge in the bottom of circulating limewater tanks and is removed periodically. In some units, KOH solution is used as a neutralizing medium, and spent KOH ($KOH + HF \rightarrow KF + H_2O$) is regenerated by lime: $2KF + Ca(OH)_2 \rightarrow CaF_2 + 2KOH$.

Thus, calcium fluoride becomes the end waste product. Acid-free process wastewater that may include rainwater from the acid-free area of the units is directed to wastewater treating systems. As a general rule there are no nonacid liquid hydrocarbon waste streams.

An acidic liquid waste stream originates from the HF acid regenerator bottoms. This material is neutralized, after which the hydrocarbon portion (heavy

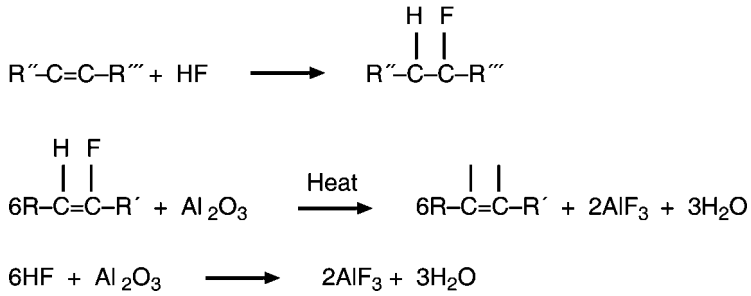

Fig. 9 Alkylfluoride formation and alumina treating in HF units. *(View this art in color at www.dekker.com.)*

alkylate) may be burned in a process heater to recover its heating value. A neutralization basin collects acidic water streams from acid regenerator bottoms (water that enters the alkylation unit usually exits through the regenerator bottoms); rainwater from the acid sections of the unit; and water used for cleaning acid-section vessels or other equipment during shutdowns. In this basin, excess lime is commonly used to neutralize the HF acid portion of these streams. Neutralized water flows from the neutralization basin into the nonacidic wastewater stream and is sent to wastewater treating facilities. Calcium fluoride sludge, which is removed periodically from the neutralization basin, is the end waste product.

SOLID-BED ALKYLATION—UOP/CEPSA DETAL PROCESS

Processing Conditions

The most recent advance in detergent alkylation is the development of a solid catalyst system. UOP and CEPSA (Compania Espanola de Petroleos SA) jointly developed the Detal process, which uses a fixed-bed heterogenous catalyst system for the production of LAB. Detal technology was commercialized by Petresa, a subsidiary of CEPSA, in Quebec, Canada, in 1995.[21] By then, two additional Detal units are in operation. Unlike HF and $AlCl_3$ catalysts, the Detal catalyst is noncorrosive and eliminates problems associated with the handling and disposal of HF (see HF alkylation section Waste Mangement and Metallurgy). Typical solid acid catalysts are amorphous and crystalline alumino-silicates, clays, ion-exchange resins, mixed oxides, and supported acids.[22] Among these solid acid catalysts, ZSM-5, Y-type zeolites, mordenite, and, more recently, MCM-22 and β-zeolite have been identified as the new commercial catalysts for various aromatic alkylation reactions.[23,24] A variety of other potential solid acid catalysts for detergent alkylation have been described in the literature.[25–28]

Flow Scheme

The flow scheme of the Detal process is presented in Fig. 10. The olefin feed and recycle benzene are

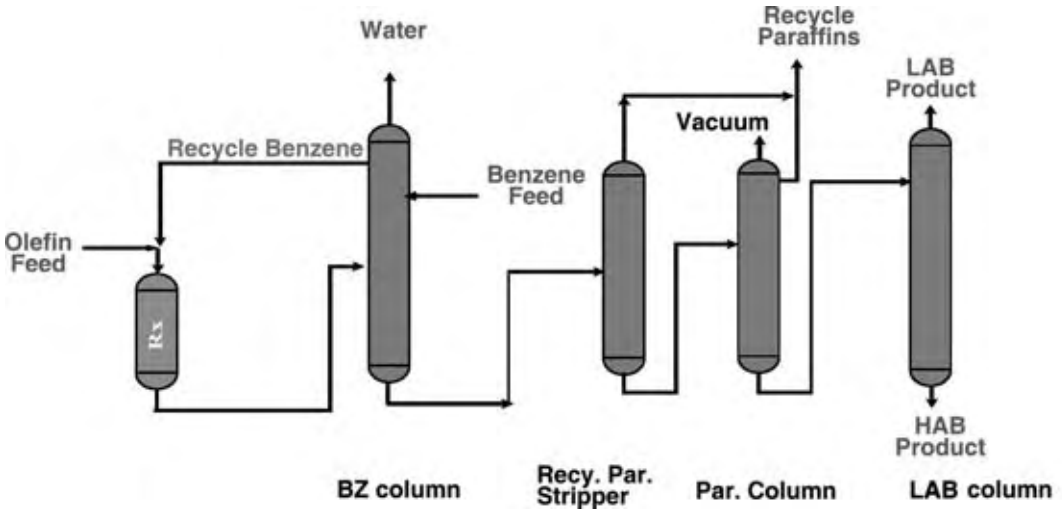

Fig. 10 UOP/CEPSA Detal process for the production of LAB. *(View this art in color at www.dekker.com.)*

combined with makeup benzene before introduction to the fixed-bed reactor containing the solid acid catalyst. As with HF alkylation, an excess of benzene is required. The reaction occurs in the liquid phase and under mild conditions to achieve optimal product quality. The reactor effluent flows directly to the fractionation system, which is similar to that for the HF alkylation process. Because the Detal process eliminates the need for HF, carbon steel metallurgy can be used in vessel and piping construction. Also, the special equipment required for HF handling is no longer needed.

UOP DeFine and PEP units must always be included in Detal-based LAB complexes for optimal performance. All LAB complexes built since 1995 employ solid-bed heterogenous alkylation catalyst system.

CONCLUSIONS

Linear alkylbenzene enjoys worldwide acceptance as a cost-effective and environmentally friendly intermediate used in the production of household and industrial cleaning formulations. Both HF acid and solid-bed alkylation processes are cost-competitive routes for the manufacture of LAB. Solid-bed alkylation process produces fewer environmentally hazardous by-products and employs a less complex facility when compared to HF route. With the breakthrough development of commercially demonstrated and expected future refinement, the solid-bed alkylation technology is expected to meet the continued growth in LAB.

INTRODUCTION

Modern laundry and dishwashing detergents contain enzymes to improve cleaning efficiency. Proteases are most commonly used, but other enzymes such as amylases, cellulases, and lipases are becoming increasingly popular. This entry describes the important properties of each enzyme class, introduces some of the obstacles involved in formulating them into detergent products, and provides information about how detergent enzymes are commercially produced.

BACKGROUND

The remarkable catalytic properties of enzymes have long been harnessed for human purposes. Ancient people unknowingly used enzymes for such processes as tanning, linen making, and indigo production.[1] Modern biotechnology and recombinant DNA technology have made possible not only to produce and purify large quantities of enzymes, but also to improve upon their naturally occurring properties through protein engineering. This has spawned a $1.5 billion annual market for ''industrial enzymes'' with over 500 commercial products.[2] Applications involve food production (dairy, brewing, baking, wine making, etc.), animal feed (largely as digestive aids), production of fuel ethanol, and various technical uses in the starch, pulp and paper, textile, and leather industries. However, the most important application of industrial enzymes, in terms of both value and volume, is in detergent products.[1]

More than 80% of all laundry detergent products sold in the United States, Europe, and Japan contain enzymes.[3] Several important market drivers support this high level of penetration. First, the last several decades have been characterized by profoundly increased worldwide awareness of the need to lower energy costs and reduce environmental pollution. This has pushed the detergent industry toward enzyme-containing products as biodegradable, low-temperature alternatives to formulations that rely on phosphate builders and high wash water temperatures. Additionally, the stain-removal performance of enzymes, even at very low concentrations, has allowed detergent manufacturers to continue their trend toward increasingly concentrated products, reducing production and shipping costs.

But perhaps the most important business driver for the use of enzymes in detergent is the need for product differentiation and branding. This problem is well illustrated in the U.S. domestic market for detergent products, which generated $3.2 billion in sales during 2003.[4] As a mature market, sales growth is essentially limited by the rate of population growth. Thus, gaining and protecting market share is crucial for the success of detergent manufacturers. With the rise of discount mass-market retailers and warehouse clubs, private label detergent products have become widespread, creating price pressure for established market leaders. This has increased the need for technical innovation to differentiate branded products, leading to the development and commercialization of several new types of detergent enzymes.

TYPES OF ENZYMES USED IN DETERGENTS

To be useful as a detergent additive, an enzyme must be compatible with existing laundry practices while simultaneously boosting soil-removal performance. The criterion of enhancing performance is often easily met, as most stains and soils are biological in nature, and enzymes have evolved to break down all kinds of biological materials, including the proteins, starches, and oils that are common laundry soils. There are some problems, however, in that many stains are

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007733

composed of denatured, cooked, baked, or gelatinized food products, which can be difficult for detergent enzymes to digest. For instance, bleach-containing detergents can cross-link the protein molecules that comprise some stains, thus rendering the soil less accessible to enzymatic removal.

Compatibility with harsh cleaning environments is often more difficult to achieve. Detergent enzymes must perform well in the soft, alkaline wash water that is best for solubilizing common laundry soils. These optimized wash water conditions were serendipitously identified in ancient times, when people cleaned their clothes by trampling them on muddy banks of rivers and then rinsed them with clean water. The process was much more effective in soft water, leading people to congregate in areas with soft water to do their laundry.[5] The beneficial aspects of washing clothes in alkaline solution were first identified around 3,500 BC, when people started adding such materials as soapwort, ashes, and soda to their wash water. These materials boost alkalinity, and accordingly, detergency.[5]

The most notable aspect of modern detergent formulations is the presence of synthetic surfactants. Laundry products contain a mixture of anionic and nonionic surfactants at weight percentages as high as 50%.[6] Modern formulations usually also contain bleaches and water-softening builders. Detergent enzymes must be compatible with all of these materials, representing a significant formulation challenge that is discussed later.

The duration and temperature conditions of automatic washing machine cycles must also be taken into account during the selection of detergent enzymes. These can vary widely from region to region. For example, in Europe, laundry cycles can be more than an hour at temperatures reaching as high as 90°C.[7] In contrast, United States wash cycles are much shorter, lasting between 10 and 12 minutes, at the more moderate temperature of ''hot'' domestic tap water.[7] In Japan, clothes are washed for 10 minutes after a lengthy presoak period in cold or lukewarm water.[8] In general, however, wash temperatures are falling worldwide owing to the desire to conserve energy. Clearly, a versatile detergent enzyme for the worldwide market must be stable for long periods at high temperatures, yet also provide significant activity at lower temperatures.

Despite these obstacles, several classes of enzymes have been successfully incorporated into detergent products. These include proteases, amylases, lipases, cellulases, and mannanases. Market data are shown in Table 1, and each class of enzyme is discussed in further detail in what follows.

Protease

Proteases are enzymes that catalytically degrade proteins, making them useful in the removal of all manner of proteinaceous and protein-containing stains such as blood, egg yolk, milk, grass, and collar soil. Because they perform well against such a wide variety of stains, proteases are the most commonly used type of detergent enzyme (see Table 1).

Proteases were first introduced as a detergent product in 1931 by the German scientist Otto Röhm.[3] This product was essentially a mixture of animal pancreatic enzymes including trypsin and chymotrypsin. It was not very effective, as these enzymes lack broad substrate specificity and do not exhibit high activity or stability at alkaline pH.

World War II spurred much advancement in the production of penicillin, particularly the advent of submerged fermentation processes. This new technique was soon adapted to the large-scale production of bacterial proteases. The first modern detergent protease, isolated from *Bacillus licheniformis*, was introduced in 1962.[3] This enzyme, a particular type of protease called a subtilase, was stable at higher temperatures, had broad substrate specificity and worked well in alkaline conditions. The appearance of this enzyme and others similar to it (i.e., subtilisins) opened up the detergent enzymes market, and by 1969, 50% of the laundry detergent products sold in the United States and Europe contained enzymes.[3]

The subtilisins used in today's detergent products are usually from *Bacillus lentus* and other *Bacillus* species. The survival and growth of these soil-dwelling organisms involves secreting large amounts of

Table 1 1995 Worldwide market for detergent enzymes in millions of U.S. dollars

	Protease	Lipase	Cellulase	Amylase	Total
United States	80	10	40	10	140
Western Europe	100	20	45	20	185
Japan	30	15	20	–	65
Others	110	10	5	–	125
Total	320	55	110	30	515

(From Ref.[34].)

hydrolytic enzymes (such as subtilisin), then absorbing the resulting extracellular degradation products as building blocks and energy sources. Biologically, this is an interesting feat as the organism is able to produce a highly active and nonspecific protease without disrupting or destroying its own internal enzymatic processes. The subtilisin genome indicates how this is possible: the gene contains a signal sequence that targets it for export through the Sec translocase complex. Once outside the cell, the signal sequence, or ''prodomain,'' is proteolytically clipped from the molecule. The final folding of subtilisin is then catalyzed by foldases, bringing it into its final, active conformation.[9] This extracellular secretion mechanism of subtilisin by *Bacillus* species has enabled the production and purification of large amounts of the enzyme in a cost-effective manner.

Another beneficial property of the commonly used *Bacillus* subtilisins is their broad substrate specificity. In contrast to other serine endopeptidases like trypsin and chymotrypsin, the subtilisins have elongated substrate binding sites that allow them to accommodate a wide variety of different peptide sequences.

There are two important disadvantages of subtilisin as a detergent protease. The first is that it is susceptible to methionine oxidation, which results in sharply decreased thermal stability and concomitantly reduced proteolytic activity at high wash temperatures. A further disadvantage is its dependence on bound Ca^{2+} ions for thermodynamic stability. Builders and other chelating detergent ingredients can remove the metal ions, destabilizing the active, properly folded conformation of the enzyme.

A tremendous amount of protein engineering effort has been directed at improving subtilisin as a detergent enzyme. Indeed, patents exist for single amino acid substitutions at nearly every site along the 275 amino acid sequence of subtilisin.[2] The much larger space defined by multisite mutations has not yet been thoroughly explored;[10] however, more sophisticated techniques such as DNA shuffling have already been successfully applied in the development of improved proteases.[11]

Amylase

After protease, the next most common detergent enzyme is α-amylase (or simply amylase). This class of enzymes hydrolyzes the α-1,4-linkages that join glucose subunits into starch polymers. Because starch is often present in food, amylase is particularly effective against food-based stains. Also, as more and more processed food products include starch as a thickening agent, amylase is becoming increasingly useful as a detergent additive. The trend toward lower wash water temperatures has added to the popularity of amylase in detergent; starch solubility is limited in cold water, and by producing the more soluble oligosaccharide and dextrin degradation products, amylase contributes significantly to stain-removing power.

Typically, the amylases used in detergent are derived from bacterial sources. *B. licheniformis* amylase is particularly desirable for detergent applications as it is highly thermostable and maintains its activity even at high pH. The primary drawback of *Bacillus*-derived amylases as detergent enzymes is that their stability (and in many cases also their activity) relies on bound Ca^{2+} ions.[12] This is problematic in detergent formulations that must also contain detergent builders to limit water hardness. Oxidation of a methionine residue close to the active site of *B. licheniformis* amylase is another common stability problem.[12]

Lipase

The use of lipase in detergent has also been driven by the global trend toward lower wash water temperatures. This is because lipase decomposes fats and oils, compounds that are generally only sparingly soluble in cold detergent mixtures, into smaller, more readily solubilized subunits. Lipase is particularly effective against triglyceride-containing stains such as butter, lipstick, and sebum (collar stain).

Lipase is unique amongst the detergent enzymes as its catalytic activity primarily occurs in oil–water interfaces. This has the important ramification that most of its stain-removal effectiveness comes not during the wash cycle, but during the subsequent drying period, when total water content is as low as 25%.[3] Thus, the benefit of lipase in a detergent formulation is not apparent until the second wash cycle. Perhaps not surprisingly, the interfacial activation phenomenon of detergent lipases is easily disrupted by the presence of surfactants.[3] This poses a difficult formulation problem that has limited the widespread usage of lipase in detergent products. Moreover, the release of medium chain fatty acids by lipases has been implicated in the creation of unpleasant odors.

Cellulase

The need for product differentiation has been the primary motivating factor for the addition of cellulase to detergent formulations. This type of enzyme degrades the cellulose that comprises cotton fibers—a fact that is counterintuitive because clothes, not stains, are made of cotton. However, cellulase is beneficial in that the enzyme preferentially acts on the cotton microfibrils that are worn or damaged, removing them from the surface of the fabric and making the garment appear softer and brighter. Removal of the fuzzy outer layer

of the cotton fibers has the added effect of making the fabric more resistant to encrustation of other soils, such as hard water deposits.[3] Detergent cellulases are generally derived from fungal sources such as *Humicola insolens* or *Trichoderma reesei*.

Mannanase

The newest type of detergent enzyme is mannanase. These enzymes catalytically degrade the β-1,4-linked galactomannans commonly found in the seeds of leguminous plants and beans of carob trees and in galactoglucomannans as components of softwood hemicelluloses. These compounds are often referred to as gums, and they are increasingly used as thickeners and gel texture agents in food and consumer products. For example, ice cream, barbecue sauce, processed foods, salad dressing, hair styling aids, and cosmetic makeup all typically contain gums that are susceptible to digestion by mannanase. The gums act like glue for particulate soils, making the clothing fabric appear dull. Full scale washing tests followed with stain-removal evaluation by expert panels have shown that mannanases are highly effective against a broad range of common fabric stains.

FORMULATION CONCERNS

Enzymes are large molecules comprising tens to hundreds of amino acid subunits. Their unique catalytic properties are associated with specific conformations of the amino acid chain. However, these active conformations are thermodynamically quite fragile, typically only 5–15 kcal/mol more stable than unfolded conformations. Additionally, the amino acid subunits that define the protein contain a variety of reactive groups that are subject to chemical degradation pathways resulting in loss of structure and/or activity. Thus, ensuring the physical and chemical integrity of an enzyme's ''native'' structure is a primary concern when adding enzymes to detergent products.

Powdered Formulations

Because of the long-term instability of proteins in aqueous solution, enzyme producers and formulators have attempted to produce stable solid enzyme formulations since enzymes were first used in detergents. Initially, commercially produced protease-containing detergents contained spray dried enzymes. As discussed earlier, proteases have the ability to digest themselves via autolysis and are often incompatible with surfactants. These problems are easily overcome by storing the protease in the solid state. Simple spray-drying provides a fast and cost-effective way of compartmentalizing two incompatible ingredients and maintaining protease activity over a typical detergent product's shelf life. However, the technologies used to produce modern powdered enzymes have evolved far beyond simple spray drying.

The main reason for this is the possible immunogenic nature of enzymes, which, similar to most other proteins, can cause allergic reactions if not handled in a safe manner. Thus, modern enzyme granules need to provide a tough barrier to prevent release of enzyme dust, whilst providing quick release once in the wash application. Enzyme granules contain coatings that are designed to withstand the physical impact and the shear forces typically encountered during powder processing. Many ways of producing enzyme granules have evolved, with just three methods being currently in common use for detergents. These include drum granulation, marumerization/spheronization, and fluid bed coating (Fig. 1). An overview is provided in Table 2. In general, fluid bed technology is the most flexible approach, giving granules a uniform appearance and smooth coating (Fig. 2), while other technologies have an edge in either cost or throughput, as they are more amenable to continuous operation.

Powdered detergents, even though appearing dry, contain between 10 and 30% moisture, allowing slow diffusion of water and other molecules in and out of enzyme granules. Bleach, and in particular its active ingredient, hydrogen peroxide, can travel together with water through thin coating layers over long storage periods. This can cause oxidation of various chemical groups on the enzyme molecule. Thus, enzyme granules for bleach-containing detergents comprise additional protective measures, either in physical form, such as through barrier layers or via chemical additives.

Liquid Formulations

The successful application of enzymes in liquid detergent formulations presents several technical obstacles that are not encountered in detergent powders. These problems stem from the fact that liquid detergent products are complex aqueous solutions, and physical separation of enzymes from potentially harmful detergent components is impractical. Table 3 describes a typical heavy-duty liquid detergent (HDLD) formulation. Surfactants, bleaches, and water-softening builders—all necessary ingredients for a viable detergent product—can affect the physical and chemical stability of enzymes. Additionally, as newer types of detergent enzymes are added to formulations that already contain proteases, proteolytic degradation of enzymes is a concern.

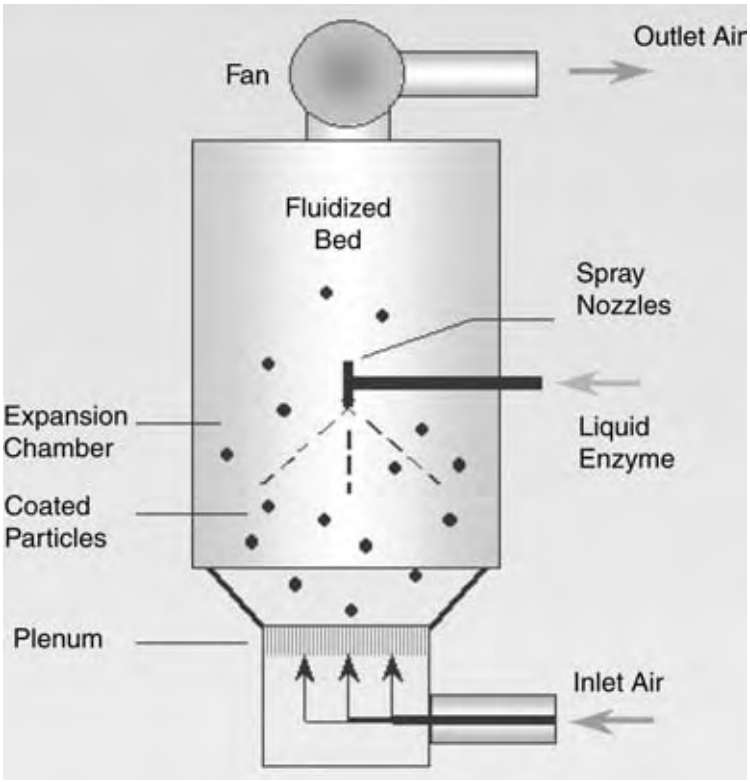

Fig. 1 Schematic view of a fluid bed granulator. *(View this art in color at www.dekker.com.)*

Market trends highlight the importance of overcoming these technical obstacles. In the United States, consumers increasingly choose liquid detergent products over powdered formulations. In 2003, liquid products outsold powders by roughly 2 : 1 margin.[4] This trend is expected to continue, and considerable research resources have been directed toward the challenge of improving enzyme stability in liquid detergent products. Liquid detergents provide convenience to the consumer and eliminate possible solubility concerns, particularly in regions where low wash water temperatures are prevalent.

The patent literature contains numerous examples of enzyme stabilization schemes based on the use of various chemical additives. Common themes are to either lower the amount of water in the formulation while retaining solubility of other components, or to add specific enzyme stabilizer/inhibitors. Some examples are highlighted in Table 4, and many others can be found in the review by Crutzen and Douglass.[3] Few published articles have addressed the mechanisms of enzyme stabilization by additives. One study examines protease stabilization by carboxylic acid salts[13] and another discusses the use of borate in conjunction with propylene glycol to inhibit protease activity.[14]

The primary disadvantages of using chemical additives as enzyme stabilizers are their cost and that valuable formulation space is lost without any direct benefit to detergent performance. Thus, an alternative research strategy involves understanding the detrimental effects of standard detergent ingredients on enzymes. This research has been primarily focused on the adverse effects of surfactants and surfactant blends. Kravetz and Guin demonstrated that anionic surfactants (e.g., linear alkylbenzene sulfonate, α-olefin sulfonate) are more harmful to protease and amylase than nonionic surfactants (e.g., alcohol ethoxylates).[15] Lalonde et al. explored the influence of total surfactant content and surfactant type on protease stability, concluding that the detrimental effects of anionic surfactants could be reduced by decreasing the water content of the formulation.[16] More recently, it has been shown that enzymes could be stabilized against a relatively harsh anionic surfactant, linear alkylbenzene sulfonate (LAS), by including highly ethoxylated cosurfactants in the formulation.[17] A common conclusion from this research is that anionic surfactants, particularly those that entirely lack ethoxylation, destabilize proteins.

Surfactant-induced unfolding of enzymes is an important issue, and it has been addressed in some more fundamental research studies. In the early 1980s, Jones et al. conducted dialysis experiments to examine binding stoichiometry between surfactants and various protein molecules.[18,19] Their work showed that anionic surfactants bind to proteins in a cooperative way, with hundreds of surfactant monomers binding to a single protein molecule. There is experimental evidence that the resulting unfolded protein–surfactant complex

Table 2 Comparison of production methods for powdered enzymes

Technology	Equipment	Advantages	Disadvantages
Prilling (hot melt)	Prilling tower	Continuous process High capacity Easy rework	High product dust Low melting point Requires predried enzyme
Extrusion/spheronization (marum)	Screw extruder, Marumerizer, Fluid bed coater	Inexpensive raw materials Continuous process	Complex multistep process High dust during process and in product Requires highly concentrated enzyme
Drum granulation (high shear)	Lödige mixer, Littleford mixer, Fluid bed or drum coater	High capacity Continuous process Tough granules	Dusty, multistep process Requires highly concentrated enzyme Wide particle size distribution
Fluid bed (layering/coating)	Fluid bed coater	Single, contained reactor Flexible formulation Tough, uniform granules	Batch process Difficult rework

consists of the protein chain wrapped around micelle-like surfactant aggregates. Taken together, these studies indicate that surfactant-induced unfolding is generally a thermodynamically favorable event.

However, even if thermodynamics dictate that unfolding of enzymes in the presence of surfactants will eventually occur, the kinetics of the unfolding process is a much more relevant issue for the detergent formulator. Otzen et al. conducted an extensive protein engineering study to compare the unfolding of cellulase in detergent and guanidine hydrochloride.[20] They reached several important conclusions: amino acid substitutions that increased stability against guanidine generally did not bring about a concomitant increase in stability against surfactant, and electrostatic interactions between cationic amino acids and anionic surfactant molecules significantly influenced the overall unfolding rate. Further studies suggest that the size and shape of surfactant aggregates may also affect the unfolding rate of proteins in detergent.[21]

PRODUCTION OF DETERGENT ENZYMES

Identification of Target Enzymes

Numerous methods have been used to successfully identify new enzymes for detergent applications. Historically, the method of choice has been to screen for new enzymes from naturally occurring microbes. The most commonly used protease, subtilisin, was initially isolated in this manner. More recently, researchers have resorted to exploring extreme environments, such as hot springs, to more closely match

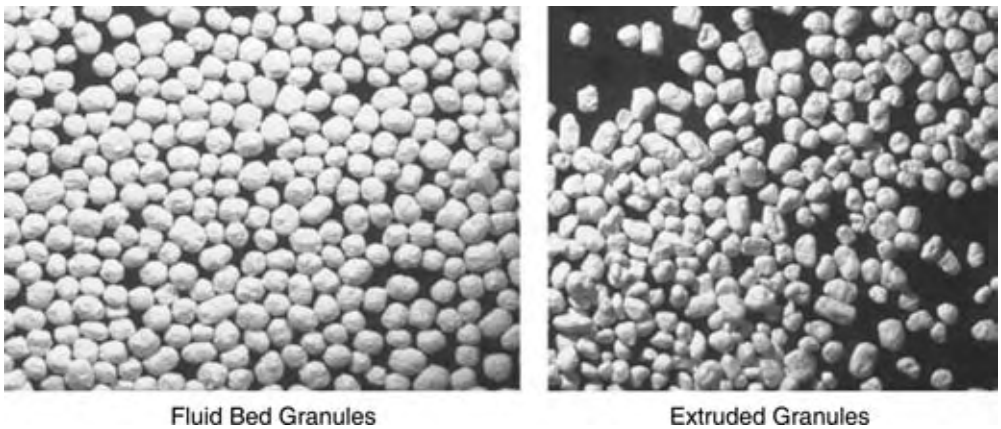

Fig. 2 Comparison of enzyme granules produced by fluidized bed and extrusion methods. *(View this art in color at www.dekker.com.)*

Table 3 Example of heavy-duty liquid detergent (HDLD) formulation

Ingredient	Weight percent
Anionic surfactant (typically alkylbenzene sulfonate, alkyl ether sulfate)	0–40
Nonionic surfactant (alcohol ethoxylate)	0–10

Fluorescent brightener	0–5

(From Ref.[6].)

the enzymes' natural environment with that found in a washing machine. This is often easier said than done in that the so-called ''extremophiles'' living in these relatively harsh environments can be difficult or impossible to culture in a laboratory setting. One way to overcome this problem is to extract the target microbe's DNA, screen it for useful protein sequences, and, if necessary, express the sequences of interest in different host organisms.[22] These methods have been enhanced by the application of robotics and other high throughput techniques, making ''genome-based screens'' a very attractive method of identifying new detergent enzymes.

A variation of this technique is the so-called ''homolog screen,'' whereby sequences of related families of proteins are aligned and probed for the best or most stable mutant.[23] Together with computational methods to identify and characterize the proteins, these technologies have enabled identification and targeted commercialization of new enzymes on an unprecedented short timescale.

Table 4 Patented additives for enzyme stabilization in liquid detergents

US Patent 4,532,064	Boron compounds, dicarboxylic acids
US Patent 4,404,115	Sodium pentaborate
US Patent 4,537,707	Boric acid and formate

Optimization of Enzymes for Detergent Applications

Before the advent of protein engineering, naturally occurring enzymes were commercialized without any form of modification or optimization. An initial technology dislocation occurred in the 1980s and 1990s, when the advent of protein engineering facilitated the improvement of enzyme performance to levels previously thought to be impossible.[6,24] Other methods for optimizing newly identified detergent enzymes include directed evolution or gene shuffling.[25,26]

In either case, whether the enzyme was initially identified using classical or postgenomic screening methods, the proven screener's mantra also applies to optimization: ''You get what you screen for!'' This phrase implies that if the optimization criteria are not specifically designed to mimic the conditions the enzyme encounters during its application, the results of protein selection and improvement will not necessarily meet the appropriate performance criteria. Indeed, heavy reliance on these modern high-throughput technologies without keeping an eye on real-world applications has, somewhat unjustifiably, led to a backlash against applying these techniques in both therapeutic and industrial biotechnology applications.[27]

Fermentation Processes

As evidenced by centuries-long experience with the arts of brewing, yoghurt and cheese making, humans long ago mastered the process of microbial fermentation. Nevertheless, early detergent enzyme production processes relied on extraction from plants or animals. In contrast, modern detergent enzymes are mostly produced using micro-organisms in large-scale fermentations. While there are variations on the theme, such as the traditional Koji process, a moist tray fermentation used in the soy sauce and sake industry and to produce specialty enzymes, today's detergent enzymes are mostly grown in submerged culture in stainless steel fermentation tanks. Both prokaryotic and eukaryotic organisms are used for production. In the case of prokaryotes, *Bacillus* species are common for the production of proteases and amylases, and eukaryotes are often used to manufacture cellulases. A typical industrial fermentor is shown in Fig. 3. Because microbial fermentations require the presence of a sufficient amount of biomass to yield economically viable levels of enzyme, fermentor volumes can be quite large, ranging up to 1,000 m^3 in size. Each large-tank inoculum begins with a seed vial, proceeding through a series of tanks of intermediate size until sufficient cell mass is obtained to inoculate the final fermentor. Many attempts have been made to improve this process, with

Fig. 3 A large-scale fermentor for the production of detergent enzymes. *(View this art in color at www.dekker.com.)*

the most notable improvement being the development of fed batch fermentations, where a slow feed of a limiting nutrient creates controlled growth and enzyme production conditions. Another principal achievement was to engineer bacterial strains that are not capable of sporulation and produce high amounts of enzyme.[28]

Much effort has also been directed toward the development of fully continuous chemostat-type fermentations in which a tank produces a steady stream of enzymes. In this type of operation, product-containing fermentation broth is drawn off while new media is fed to the tank to maintain a constant volume. Reasonable successes with this method have been reported in the biopharmaceutical industry. However, similar examples of successful application of this technique have not yet appeared in the industrial biotechnology literature.

Microbial fermentations must be tightly controlled to ensure optimal growth of micro-organisms and efficient production of enzymes. As shown in Fig. 4, a modern fermentor will allow operators to control the temperature, pH, redox potential, and dissolved oxygen of the growth medium. Large-scale fermentation operations have been optimized and standardized to the point that most room for improvement is associated with the physiology of the microbial production strains themselves. Thus, much research has been done to explore and understand both the metabolic and the catabolic pathways of enzyme-producing bacterial strains, facilitating the design of even more highly optimized fermentation processes.[29] This knowledge has also allowed enzyme manufacturers to implement effective environmental control systems aimed at protecting workers, products, and the environment from the release of enzymes or micro-organisms.

Purification and Formulation

In contrast to fermentation processes where reasonably standardized equipment is used, a number of varying techniques are necessary to accomplish purification and formulation of enzymatic products from the

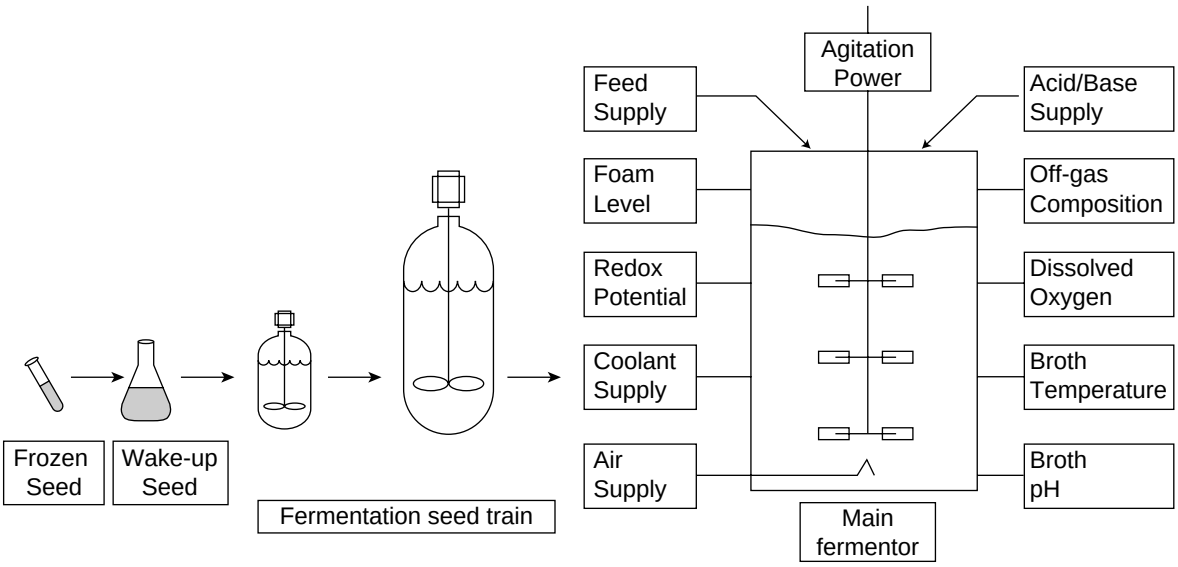

Fig. 4 Industrial fermentation scheme.

fermentation broth. The collective term ''downstream processing'' encompasses methods that can vary widely between enzyme products. A schematic overview of a typical downstream process is given in Fig. 5. The early part of the enzyme separation is usually referred to as recovery, while the elements further downstream are called purification.

To begin, enzyme products can be inside the cell (intracellular), loosely associated with the cell, or secreted (extracellular). Each of these products requires a different approach on how to purify the enzyme. The majority of presently commercialized detergent enzymes is of the extracellular variety and can be recovered directly from the fermentation broth. Thus, the primary recovery challenge involves removing the cells from the broth, aptly called cell separation. Three different techniques are commonly used to achieve this goal: filtration, microfiltration, and centrifugation.

Filtration can include filter presses, rotary vacuum drum filters, and variations on synthetic membrane filtration equipment, such as filter cartridges, pancake filters, or cellulosic filter pads (Fig. 6). These processes typically operate in a batch mode: When the filter press is filled up or the vacuum drum cake is exhausted, a new batch must be started. This type of filtration is also called dead-end filtration because the only fluid flow is through the membrane itself.

Microfiltration is in principle a more technically advanced version of classic dead-end filtration processes. Microfiltration, along with related technologies such as ultrafiltration, nanofiltration, and reverse osmosis, relies on synthetic or ceramic membranes with a defined pore size. These operations use ''cross flow'' or ''tangential flow'' in which the filtrate is pumped in a direction parallel to the membrane surface.[30] The microbes are retained on one side of the membrane, while the aqueous enzyme solution passes through the membrane. The primary advantage of tangential flow is that membrane fouling is reduced to fouling of the membrane pores themselves while particulate

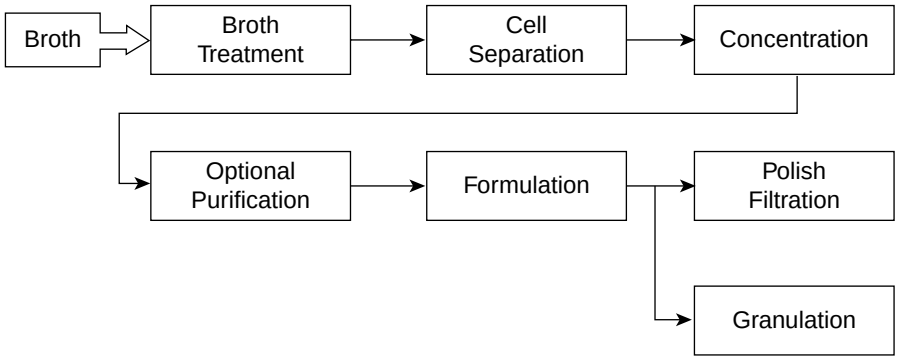

Fig. 5 Recovery of industrial enzymes.

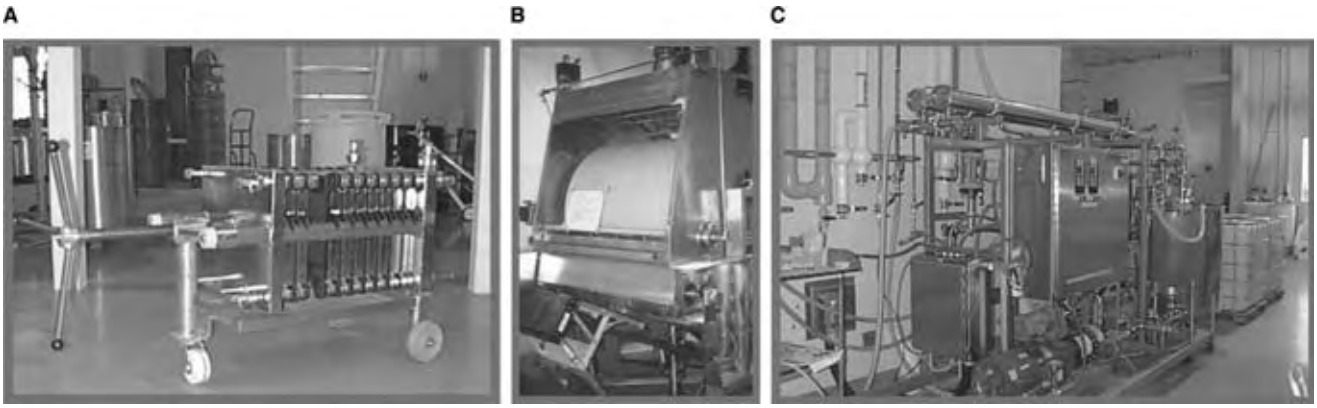

Fig. 6 Examples of downstream process equipment: (A) filter press; (B) rotary vaccum drum; (C) microfiltration unit. *(View this art in color at www.dekker.com.)*

matter on top of the membrane is continuously swept away.

Centrifugation is another viable method of removing microbes from the fermentation broth. Two types of centrifuge are available: disk stack centrifuges (clarifiers) and decanter centrifuges, which contain solid removing scrolls. Both devices can be operated in a continuous mode, speeding processing.

Once the cells have been removed, the enzyme broth is concentrated by evaporation or ultrafiltration. In ultrafiltration, membrane pore sizes are much smaller than in microfiltration, allowing only water and small molecules to travel through the membrane. Thus, enzymes can be concentrated under mild process conditions. Typical molecular weight cut off pore sizes for ultrafiltration membranes are 5000, 10,000, or 30,000 Daltons.

After recovery, purification of the enzyme is the next step. This can be achieved in many ways, through precipitation with salts, crystallization, chromatography, and aqueous two-phase extraction. Many of these methods are associated with substantial capital cost, low throughput, or low yields and are not commonly used for detergent enzymes. However, authors have reported the use of crystallization and aqueous two-phase extraction for large-scale preparations.[31,32] These methods are also effective in concentrating enzyme broths.

The final formulation of liquid detergent enzymes includes addition of stabilizers, antimicrobial substances, and glycols. This is followed by a final polish filtration to provide a clear liquid. If the enzyme broth is slated for dry product, the concentrate can either be stored for later use or applied directly for granulates. As with fermentation and downstream processing, formulations are often kept as closely guarded trade secrets in the biotechnology industry, and few publications on new approaches or new technologies are available in the literature.

ENVIRONMENTAL HEALTH AND SAFETY ASPECTS OF ENZYMES

Enzymes are important factors in the worldwide push to use sustainable and environmentally sound technologies. Enzymes have allowed detergent manufacturers to respond to the consumer desire for lower wash temperatures without compromising performance. Additionally, as completely biodegradable catalysts, enzymes do not persist in the environment.

However, there are some risks associated with the large-scale production and use of enzymes. These are: a) release of micro-organisms into the environment; b) contact by people with enzymes at the enzyme and detergent plants; and c) contact with enzymes by the consumer.

Release of enzymes is not considered a problem because detergent enzymes occur naturally in the environment. In fact *Bacillus* species, common hosts for the production of enzymes, are found in the soil and are part of the microbial population used in composting.[5] Nevertheless, the bacterial fermentations carried out in enzyme plants are carefully contained, and no live organisms should be detectable in the final enzyme product. As an additional safety measure, engineered bacterial strains are designed so that they cannot compete effectively with natural strains in the environment.

As is true for most proteins, detergent enzymes can cause allergic reactions in susceptible individuals. Inhalation of enzyme dust poses the greatest threat. These allergies typically manifest themselves with hay fever-like symptoms. The health effects are completely reversible once the allergen has been removed. Another health risk with proteases can be skin irritation; however, this has been described as a mild side effect.[33] Because of these health risks, enzyme and detergent manufacturers have employed advanced granulation technology to protect plant workers and consumers

from exposure to enzyme dust. In addition to engineering the products themselves, engineering controls, work-practice controls, and personal protective equipment have been implemented in plants handling enzymes to minimize exposure. Thus, enzyme technology provides the contemporary detergent manufacturer with a safe alternative to include more harmful chemical catalysts or surface-active agents in their formulations.

CONCLUSIONS

Enzymes are an increasingly important component in detergent formulations, both in terms of effectiveness and as a means of product differentiation. The primary types of detergent enzymes are protease, amylase, lipase, and cellulase; all are derived from bacterial and fungal sources. Enzyme activity is subject to various forms of chemical and physical degradation, problems that are particularly acute in liquid formulations, where the enzymes cannot be physically isolated from the harmful effects of surfactants and bleaches.

INTRODUCTION

Advances in technology are oriented not only toward the optimum performance of components, but also in the selection of the most reliable materials that allow technology to push the envelope. With improved material growing techniques, devices are designed to meet the desired characteristics for a specific application. Diamond materials have met this demand with good performance. With the increased use of diamond film in technology, research is constantly improving the materials and opening new doors. For example, diamond is being incorporated in complex multicomponent matrices. This has been possible because of the development of innovative deposition methods to deposit good-quality diamond films that show good adhesion properties and longer lifetimes. Widespread applications of diamond materials have been found in mining, tooling, electronics, optics, medicine, biology, and related fields.

DIAMOND FILMS

What Is a Diamond Film?

The two most important forms of carbon are graphite and diamond. Graphite consists of six-membered aromatic rings of sp^2 hybridized carbon atoms arranged in layers (Fig. 1). The layers are held together by a weak van der Waals force while the atoms in the ring are tightly bound by covalent bonds. The layers can slip, thus giving the graphite excellent lubrication properties. Diamond is the densest phase of carbon. The carbon atoms are covalently bonded through sp^3 bonds forming tetrahedral cells (Fig. 2). A rare form of diamond, hexagonal diamond, called lonsdaleite is also possible (Fig. 3). Essentially, the difference in the structures is the type of hybridization, sp^2 or sp^3, or the ratio of sp^2 and sp^3 bonds and the structure type.

Diamond-like film or amorphous diamond is made up of sp^2 and sp^3 bonded carbon. The amount of sp^2 bonds depends on the method of deposition and can be as high as 60%. The higher the number of sp^3 bonds the harder the material, the higher the band-gap, and the better the overall physical properties of the material.

HISTORY

Natural Diamond

When humankind first discovered diamond is not known, but the fourth century B.C. Sanskrit manuscript, the Artha-Sastra of Kautilya, tells about the diamond trade in India. The diamonds were mined from riverbeds (alluvial deposits). Industrial uses of diamond were described in a second-century Chinese text suggesting diamond trade with India. India was the only source of diamond until the discovery of diamonds in the Diamantina region of Brazil in 1725. Like India, the deposits were alluvial. In 1866, South Africa's alluvial diamond deposits were discovered on the Vaal River. Other alluvial deposits were discovered on The Orange River. In 1870, a series of diggings in present-day Kimberley identified the nonalluvial source of diamond, a volcanic rock that was named kimberlite. Five kimberlite pipes were discovered in this region. In 1888, DeBeers Consolidated Mines Ltd consolidated the diamond mining operations in Kimberley and became the world's leading diamond producer. A new diamond bearing kimberlite pipe was discovered in Pretoria in 1902. This mine, called the Premier Mine, proved to be very productive and was the site of the largest diamond gem discovered, the 3106-carat Cullinan.

A worldwide search for other diamond bearing deposits followed. In 1908, diamonds were found in the German South West African (present-day Namibia) desert sands. The significance of this discovery is that after World War II, this field came under the control of a mining company called Anglo-American. This mining company was formed in 1917 by Ernest Oppenheimer, who was backed by a mining engineer named Herbert Hoover (future president of the United States), the U.S. Newmont Mining Corporation, and J. P. Morgan Bank. Eventually, Oppenheimer's control of Anglo American Corporation was used as leverage for his chairmanship of DeBeers.

A diamond bearing kimberlite pipe was discovered in Siberia in 1954. There are at least 300 kimberlite pipes in Siberia. The most productive of these is the Udachnaya mine near the town of Udachnaya.

In the early 1970s, the Ellendale pipes were discovered in the Kimberley region of Western Australia.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120025845

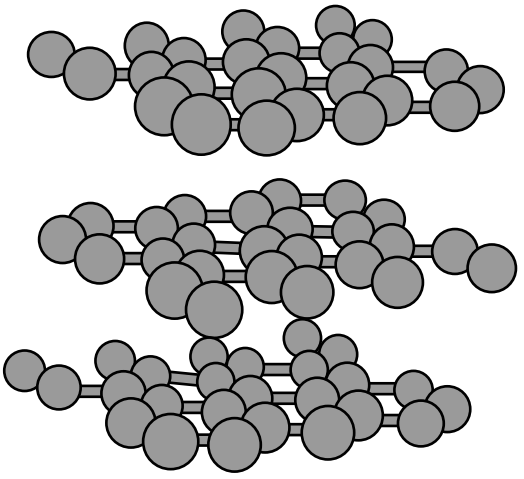

Fig. 1 Structure of graphite.

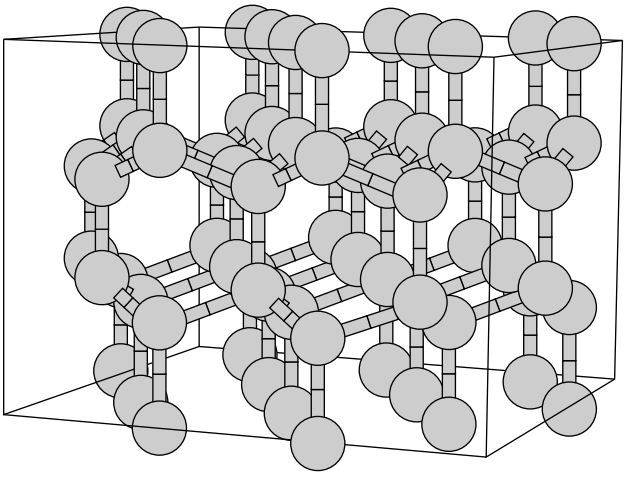

Fig. 3 Structure of lonsdaleite.

This discovery was significant because the pipes were not kimberlite, but a different type of volcanic rock called lamproite. One of the most productive diamond mines in the world, the Argyle mine with an ore that produces 400 carats of diamond per 100 tons, is a lamproite pipe. Albeit, the diamond is small and 90% is industrial grade.

In 1991, Canadian geologist Chuck Fipke's 1991 discovery of diamond bearing kimberlite in the Northwest Territory of Canada led to the construction of Canada's first diamond mine, the Ekati Mine. Canada is poised to become the leading producer of diamonds.

Synthetic Diamond, High Pressure and High Temperature

In 1797, Smithson Tenant discovered that diamond was made of pure carbon.[1] The quest to make synthetic diamond dates back to the early 1800s when C. Cagniard de la Tour claimed to have synthesized diamond from a solution. His crystals turned out to be aluminum and magnesium oxide. Many other claims and attempts were made but until the discovery of diamond in kimberlite, the role of high pressure and high temperature (HPHT) in the formation of diamond was not known. Diamond can be formed at great depths in the earth because of HPHT; it is the dominant phase of carbon; while at low pressures like those attained in a typical laboratory experiment, graphite is the dominant phase (Fig. 4).

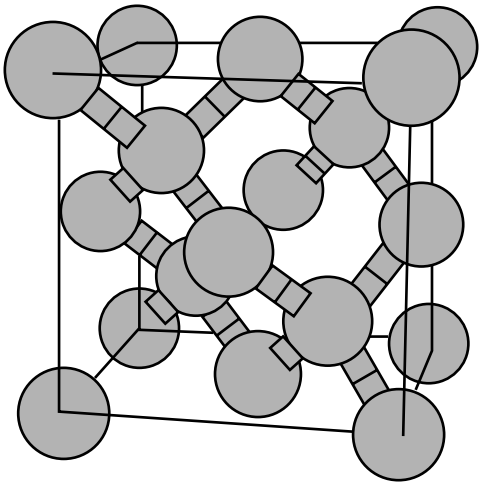

Fig. 2 Structure of diamond.

High-pressure research was revolutionized by Percy Bridgman in 1905 with his high-pressure press. Bridgman in that year solved the problem of the high-pressure seal; the same method used today. He used a very soft solid seal material (Sioux Indian pipe stone), but had the insight to keep the seal at a slightly higher pressure than the sample. He achieved this by using a two-piece piston and the fact that pressure is force acting on an area. Making the area of his seal less than that of his sample, and by exerting the same force on both the sample and the seal with his two-piece piston, he ensured that the seal was at a slightly higher pressure than the sample. Bridgman was also the first to use tungsten carbide, a material with much greater stiffness and hardness than steel, as a high-pressure anvil. Although Bridgman tried to make diamond, pressure alone was not sufficient.

The key to making diamond is the combination of pressure and temperature. The partnership of inventor Baltzar Van Platen and the company Allmanna Svenska Elektriska Aktiebolaget, or ASEA, was the first to grow diamond on February 16, 1953, but strangely failed to announce their discovery to the world. To achieve high pressures, ASEA used von Platen's split sphere device, which incorporated six wedge-shaped anvils, each directed at a cube-shaped sample chamber. The sample was carbon-rich at the center and

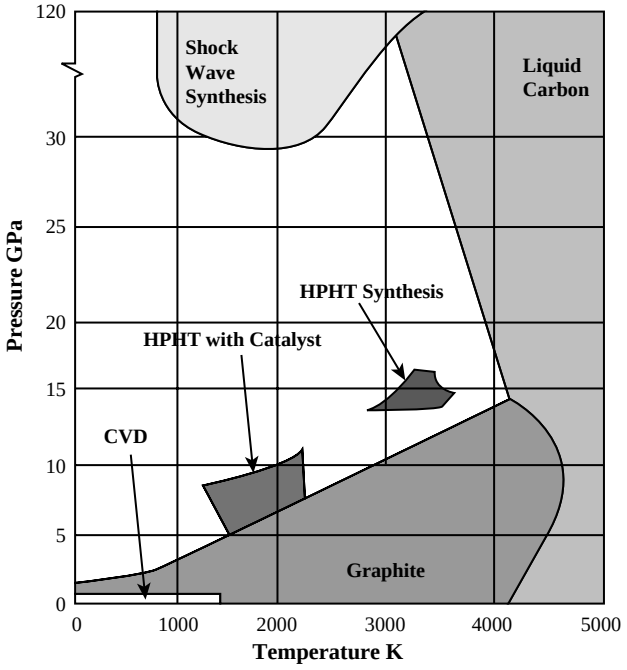

Fig. 4 Phase diagram of diamond.

surrounded by thermite (which ignited and burned to create a high temperature) and a copper jacket. The sample was placed inside the split sphere and this assembly was jacketed with copper. The split sphere was then placed in a high-pressure water tank. The high-pressure water tank was capable of achieving a pressure of 6000 atm. This 6000 atm when applied to the spit sphere would focus more than 80,000 atm of sustained pressure on the sample. In the first experiment that formed diamond, the sustained pressure was 83,000 atm and the carbon-rich material was a mixture of iron carbide and graphite. The iron was a critical component because it acted as a catalyst in the HPHT catalytic regime (see Fig. 4).

A team from GE grew diamond on December 8, 1954. The team had implemented many innovations in their high-pressure apparatus. The first challenge was to secure a suitable sealing material. High-quality Sioux Indian pipe stone was extremely difficult to get and Percy Bridgman kept his source secret. The GE team found an alternate sealing material, the mineral pyrophyllite or wonderstone, which was commercially available. In addition, high temperature was achieved by passing current through a graphite heating element. GE also had two high-pressure press designs, both of which eventually grew diamond, Herb Strong's cone apparatus and Tracy Hall's belt apparatus. The team had the high-pressure and high-temperature capability required to grow diamond but did not understand the need for a catalytic material (Fig. 4). Their breakthrough came when, in November 22, 1954, Herb Strong noted that diamond was discovered in some iron meteorites. He wrote in his notebook: ''The (iron–nickel) alloys should be investigated at high pressure for (melting point) and as a solvent for carbon in the liquid state.'' Indeed, iron, nickel, and cobalt are catalysts for diamond growth in the HPHT catalytic regime. On December 8, 1954, Strong wrapped a commercial carbonizing powder called Steco, with two seed diamonds, in iron foil. He used an estimated pressure of 50,000 atm with a temperature of 1250°C. His experiment was run for 16 hr. On December 15, x-ray analysis proved that two shard-like crystals, 1/16 of an inch in the long direction, were diamond. The results were not immediately repeatable and there is considerable evidence from a 1993 analysis of the larger of the two crystals that the diamonds were probably natural. On December 16, however, Hall used iron sulfide and two diamond seed crystals with his belt press and did produce synthetic diamond. This experiment was repeated at will.

In the last 40 yr, the development of synthetic diamond in various forms has fueled a revolution in the use of diamond as an engineering material. The process of HPHT diamond synthesis was responsible for stunning growth in the abrasives market. During that time, the world's consumption of diamond abrasive materials increased from 5 to over 100 tons/yr.

SYNTHETIC DIAMOND, CHEMICAL VAPOR DEPOSITION

Between November 26, 1952, and January 7, 1953, W. Eversole reported the synthesis of diamond by chemical vapor deposition (CVD). Going strictly by the phase diagram of carbon, it was very difficult for many scientists to accept the proposition that diamond could be obtained by CVD. In 1956, Soviet scientists B. V. Spitsyn and B. V. Deryagin filed a patent disclosure covering the growth of a diamond from carbon tetraiodide, which set the stage for substantial CVD work in the USSR. In the 1960s J. Angus in the United States duplicated the earlier work of Eversole. Meanwhile, progress was also made in Deryagin's laboratory in the USSR. The major breakthrough in the CVD process was the use of atomic hydrogen during the growth phase. Understanding the role of atomic hydrogen began in the late 1960s. Boris Spitsyn noted that when hydrogen gas was added to his thermal decomposition experiment, diamond crystals grew at rates thousands of times faster than in previous experiments. The mechanism of this process was not understood fully until several years later when it was explained independently by Angus' group and by Deryagin's group. In 1971, Derjaguin and Dimitri Fedoseev published a summary of their group's work, which demonstrated

a high-growth-rate CVD process.[2] The Western world became familiar with this work when Derjaguin and Fedoseev published an article in Scientific American.[3] This announcement was greeted with skepticism by scientists worldwide, primarily because Derjaguin's earlier claim of discovering a new form of water called polywater was discredited. In the late 1970s and early 1980s, however, N. Setaka's group in Japan also reported high-growth-rate CVD diamond films. These reports motivated the U.S. Department of Defense to increase research funding for CVD diamond in the mid-1980s.

Chemical vapor deposition diamond films have been expanded into the markets of electronics, cutting tools, and wear-resistant coatings and have demonstrated other applications in the areas of thermal management, optics, and acoustics. The CVD diamond market is growing broader as new products continue to be developed, such as chemical process electrodes and radiation detectors. Additional applications such as cold cathode emitters, high-temperature sensors, and, ultimately, semiconductors are also being developed. The impact of diamond on people's lives, while not always immediately obvious, is definitely becoming increasingly significant.

SYNTHETIC DIAMOND, EXPLOSION

One of the by-products of a large meteor collision with the earth is the formation of fine diamond crystals due to the explosion. The presence of fine diamond crystals in a layer 65 million years old helped to formulate the theory that a large meteor impact was responsible for the extinction of the dinosaurs. One of the distinctive aspects of diamond created by explosion is that cubic as well as hexagonal (lonsdaleite) crystals are formed. An explosion is capable of creating millions of atmospheres of pressure in microseconds. In 1959, Paul DeCarlie and John Jamieson used a simple apparatus where explosives were packed behind an aluminum metal plate and detonated. The plate accelerated into a graphite sample generating a pressure approaching 300,000 atm. The experiment produced fine diamond crystals. In the mid-1960s Dupont used their expertise in explosive technology to develop a commercial diamond producing explosive process. The finely grained diamond product, trade name Mypolex, has sold millions of carats per year because it is suitable for fine polishing applications.

Owing to the short time the pressure is created in an explosion, the diamond growth time is short, thus leading to small crystal size. In the laboratories of the former Soviet Union, an explosive process was developed to create ultra-dispersed detonation nanophase materials (UDDNM), which are composed of nanograin-sized crystals of various materials. This process has been used to synthesize nanophase diamond, zirconium dioxide, and aluminum oxide. This process, having no natural analogs, forms the material by direct synthesis in a detonation wave. Synthesis occurs under HPHT conditions. There are several former defense centers in the former Soviet Union that are capable of producing UDDNM.

The former Soviet Union used materials produced by this method as abrasives for polishing, production of composites, and lubrication. There are other important applications that need to be explored as well, which take advantage of the optical, electronic, and magnetic properties of these unique materials. The ultradispersed detonation process uses an explosive substance to create a synthesis wave. Synthesis occurs at high pressures (20–30 GPa) and temperatures (3000–5000 K) and over short time periods (0.1–0.5 μsec).[4,5] In the fabrication of diamond, the carbon from the explosive substance itself is used in the synthesis process. The resulting particles have specific surface areas of 270–390 m^2/g with shapes close to spherical. The size distribution is between 4 and 6 nm (see Table 1). In addition, the particles have high porosity, a high degree of chemical inertness, and high sorptive capacity.[6]

METHODS OF SYNTHESIS

High Pressure and High Temperature

High pressure and high temperature is a method used to grow diamond under an HPHT environment. The process is performed in the diamond stable region at pressures ranging from 7 to 10 GPa and temperatures ranging from 1700 to 2000 K. Graphite or other carbons are dissolved in molten transition metals and then precipitated in diamond form.

Chemical Vapor Deposition

Chemical vapor deposition is a growing technique in which a solid material is deposited from its gas phase

Table 1 Properties of nanophase diamond

Property	Value
Percentage of diamond phase (%)	85–91
Original particles size (nm)	4–6
Aggregates size (nm)	50–1000
Density (g/cm^2)	3.10
Specific surface area (m^2/g)	300 ± 60
Carbon percentage (%)	85–91
Chemical impurities	O, N, and H

on to a substrate. Diamond crystals grown by this technique require a carbon-containing gas, usually CH_4, and H_2. Hydrogen plays a double role in the active chemistry. In its atomic form it provides the path to carbon matrix formation when it reacts with a previously formed hydrocarbon surface by extracting a hydrogen atom and leaving a carbon surface.

$$H(g) + CH(s) \longleftrightarrow H_2(g) + C^*(s)$$

$$H(g) + C^* \longleftrightarrow CH(s)$$

This mechanism occurs in a continuous process allowing the growth of diamond crystals at low pressure (usually below atmospheric pressure) and high temperature (approximately 2000°C). Hydrogen also prevents the formation of aromatic species that lead to graphite formation through a selective etching process.

Hot Filament

Diamond deposition by the hot filament method consists of a carbon containing gas and hydrogen, which undergo dissociation by passing through a hot filament usually made of tungsten wire. The dissociated molecules then deposit on a substrate (at approximately 900°C) where a carbon matrix grows in the form of diamond. Deposition dynamics is described by the CVD process.

Thermal Decomposition

During diamond growth, carbon atoms are extracted from organic species, usually methane (CH_4), methyl (CH_3), and acetylene (C_2H_2). Atomic hydrogen is necessary to prevent graphitic formations at the diamond surface. To break apart molecular hydrogen, certain conditions of temperature and pressure must be met. At equilibrium, the atomic hydrogen concentration is given by Eq. (1):

$$[H]eq. = \frac{\{[(P^0)^2 + 4K^{-1}P^0P_T]^{1/2} - P^0\}}{2K^{-1}RT} \quad (1)$$

where P^0 is the standard pressure, P_T is the total pressure, R is the gas constant, T is the temperature, and K is the equilibrium constant for hydrogen dissociation.[7]

Because the dissociation reaction is endothermic, diamond synthesis processes like combustion synthesis, plasma torch, and hot filament provide enough energy to maintain a high rate of hydrogen dissociation. Flame nozzles achieve higher deposition rates compared to other CVD processes. The use of multiple flame burners increases the deposition area with high growth rates.[8]

Plasma Phase

Diamond CVD using a DC-arc plasma jet is one of the methods that are used for high growth rate diamond deposition. A gas mixture of H_2/Ar and CH_4 is necessary to enable the deposition of carbon for growing crystals on the substrate. A high-energy thermal plasma produces the high dissociation rates of chemical species that allows a high deposition rate. Thermal plasmas have high energy densities (up to $10^8\,J/m^3$), and temperatures that may exceed 10,000 K. Many parameters have been studied including gas mixtures, temperatures, and environmental conditions in the chamber to maximize the efficiency of the process. Studies of the deposited material demonstrate that a high-quality film can be grown by this technique. The deposition areas still remain relatively small and work continues to enhance the deposition areas. Large deposition areas become especially important for coating processes where uniformity is required. Besides high gas and power consumption, this method is economically reliable for the industrial scale. Linear growth rates of 1 mm/hr have been reported and this rate is three orders of magnitude larger than those achieved with hot filament CVD (HFCVD) and microwave CVD (MWCVD).

Microwave CVD uses microwave energies ranging from several hundreds of watts to tens of kilowatts at a frequency of 915 MHz or 2.45 GHz to dissociate active species. The most common MWCVD systems use 2.45 GHz.

Thermal plasma chemical vapor deposition (TPCVD) has many advantages over other methods, as deposition rate is the determining factor in the cost of diamond-coated materials.

INDUSTRIES

Tool and Die

Tool performance depends greatly on its interface with other materials under circumstances that are less than ideal. The properties of diamond abrasives make it suitable for tool design. Specifically, when operational conditions of heat, corrosion, vibrations, torsion, stress, strain, and force are considered, diamond is the material of choice. Increasing demand in the use of lightweight and other advanced materials has had positive effects on using diamond deposition as an alternative to design tools that hold their properties during cutting, drilling, and polishing work. Although

diamond is considered an ideal material for coating because of its hardness, not every diamond morphology necessarily meets the required standards for a given application. Other aspects, such as adhesion, film thickness, uniformity, and edge sharpness, also play an important role for each application. Diamond coatings on cutting tools can be classified according to their method of synthesis: polycrystalline diamond (PCD), CVD diamond, and single-crystal diamond. Polycrystalline diamond refers to a diamond that is made by sintering diamond particles together in a metal matrix under HPHT conditions.[9] Its structure exhibits a high abrasion resistance and hardness. It is mainly used for cutting nonferrous metals, nonmetallic (e.g., plastics, wood, chipboard, and rubber) substances, and wear parts. Major applications are for automotive and aerospace components. The mechanical and thermal properties of diamond are shown in Table 2.

In the production of wire dies, single-crystal diamond type Ib is used because of its thermal stability at higher temperatures (over 1000°C) and a metal-inclusion-free matrix. The wear region is allocated in the crystallographic {111} plane to get the highest abrasion and wear resistance. Although diamond exhibits more wear resistance characteristics than tungsten carbide, crystal morphologies may cause catastrophic failures during the drawing process owing to high pressures.

Grinding and Polishing

The grinding process is characterized by material removal. It is achieved by applying a force and movement during the process. To increase the removal rate, one of the two parameters should be increased. A diamond tool design is dependent on both diamond toughness and hardness properties and plays a role in the G ratio, which is defined as the volume of material removed over volume of tool worn. Toughness describes the way diamond fractures during use. It is also known as friability. Hardness describes diamond's resistance to abrasion and is also known as scratch and indentation. Its value ranges from 57 to 104 GPa and depends on crystal orientation, e.g., (100) and (111) surfaces, respectively, for single crystals. Polycrystalline diamonds have no orientation dependence for hardness parameters because of the statistical nature of surface orientation. A bulk value for hardness is used instead.

A crystal that exhibits large smooth faces tends to polish because it has a higher rub than cutting action. This creates excessive heat and low material removal. This kind of morphology works better in metals, glass, concrete, and stone. Irregular texture in small crystals gives a friable characteristic to diamond crystals with a higher tendency to fracture. Crystal fracture is a desirable effect in tool performance because it establishes the effective concentration of working crystals on the tool surface and generates new and sharp cutting surfaces. Resin-bonded tools have a longer life because of high crystal retention. Mechanical bonding is strengthened by rough crystal surfaces. Mesh size in the resin bond is an important parameter as smaller sizes can be pulled out with less force. Crystal retention can increase even for small mesh sizes by using spiked metal coatings that increase the surface contact area. Nickel, copper, and titanium are used for coating diamonds. The first two provide an enhanced mechanical bonding in wet and dry grinding processes, respectively. The third provides both mechanical and chemical enhanced bonding. The metal cladding can be 60% of particle weight

Table 2 Mechanical and thermal properties of synthesized diamond

Property	CVD diamond	Single-crystal diamond	PCD
Young's modulus (GPa)	1000–1100	1000–1100	776
Hardness (Gpa)	85–100	50–100	50
Tensile strength (MPa)	450–1100	1050–3000	1260
Compressive strength (GPa)	9.0	9.0	7.60
Fracture toughness [MPa(m)$^{1/2}$]	5.5–8.5	3.4	8.81
Transverse rupture strength (GPa)	1.3	2.9	1.2
Poisson's ratio	0.07	0.07	0.07
Thermal conductivity at 20°C (W/m/K)	500–2200	600–2200	560
Thermal conductivity at 200°C (W/m/K)	500–1100	600–1100	200
Thermal diffusivity (cm^2/sec)	2.8–11.6	5.5–11.6	2.7
Thermal expansion coefficient at 300 K	1.21	1.21	4.2
Thermal expansion coefficient at 500 K	3.84	3.84	
Thermal expansion coefficient at 1000 K	4.45	4.45	6.3

and also can act as a heat sink, improving tool performance in resin-bonded tools like grinding wheels.[10]

High removal rates have been achieved for abrasive tools where cutting surfaces are coated with rough diamond. Roughness depths of around 30 μm in microtool grinding surfaces have performed well in machining brittle materials achieving not only a high removal rate but also high quality.[11] This feature is very important for machining low-dimension structures like printed circuit boards, micromechanical systems (MEMS), and dental tools. In dental burs, alternative techniques like HFCVD for growing crystals and WC–Co substrate pretreatment have shown that adhesion toughness can be enhanced thereby improving tool performance and life.[12,13] In CVD, diamond abrasive roughness value, *Rz*, increases with crystal width ranging from 2 to 6 μm for crystal widths of 17 and 50 μm, respectively.[14] In optical applications, the grinding energy, that is, energy expended for material removal during glass grinding, is independent of the tool speed and in-feed rate; however, for slow tool speed and high in-feed rate an increased bond wear and enhanced self-sharpening effect have been identified.[15] In woodworking industries increased feeding rates up to 150 m/min are needed for milling tools with higher cutting edges. Increasing the number of PCD edges on the tool increases the efficiency removal capacity for this kind of process.[16]

Material removal by electrical discharge diamond grinding is a grinding method in which spark discharges between the metal bond and workpiece thermally soften the material while simultaneously having the diamond grains perform the abrasive action. This method is attractive for grinding conductive materials with a hard profile. Although normal force increases as wheel speed increases, this method reduces the normal force and grinding power when compared with other methods.[17]

Polishing processes are characterized by material removal by abrasive action in which grit size determines material finishing. Diamond grits for this process may be bonded in resin, vitrified, or metal matrix, although most polishing and fine finishing work is performed using an abrasive of loose powder. Major applications are for lens polishing, polishing of diamond tools, glass, ceramics, and semiconductors. Chemical vapor deposition diamond is used as an abrasive because it is found to be efficient in polishing other CVD diamond surfaces by achieving a higher polishing rate and reducing roughness values from 3.32 to 0.55 μm.[18] This has a major impact in applications that require high-quality crystals for electronic, electrical, thermal, and optical applications. Polishing action is direction oriented, having soft and hard directions during the process. Selection of hard direction ⟨100⟩ could end in tool damage. At the microscopic level, polishing action strongly depends on the deformation energy and mechanical characteristics in the diamond matrix that contribute to atom displacements.[19]

Drilling

A major limitation in the use of PCD is that it is not suitable for ferrous materials. Diamond reacts with iron in the presence of oxygen at high temperatures. This limitation forces the use of other hard materials, such as cubic boron nitride.

Substrates help to prolong tool life but can introduce problems of differential thermal expansion because of the inherent characteristics of both materials. Because drilling activity generates high temperatures, it is necessary to use a secondary phase with high thermal stability. Microcrystalline diamond in ceramic material accomplishes this task. Matching coefficient of thermal expansion and diamond cube orientation allows drill bits to remain sharp for drilling medium and hard rock at very high penetration rates.

Increasing the use of microdrills in electronics makes it necessary to enhance the cutting efficiency of tools that are designed to operate at very high cutting speeds. An enhanced technique for HFCVD is used to ensure better thermal distribution and uniform coating of WC–Co microdrills with PCD.[20] Tool design for drilling surfaces depends strongly on crystal formation, nucleation, growth, and adhesion. Any imperfection in these parameters, such as protusions or supercrystal formations, can precipitate a catastrophic tool failure.[21]

Mesh size in drilling tools has a dramatic impact in drilling speeds, which can be increased from 1000 to 6000 rpm along with a force reduction on the diamond core bit by a factor of nearly 6.8.[22]

Mining

Mining work requires specialized tools to perform work under the harshest and most aggressive conditions. This is when diamond abrasive properties combined with the hardness properties of other materials become crucial to drilling or cutting action that is subjected to extreme loading during prolonged periods.

ELECTRONICS

Heat Sinks

The state-of-the-art technology in electronics is characterized by continuous reduction of circuit etch. This represents an enormous electronic activity packed in a reduced volume, giving rise to higher temperatures.

This fact could not be overlooked making it necessary to implement effective heat sinks to ensure the desired device performance.

Diamond has the highest thermal conductivity when compared to other substances. For type Ia natural diamond the thermal conductivity is about 2000–4000 W/m/K. For type IIa it is up to 17500 W/m/K. A major problem in heat transfer is an effective heat sink that depends on the effective contact area, forces between both the materials, and the gap interface. Diamond exhibits the best characteristics for a heat spreader, which is the interface material that transfers heat between heat source and heat sink.

At a microscopic level the contact surface is restricted by peaks and valleys and even highly polished surfaces may exhibit a high peak to valley ratio. This makes it necessary to use an extremely flat contact surface between the heat source and thermal spreader to guarantee an efficient transfer of heat. Chemical vapor deposition diamond with a thickness of 1000 μm has been used for Multi Chip Modules (MCM) for this purpose. Heat spreaders are used in the electronic industry for IC packaging and solid-state lasers.

Insulators

The electrical properties of undoped diamond crystals make it suitable to be used as an insulator. It can support electric field strengths as high as 10 MV/cm before conduction and has a resistivity value as high as $10^{14}\,\Omega$. Its higher band-gap of 5.46 eV makes it difficult to promote an electron to the conduction band. This makes diamond a first-class insulator. Diamond insulators are being used in electronics as an intrinsic interface with doped diamond.

Semiconductors

Diamond's natural properties make it an ideal material for semiconductor applications. Although it has a wide band-gap of 5.5 eV, its intrinsic properties of carrier velocity of 2.7×10^7 cm/sec and mobility of 2200 $cm^2/V/sec$ for electrons, and dielectric constant of 5.5 give this material a broad advantage over other wide-band-gap semiconductors in high-power and high-frequency applications. Its low intrinsic carrier concentration of 10^5 at 1000 K makes it a good candidate for high-temperature electronics. The properties of diamond are attractive for the development of microsystem devices as an interface mainly due to diamond's high heat conductivity.[23]

When diamond is doped with either boron or nitrogen it becomes a semiconductor but it is not activated at room temperature because of the dopants' activation energies of 0.37 and 1.7 eV, respectively. Activation and conductivity at room temperature are problems that can be addressed by the incorporation of other electronic structures that increase carrier transport. Crystal morphology is an important parameter in the boron doping process to determine uncompensated acceptors (N_A–N_D) for different crystal facets as a function of doping concentration. The temperature coefficient of resistance for a CVD diamond film can be changed by boron doping. As conductivity depends on the crystal phase, the combined electromechanical properties can be exploited in sensor applications both for resistive temperature detectors and for pressure transducers.[24] As electrical conductivity is related linearly with boron concentration, a better-controlled process may allow for the development of better semiconductor devices improving crystal quality and operating limits.[25]

Diamond-like carbon (DLC) devices are also being developed in the electronic field. Although potential applications range from heat sinks to solar cells, its low-mobility characteristics, ranging from 10^{-4} to 10^{-5} $cm^2/V/sec$, and crystal structure defects still have to be improved for practical applications.[26] Most recent applications are for masking integrated circuits with satisfactory results for p–n junction yield rate through DLC mask, being better than polymer mask materials.[27]

A larger band-gap enables the fabrication of diodes with higher breakdown voltages. Diamond has a higher band-gap than SiC, GaN, and Si. However, its breakdown voltage is dependent on impurities in the crystal lattice. To achieve the highest breakdown voltage, high-purity diamond is required. Hydrogen and boron deteriorate electrical characteristics. Hydrogen diffusion depends on boron concentration. It has been observed that hydrogen diffuses as a positive ion for a homoepitaxial diamond layer with a high boron concentration and as a negatively charged species for a CVD layer with a low boron concentration.[28] Diamond Schottky diodes have large forward resistances of 300 Ω/cm^2 that are 10 times the value for Si diodes owing to compensated impurities, device geometry, and lack of a good ohmic contact. Under uncompensated conditions the forward resistance value for a Schottky diode could range between 0.01 and 0.1 Ω/cm^2 with a breakdown voltage of 10 kV.[29] A diamond Schottky diode should be a superior device over a Si diode for these parameters.

Chemical vapor deposition films have been grown on an $Ir/SrTiO_3$ substrate of around 0.6 cm^2 for a field effect transistor application achieving for the first time an RF output power for a device operating at frequencies of the order 10^9 Hz. Larger-size substrates will eventually allow the development of power diamond transistors at wafer scale.[30]

With the fast pace development of MEMS, diamond is gaining more applicability because of its flexible

properties of being an insulator or a conductive material when necessary. A major area is microswitching. In air, the frequency of operation of a diamond microswitch is about eight times that of its Si counterpart.[31]

Tribology

Diamond exhibits low-friction properties. This makes the diamond suitable for tribological applications where high friction and wear is present. Tribological properties depend on many factors including crystal orientation and particle size. High material removal rate is achieved during polishing with diamond particles because of their high deformation resistance.[32] Diamond-like carbon films are used as solid lubricants. Laser treatment of the surfaces in tribological DLC films is performed to reduce wear by lithography processes and prolong surface lifetime.[33] Multilayer DLC coatings have a better performance than a single-layer DLC coating; however, the latter exhibits less stress characteristics compared to intrinsic stress and applied stress with higher loads in multilayer DLC. Single-layer friction partners exhibit low friction and wear.[34] Other techniques like sputter ion plating have been used to deposit hydrogenated DLC, a-C : H coatings. These coatings exhibit low friction and wear behavior under high contact pressures ranging from 1 to 3.5 GPa.[35]

CONCLUSIONS

Diamond's properties make it the desirable material in thermal, optical, electrical, electronics, and mechanical applications. It has not been exploited to its maximum potential. Future trends are toward applications in medicine, biology, and the nuclear field. These fields already have applications that use diamond but continuous improvements are being made through research. Diamond is a strong candidate as a substitute for materials currently being used in a variety of applications. Although implementation may be deterred by cost factors or technical issues, the development of new deposition techniques may overcome this limitation. Deposition techniques and a higher control of processes surely will help to launch more sophisticated electronic applications that eventually will realize diamond's superior performance over other materials.

Diamond-Like Carbon Films

Angel Velez
Mark A. Prelas
Nuclear Science and Engineering Institute, University of Missouri–Columbia, Columbia, Missouri, U.S.A.

INTRODUCTION

Diamond-like carbon (DLC) films have been known since 1962. The applications of DLC gained serious attention in 1971.[1] A wide range of applications have been found for DLC in the industrial and biological fields with promising growth also in the electronics field. Because DLC is composed of sp^3, sp^2, and possibly sp^1 coordinated atoms, the physical properties vary with sp^3 to sp^2 ratios and deposition conditions. This allows a heterogenous mixture of crystalline and amorphous phases in different film structures as required by specific applications. The sp^3/sp^2 ratio also determines the density of the film and is affected by the presence of hydrogen. Graphite-like films are characterized by a high content of sp^2 bonding while diamond-like films have a high percentage of sp^3 bonding. When the structure content has more than 80% of sp^3 it is classified as tetrahedral amorphous carbon (ta-C) and this type of film is essentially hydrogen free.

APPLICATIONS

Diamond-like carbon has found a number of applications in the areas of optics, semiconductors, electronics, medicine, and nuclear instrumentation. Diamond-like carbon is predominantly made using chemical vapor deposition. As the technology matures new applications will evolve.

Optics

The optical properties of DLC make it suitable for scratch-resistant antireflection coatings. Although it absorbs in the visible region, it has a good transmission in the IR region. It is used in germanium optics and provides protection against harsh environments (e.g., rain, sea) and abrasion. The use of these films sometimes is limited by the allowed thickness because of the mechanical stress and optical absorption limitations. This makes necessary the use of other primary coatings before DLC is deposited.[2] The use of DLC on aluminum mirror surfaces improves the optical performance of the mirror because there is no destructive interference in the coating boundaries, which affects mirror reflectivity. The exhibited high reflectivity, however, limits the use of DLC coatings in photothermal conversion of solar energy where high absorption in the IR region is required. It has been observed that the absorption properties of DLC films within the visible region and near-IR region are strongly affected by the presence of oxygen and silicon impurities.[3]

Semiconductors

The semiconducting properties of DLC are being studied for photovoltaic applications. A boron doped hydrogenated amorphous carbon (a-C : H) on an n-type silicon substrate heterojunction exhibits rectifying behavior when exposed to light. Although a photocurrent in the a-C : H is generated for wavelengths ranging from 300 to 700 nm, the conversion efficiency is still low because of the recombination process at the interface with the Si substrate.[4]

Electronics

Major applications of DLC films in electronics mainly depend on their mechanical and chemical properties. For data storage, both surface roughness and chemical composition are important parameters when hard disks are coated. To increase the data storage it is necessary to reduce the head-disk interfacial spacing, that is, the height between the flying recording head and the disk. Diamond-like carbon coatings of 10 nm have been deposited on hard disk surfaces to achieve high-density recording. Diamond-like carbon films also provide a smoother surface with a roughness value of 2.3 Å and corrosive protection to these devices.[5] Specifically, DLC deposition by ultrathin ion beam is performed to overcoat the magnetic recording medium. Films of 20 Å have been deposited showing good wear and corrosion protection on this medium.[6]

The use of DLC in field emission displays is growing because of its properties as an electron emitter for field emission array applications. By controlling the $sp^3/(sp^3 + sp^2)$ ratio the activation energy can be

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120037648

reduced to increase the release of electrons. The use of DLC can increase emitter current or decrease the necessary voltage. The voltage reduction is achieved through the adjustment of asperity height. Varying the current values during cathodic arc deposition can control these characteristics. It has been found that a maximum ratio of 50% is achieved at 80 A and the maximum asperity roughness at 100 A.[7] The asperity height is the main factor to be controlled because electron emission is highly dependent on it. Another approach in the development of field emission surfaces consists of irradiating DLC films of 70–80% sp^3 content with U or Au ions of approximately 1 GeV or 340 MeV, respectively.[8] With this technique sp^2 cylindrical ion tracks with the conductive properties of graphite-like carbon allow electron transport from the substrate to the surface through the DLC material. Continuous conductance along the track is only achieved by irradiating with heavy ions. Low hydrogen concentration is necessary to prevent the inhibition of sp^3 to sp^2 transformation.

Modifications of surface structures are still under analysis to reduce the onset voltage to operating conditions without damage. Novel structures based on the mechanical characteristics of ta-C combined with SiN are being developed to produce microcantilever structures that enhance the anode field emission.[9]

Medicine

Applications in coating biomedical devices are growing quickly because the DLC material is chemically inert and offers corrosion and wear resistance. Diamond-like carbon or amorphous carbon has the necessary smoothness required by many applications in biomedical devices, being preferable to polycrystalline structures. The development of medical implants requires a biocompatible material that could be exposed to the body fluids, some being highly corrosive, with minimum deterioration while at the same time preventing adverse reactions. Those implants used for joints also need to tolerate sliding motion that causes wear of contacting surfaces. In applications for body implants, wear is a critical parameter because it limits the effective lifetime of the implant. Simulations of the effects of body fluids on the implant have been performed. A lower coefficient of friction is obtained for DLC coatings with a considerably reduced wear rate. This has been observed on titanium surfaces used in orthopedic applications.[10] It has been demonstrated that hydrogen-free coatings like ta-C and a-C perform well during sliding wear tests with coefficients of friction ranging from 0.04 to 0.05. Hydrogenated structures exhibit higher wear rates under water-lubricated conditions and are not suitable for these applications.[11] Diamond-like carbon material should still perform well even if it is delaminated. It has been observed that bone marrow cells do not react to the presence of DLC particulates, and hence, neither inflammatory nor toxic reaction is expected in the body from the use of DLC.[12] The absence of a toxic response, besides the wear and tribological properties, makes DLC coatings attractive for long-term use where biocompatibility is necessary because of the biological system's natural response.

In vivo behavior the tissue–implant interaction and bioreactions related with cell attachment, proliferation, and differentiation are influenced by the surface texture of a film. Surface chemistry also plays an important role in bioreactions. When DLC is alloyed with other materials, the bioproperties of both materials interact to control biological responses like inflammatory reactions, protein adsorption, and cell differentiation. Metal alloy coatings prevent metal ion release, which causes adverse biological reactions like bone resorption, and platelet activation, which triggers thrombosis. This is a critical parameter in intracoronary heart stents. Platelet deposition is highly reduced with DLC coatings. This characteristic makes DLC films hemocompatible. This meets the requirement for implants that are continuously exposed to blood where a high ratio of albumin/fibrinogen is required to lower platelet adhesion to reduce thrombus formation.[13] Diamond-like carbon surfaces also offer other advantages like antibacterial activity, good growth of neurons, and white blood cell interaction.[14]

Diamond-like carbon can be alloyed with toxic materials. This is necessary when no cell adhesion should be allowed specifically when equipments or implants are of temporary use. When this alloy makes contact with the biological environment, the cytotoxic materials, like copper, vanadium, and silver, inhibit cell growth on the material surface because of the toxic action of the alloy. Changing alloy components can control the bioreactions. When DLC is mixed with silicon oxide a reduction of the inflammatory reactions is observed.

Nuclear Instrumentation

In the nuclear field, DLC coatings are used to improve instrumentation performance. In microstrip gas counters the signal generation is due to the avalanche of positive ions migrating away from the anode surface and it is proportional to the energy of the incoming radiation. The cathode and anode strips require a stable substrate with low resistivity, which is necessary to prevent positive ion collections that cause voltage instabilities. To reduce surface charging, DLC films are used for coating ionic conducting glasses to

increase microstrip gas counterstability. This allows an improvement in the rear signal measurement from the anode up to 60% of its value and the construction of two-dimensional detectors with thinner glasses.[15] Diamond-like carbon's surface properties make it suitable for use as a material for storing ultracold neutrons. Suppression factors for neutron transmission of 2.7 and a suppression factor for neutron storage of 4 have been independently observed. The suppression factor for transmission is measured by examining the neutrons being transmitted from a source when surrounded by a quartz wall vs. the neutrons being transmitted from a source when surrounded by a quartz wall coated with deuterated diamond-like films. The suppression factor for storage is measured by examining the neutrons stored from a source when surrounded by a quartz wall vs. the neutrons stored from a source when surrounded by a quartz wall coated with deuterated DLC films. This collection method has been successfully used in neutron–electric dipole moment experiments.[16]

CONCLUSIONS

Diamond-like carbon since its inception in 1962 has found applications in some very important areas. These applications include coatings used in scratch-resistant optics, razor blades, prosthesis in medical applications; electron emission surfaces in electronics; as an insulator material for copper heat sinks; in semiconductors such as solar cells and sensors for visible to infrared radiations; and as structural materials such as deuterated DLC film used for neutron storage in advanced research instrumentation. As technology matures the unique properties of DLC will find new and important applications.

Differential Scanning Calorimetry

John O. Hill
La Trobe University, Melbourne, Australia

INTRODUCTION

It has always been recognized that there is a subtle difference between the titles ''thermal analysis'' and ''calorimetry'' and the associated groups of experimental techniques which is not simply one of ''semantics.'' There have been generations of interest in ''thermal events'' as a means of articulating changes in the thermodynamic behavior of materials. The analysis of thermal events may be approached in two different ways which intrinsically overlap. Either the analysis is designed to measure specific properties of a material, such as heat capacity, enthalpy, entropy, or free energy with high precision and accuracy at predefined temperatures and conditions, or thermal properties may be measured over a temperature range using a controlled temperature program. Thus, calorimetry is the measurement of heat changes which occur during a process whereas thermal analysis measures a property of a material as a function of temperature. It is therefore evident that ''thermal analysis'' and ''calorimetry'' are not synonymous terms. However, even with these simple definitions of both types of techniques, it is difficult to classify a technique such as differential scanning calorimetry (DSC) either as a calorimetric or a thermal analysis technique since in DSC, heat changes are measured as a function of temperature and hence DSC clearly epitomizes the synergy between calorimetry and thermal analysis. This review concentrates on the historical development of DSC and on the more recent development of temperature modulated DSC (tmDSC), together with selected applications and possible future enhancements. DSC is recognized as the primary thermal analysis technique which has revolutionized the characterization of the thermal properties of synthetic polymers and the chemical processing thereof. It is used as a routine analytical technique in materials science.

DIFFERENTIAL SCANNING CALORIMETRY

Historically, DSC is a development of differential thermal analysis (DTA) and both techniques measure the heat flux in a sample as a function of temperature. In DTA, the heat flux is measured as a temperature difference between a sample and a reference material as a function of temperature whereas in DSC, the heat flux in the sample is measured directly as a function of temperature. Thus, DSC is essentially ''quantitative DTA,'' or more precisely, DSC is a combination of DTA and adiabatic calorimetry. DSC is thus a ''differential calorimeter'' that achieves a continuous ''power compensation'' between sample and reference.

The practical distinction between DTA and DSC is simply related to the nature of the signal output from the equipment. For DTA, this is proportional to the temperature difference between the sample and a thermally inert reference material, usually alumina, when both are subjected to the same temperature program. For DSC, this is proportional to the difference in thermal power between the sample and the inert reference. For both DTA and DSC, the usual temperature program is a linear temperature change with respect to time. In classical DSC, the sample and the reference material are maintained at the same temperature throughout the controlled temperature program by a differential power input to the sample and reference material. This differential power input is recorded against the programmed (reference) temperature. Thermal events in the sample thus appear as deviations from the baseline in either an endothermic or exothermic direction, depending upon whether more or less energy has to be supplied to the sample relative to the reference material. The operating temperature range for DSC is typically subambient to 700°C. At subambient temperatures, the DSC sample container unit has to be protected from moisture condensation. In simple terms, the area of a DSC endotherm or exotherm is proportional to the associated enthalpy change of the identified thermal event. Thus, DSC instruments require calibration both in terms of ''temperature'' and ''energy'' and certified reference materials (CRMs) have been proposed for this purpose.[1] In simple terms, temperature calibration of a DSC is effected using metals such as indium, tin, or aluminium, which have well-defined melting points and energy calibration is effected using metals such as indium or tin or compounds such as potassium perchlorate or silver sulfate, which have well-defined fusion or transition enthalpies.[1]

A major application of DSC has been the measurement of heat capacity of a material, particularly at subambient temperatures. In simple terms, in the absence

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007736

of a sample and with both sample and reference crucibles empty, the DSC baseline is a horizontal line. When a sample is introduced, the DSC baseline is displaced in the endothermic direction and the displacement is proportional to the total heat capacity of the sample. The associated proportionality constant is determined by using a standard material such as sapphire,[1] scanned under similar conditions as the sample. DSC may also be used to measure the heat capacities of a material before and after a physical transition such as melting and thus a complete monitoring of the heat capacity of a sample is possible.

Another general application of DSC is for the determination of purity as described by Laye.[2] This application depends on an analysis of the shape of the fusion peak of the material in question. The DSC method mirrors the classical approach which depends on the depression of the freezing point by the presence of an impurity, as defined by Raoult's law. There is an increase in fusion peak width with increasing proportion of impurity and the subsequent analysis depends on using fractional areas of the fusion peak to calculate the extent of melting. It is assumed that the components of the impure mixture form an ideal solution on melting. Clearly, the DSC method is not applicable to samples which decompose at or near the melting temperature or to those which interact chemically with the impurity. Despite these restrictions, the DSC method has been widely used to determine the percentage purity of the active ingredient in pharmaceutical preparations and to determine the purity of metals such as silicon in electronic applications.

DSC has a wide and diverse application range. It is routinely applied to study the thermal behavior of polymers, glasses, ceramics, resins, oils, fats, waxes, clays and minerals generally, coal, lignite, wood, liquid crystals, explosives, pyrotechnics, propellants, pharmaceuticals, biological materials, metals and alloys, natural products, and synthetic catalysts over a wide temperature range. It is also used in quality control and chemical processing procedures, particularly as applied to synthetic polymers. DSC curves have also been used in ''fingerprinting'' and identifying components of mixtures. The identification of polymorphs in the context of pharmaceuticals is particularly relevant since different components may have different physiological activities. The investigation of potential reactivity between components of a drug preparation, as revealed by DSC, represents another significant application of this versatile analytical technique.

DSC is a valuable analytical technique in materials science and in particular, in the development of phase diagrams. This application is illustrated with reference to the binary system, triphenylmethane(A)/transstilbene(B).[3] The melting points of the pure components are obtained from the corresponding DSC curves and the melting behavior of mixtures of the components depends on the ''history'' of mixture preparation and for this general discussion, it is assumed that all mixtures have been prepared in completely molten form initially without any volatilization or decomposition. There is no deviation from the baseline until solid B crystallizes out and this corresponds to the first endotherm. The area of this endotherm depends upon the amount of B present in the mixture. As the temperature of the mixture decreases further, the eutectic temperature is reached and subsequently, solid A crystallizes out as a sharp exotherm. By studying a range of mixture compositions by DSC, the complete phase diagram for the binary system is obtained. This procedure has been particularly useful for study of metal mixtures and alloy systems. The phase diagrams of the ternary Ge-Sb-Bi system[4] and the very complicated Ag-Te-S-Se system with 17 phase regions[5] serve to illustrate the power of DSC in rationalizing the phase diagrams of these systems.

The dehydration of inorganic salt hydrates is usually stepwise but not always predictable. For copper sulfate pentahydrate, three DSC peaks are apparent corresponding to the loss of 2, 2, and 1 waters of hydration. Further, there is an increase in dehydration enthalpy of this salt with increasing numbers of hydration waters removed. This type of study is of importance in the estimation of the purity of the sample since the dehydration enthalpy is directly proportional to the water content of the sample. Similarly, DSC can be used to determine the moisture content of materials generally, since the measured endothermic dehydration DSC peaks are directly proportional to the water content of the material.

The application of DSC to study the thermal behavior of synthetic polymers has been most extensive and intensive and has been comprehensively reviewed by Turi.[6] Most solid polymers are formed by rapid cooling to low temperatures from the melt by a process known as quenching and are thus initially in the glassy state. The transition from a glass to a rubber, termed the ''glass transition'' is accompanied by a change in heat capacity but no change in enthalpy. The transition thus appears on the DSC curve as a discontinuity of the baseline at the glass transition temperature. This is a characteristic property of a polymer and of its processing. As the temperature is subsequently increased, the polymer may crystallize giving rise to an exotherm before melting occurs. At higher temperatures, the polymer may decompose (degrade) or oxidize depending on the nature of the surrounding atmosphere. Thus, a single DSC scan of a polymer is able to define its thermal characteristics and, most importantly, its thermal stability. As an example, the DSC analysis of poly (ethyleneterephthalate) (PET) heated in nitrogen reveals the glass transition, exothermic crystallization, and endothermic melting in a single scan.[7]

Recycling of plastic waste has huge commercial significance but the process is slowed by the problems of component identification, sorting, and collection. DSC can be used to identify the components of a plastic waste.[8] The components are unambiguously identified by their respective exothermic crystallization peaks. Other peaks can be used for this purpose but glass transitions are generally not used in fingerprinting operations due to their poorly defined temperature ranges.

DSC has been used to test the completeness of curing of epoxy resins. The completeness of curing is revealed by a second DSC scan of the sample, which shows no residual exotherm but indicates the glass transition for the cured resin. This application again shows the uniqueness of DSC in revealing a complex chemical processing phenomenon.

One of the more celebrated applications of DSC in materials science which is of very significant commercial significance relates to a DSC analysis of high alumina cement.[9] Some three decades ago, alumina diluted cement led to the weakening and in some cases, the collapse of concrete structures, particularly in third world countries. The weakening process is due to a conversion of the initial product of setting into gibbsite or hydrated alumina. DSC can be applied to determine the extent of such conversion by measuring the relative peak heights of the alumina cement DSC scan. In practice, a calibration is carried out using a cement sample of known composition, but the analysis is rapid and reliably quantitative.

DSC has also been used as an analytical technique in food science. Structural changes in fats and waxes characterize the product such that it is possible, for example, to easily differentiate between butter and margarine on the basis of their different DSC profiles.[10] Although it is not usually possible to unambiguously characterize each of the peaks and shoulders, the overall profile is a fingerprint of a particular fat or fat blend.

Finally, DSC has been applied with some success to the study of kinetics of chemical reactions. This study has as its foundation the identification of reaction rate with DSC signal output and the extent of reaction with fractional DSC peak area. This application has many difficulties and shortcomings which have been reviewed by Laye.[11]

These examples are sufficient to clearly reveal the pre-eminence of DSC as the thermoanalytical technique of choice in materials science.

TEMPERATURE MODULATED DIFFERENTIAL SCANNING CALORIMETRY

In classical DSC, the imposed temperature program is a linear change with respect to time. However, more complex programs can be invoked by overlaying the conventional linear heating with a regular modulation, thereby creating temperature modulated DSC. In the original form of the technique described by Reading et al.[12,13] in 1993, the modulation was sinusoidal. Other forms of modulation have since been introduced such as square wave and saw-tooth. Three developments of calorimetry have thus combined over the past decade to dramatically enhance the capabilities of DSC. These are the high precision of adiabatic calorimetry, the speed of operation, and small sample size associated with DSC and the superimposition of measurement of frequency dependence of thermal events thereby leading to the evolution of tmDSC. ''Modulation'' is perhaps the most significant development with respect to thermal analysis techniques, paralleling in impact the ''Fourier transform'' development of infrared spectroscopy.

The essential comparative features between conventional DSC and tmDSC are shown schematically in Figs. 1A and B. In conventional DSC, the multiple temperature sensors average the calorimeter temperatures. In tmDSC, the linear temperature program of conventional DSC is modulated by superimposing a periodic wave form of small amplitude on the linear temperature program. The most commonly applied wave form is a sine wave, as shown by the equations for sample temperature in Fig. 1B. Essentially, tmDSC provides periodic heating and cooling within each cycle but the overall effect is the same as in conventional DSC namely, a linear change in average temperature with time. The resultant heat flow signal is a composite of the response to a thermal event occurring in the sample and the response of the underlying heating program. Five component signals thus derive from a tmDSC experiment, which are described as: i) the average or underlying signal, equivalent to DSC; ii) the in-phase cyclic component; iii) the out-of-phase component; iv) the reversing component to the underlying heat flow; and v) the nonreversing heat flow. Two of these components are inter-related: the reversing component (iv) is derived from multiplying the heat capacity of the sample by the heating rate, and subtraction of (iv) from the underlying signal (i) gives the nonreversing heat flow (v).

Hence, in the simplest terms, tmDSC is a description of the heat flow into the sample resulting from the sinusoidal modulation of the temperature program. Two properties of the sample can be investigated by tmDSC, the heat capacity which is directly related to the ''reversing component'' and a kinetically hindered thermal event which is related to the ''nonreversing'' component. Conventional DSC provides only a measure of the total heat flux into a sample as a function of temperature whereas tmDSC allows the heat capacity and kinetic components to be separated. However,

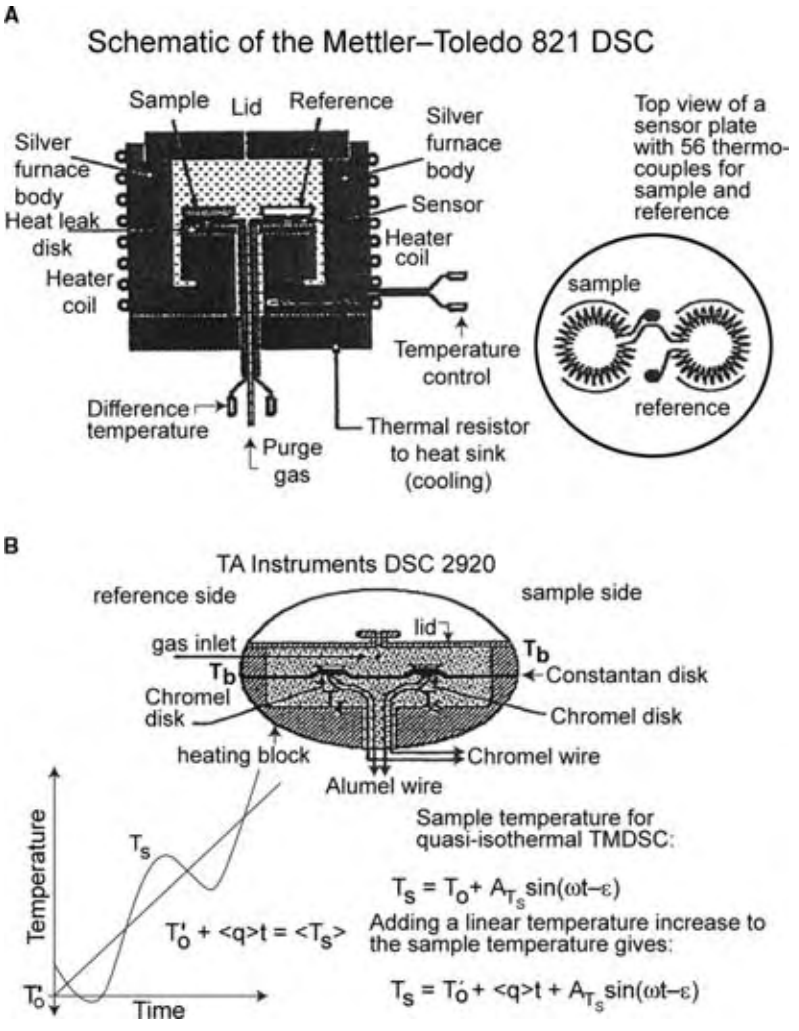

Fig. 1 Schematic diagram of: (A) classical heat flux DSC; (B) tmDSC.

the conditions of a tmDSC experiment are more critical than in conventional DSC since the selection of the period and amplitude of the modulation need to be selected in addition to the underlying heating rate. Sample size and period of modulation influence the ability of the sample to follow the temperature modulation and hence the apparent value of the heat capacity. A more detailed theoretical treatment of the relationship between heat capacity and the reversing component of tmDSC shows that a ''reversing time correction factor'' has to be included which depends on the nature of the sample and its mass. By using multiple frequencies for modulation, the required correction factor can be determined in a single tmDSC run, which further indicates the supremacy of tmDSC for heat capacity measurements. A further variation in tmDSC is that the underlying heating rate can be set to zero, in which case, measurements are carried out under quasi-isothermal conditions. As for DSC, calibration of tmDSC is essential and this has presented a challenge. At present, the nematic to smetic-A transition in a cyanobiphenyl liquid crystal (80CB) has been suggested[12] for calibration of tmDSC.

Alternative modulation functions and data analysis procedures have been applied in tmDSC. Different instrument manufacturers have applied square wave or saw-tooth modulation, coupled with Fourier transform analysis methodologies. Alternative modulation functions provide some additional advantages. For example, a square wave function ensures that a steady state is achieved over an isothermal plateau since the signal during such a period is the nonreversing contribution. The amplitude provides a measure of the reversing signal. However, there are some disadvantages of these alternative modulation functions in that accuracy and resolution may be compromised since not all the necessary data are made available. The Wunderlich ATHAS Laboratory has investigated other types of modulation in tmDSC[14–16] and has shown that such modulations are likely to be incorporated into future generations of tmDSC systems for enhanced precision of measurement of heat capacity and glass transitions.

Wunderlich[17] has also comprehensively reviewed the development of temperature modulated calorimetry into the 21st century in conjuction with its predicted scope for further application in the physical, chemical, and materials sciences.

There are many advantages of tmDSC over conventional DSC. Use of the former technique with appropriate frequencies and amplitudes allows separation of reversing processes, such as glass transitions, from nonreversing processes, such as relaxation endotherms or cure processes. With tmDSC, baseline curvature of the cyclic signal is usually insignificant, thereby making it easier to distinguish between baseline effects and real thermal transitions. The signal-to-noise ratio of the cyclic measurement of heat capacity is generally greater, since all drift or noise at frequencies other than that of modulation is ignored by the Fourier transform analysis. In general, in tmDSC, resolution of thermal events is improved because very low underlying heating rates are used.

Applications of tmDSC in general rely on the enhanced precision of the technique compared to conventional DSC as attained by the maintenance of a steady state and a negligible temperature gradient within the sample throughout the run and hence, it is possible to measure heat capacity quasi-isothermally. In order to achieve the highest precision in tmDSC, the theory of the technique indicates that a high heating rate should be applied together with a large sample mass.[12] These conditions lead to rapid analysis of large samples and provide a further advantageous feature of DSC over other thermal analysis techniques.

It is generally acknowledged that DSC is the pre-eminent thermal analysis technique and that it has progressively become the established technique for the study of the thermal behavior of polymeric materials. Conventional DSC correlates thermal power with heat capacity and the integral thereof to energy and entropy. Thus, DSC has been applied to determine heat capacities of a wide range of materials. Conventional DSC is able to determine heat capacity to an uncertainty of 1–2%: tmDSC is able to measure this parameter to an uncertainty of less than 1% with reproducible reliability. It is the ''temperature modulation'' feature of tmDSC which has confirmed this technique as the most versatile and most reliable of the thermal analysis techniques. Its versatility is further qualified by its ability to characterize the thermal behavior of materials without the need to have a detailed knowledge of the fundamental theoretical principles which underscore the basis of the technique.

Apart from the determination of heat capacities of a wide variety of materials, the other most common use of tmDSC is to determine the thermal behavior of synthetic polymers. A tmDSC analysis of poly(ethyleneterephthalate) has been described by Haines et al.[18]. The five components of the tmDSC signal are revealed and the difference in the heat capacity profiles corresponding to ''reversing Cp,'' ''kinetic Cp,'' and ''nonreversing Cp'' are particularly striking and collectively reveal the ability of tmDSC to provide complete heat capacity characterization of a polymer sample.

tmDSC has major advantages over conventional DSC in terms of differentiating overlapping thermal events. A tmDSC analysis of a poly(ethyleneterephthalate)–acrylonitrile/butadiene/styrene (PET–ABS) polymer blend has been reported by Laye.[19] The total heat flow profile for the blend and its separation into the reversing and nonreversing components is apparent. The glass transition temperature for PET is around 65°C and that for ABS is 105°C, which would mask the glass transition of ABS in conventional DSC. Since the glass transition is a major identification characteristic of a polymer, it is important that this is unambiguously defined in the thermal analysis of polymer blends and hence in the chemical processing of polymers.

tmDSC also offers a quantitative investigation of polymer glass transitions as a function of ''thermal history'' of the sample, since glass transition kinetics vary with the enthalpy of the glassy state. Further, the ability of tmDSC to separate reversing and nonreversing processes during phase transitions offers quantitative investigation of cold crystallization and melting with superheating transitions. tmDSC therefore offers unparalleled opportunities for the quantitative analysis of the thermal properties and thermal behavior of materials, particularly synthetic polymeric materials.

Reactions involving partial diffusion can be studied by tmDSC such as epoxy resin curing.[13] The glass transition temperature is measured as a function of the conversion fraction. tmDSC is able to separate the glass transition and the melting transition in interpenetrating polymer networks prepared by in situ copolymerization.[13] Additionally, an estimate of the degree of crosslinking in the copolymer is possible from the composite thermal data, together with an estimate of the glass transition temperature of the copolymer phase.

Numerous tmDSC applications were presented at the Eighth European Symposium on Thermal Analysis & Calorimetry (ESTAC 8) in Barcelona in 2002[20] and a selection of these is briefly summarized here to illustrate the present scope of applications of this technique. tmDSC has been applied to study the morphology and recrystallization kinetics of nickel sulfide. Such information is of significance in understanding the failure of toughened glass panels when subjected to external stresses. tmDSC is shown to be ideal for rationalizing the melting behavior of polytetrahydrafurans and their blends. The PTHF oligomer shows two endothermic peaks. The lower peak shows temperature dependence on molar mass whereas the

higher peak is independent of molecular mass of the polymer. The order–disorder transition temperature of triblock copolymer gels, swollen with parafinic oils has been studied by tmDSC. The order–disorder transition temperature of these gels is detected as an abrupt change in heat capacity of the sample and is dependent on the polymer content of the gel and on the molar mass of the oil. Thus, tmDSC assists an understanding of the mechanism of order–disorder transitions in triblock copolymers swollen with solvents. tmDSC has been applied to study ''intelligent'' polymer systems which show major changes in properties with small physical or chemical stimuli. The kinetics of ''demixing'' (shrinking) and ''remixing'' (swelling) are important considerations in possible applications of these ultra-new hi-tech systems. In this context, it is shown that tmDSC is ideal for the characterization of the kinetics of phase separation in partially miscible polymer blends and polymer solutions. ''Mixing/demixing'' phenomena are manifested as large excess contributions to the apparent heat capacity signal of the system on the time scale of temperature modulation which enable the real-time monitoring of demixing, remixing, and vitrification processes occurring. tmDSC thus allows investigation of nano-scale miscibility phenomena in water-soluble polymers and related hydrogels. tmDSC has been shown to be valuable for studying the deconvolution of ''nonreversing'' and ''reversing'' heat flow effects in reacting polymer systems. tmDSC has been further extended to study temperature-induced phase separation in poly(ethylene) /poly(ethersulfone) (PEO–PES) blends. tmDSC has also been applied to model the effect of additives on the cure kinetics of epoxy resins and for in situ detection of reaction-induced phase separation. The cure temperature is crucial in determining the final phase-separated morphology and impact properties of such resins. tmDSC, in conjunction with TGA, has been applied to characterize elastomers. From the component pyrolysis temperatures, tmDSC can be used to quantitatively determine the individual polymer compositions. tmDSC has also been applied to study the vitrification, devitrification, and dielectric relaxations associated with the nonisothermal curing of an epoxy-amine system. Such systems are characterized by continuous heating transformation cure diagrams, which are readily obtained by tmDSC. tmDSC has also been applied to study high temperature polymeric materials, such as bis-maleimide resins which find extensive use as lightweight fiber-reinforced structural composites and electrical insulators. The cold crystallization and melting of PET and poly(ethylene-2,6-naphthalene dicarboxylate) (PEN) have been studied by tmDSC with a net zero heating rate.[21]

Finally, maximum precision in tmDSC is obtained with very slow underlying heating rates which allow an adequate number of temperature modulations over a region of changing heat capacity such as a transition region. This condition has recently been achieved by the new DSC cell and ''Tzero'' technology, developed by TA Instruments (U.S.A.).[20] The thermal capacitance and resistance of the DSC measuring system are effectively eliminated and this feature, coupled with the overall temperature control capabilities, has made much shorter modulation periods practical. Hence, ''fast tmDSC'' is now a reality.

SIMULTANEOUS THERMOGRAVIMETRIC ANALYSIS–DIFFERENTIAL SCANNING CALORIMETRY

Half a century ago, the Pauliks[22] launched the ''derivatograph'' which was a combination of a thermogravimetric analysis system and a differential thermal analysis system and constituted the first simultaneous thermal analysis system. STA systems involve the mounting of a DTA head onto the thermobalance suspension or rise rod, which is connected directly to a microbalance. Modern STA instruments are capable of a resolution of the order of 1 microgram with sample masses ranging from 5 to 100 mg. Essentially, STA involves measurements of two thermal properties on the same sample subjected to the same temperature program. There are advantages of STA over individual TGA and DTA systems. Fundamentally, it is difficult to correlate results obtained on different portions of a sample with different thermal analysis techniques due to ''sample'' and ''instrument'' factors whereas, in general, results obtained on the same sample by two thermal analysis techniques simultaneously are reproducible. In general, STA may be viewed as yielding data which are more significant than the sum of the two sets of data obtained individually and thus, a synergistic effect operates in STA. This effect is readily apparent. TGA can only detect thermal events associated with a mass change, so a phase change such as melting is not detected by this technique. However, melting is readily detected by DTA as a sharp endotherm. A combination of TGA and DTA shows no sample mass change associated with the melting DTA peak. Further, melting with decomposition is readily identified by STA since the endothermic DTA peak shows shoulders which correlate with a sample mass decrease. Other obvious advantages of STA are ''time saving''—only one experiment is necessary instead of two—and ''sample saving.'' The latter is particularly advantageous for samples available in short supply or for expensive samples such as the active ingredient of drugs and biological materials. However, there is a perceived disadvantage of STA in that the sensitivity of individual thermal analysis

techniques is decreased on combination due to essential compromises in instrumental design. It is this feature which has limited the development of TGA–DSC systems. It is not possible to incorporate power compensated sensors into a STA system but heat flux sensors have replaced DTA sensors in STA systems and the latter are available commercially. The essential difference between ''heat flux DSC'' and DTA lies in the conversion of the temperature difference between sample and reference into differential power. The algorithm for this conversion is contained in the instrument software and the design of the DSC cell is critical if this algorithm is to be transferable from one experiment to another and independent of the sample. This is the most critical limitation in the design of a combined TGA–DSC cell. The DSC sensor must not change position with different sample masses so as to avoid changes in heat transfer characteristics and subsequent instrumental base-line shifts with concomitant loss of overall sensitivity. However, if such instrumental challenges can be overcome, STA in the form of TGA–DSC offers all the advantages of TGA–DTA with the added advantage of quantification of the identified thermal events both in terms of mass and energy changes.

Applications of TGA–DSC are not as numerous as for TGA–DTA and largely involve studies of solid-state phase changes. Simultaneous TGA–DSC has been applied by Warrington[23] to study the thermal characteristics of ammonium nitrate. The combined curves reveal that partial sublimation, then vaporization of the sample occurs before and after the melting point. More accurate estimates of the transition and fusion enthalpies are thus available based on the associated sample mass, as derived from the TGA curve. Further, it is known that traces of moisture in the sample can affect the temperature ranges of the transitions both on heating and cooling. Using TGA–DSC, the moisture content is known precisely at each stage of the thermal analysis.

TGA has been used with some success to determine the extent of sublimation of volatile solid materials.[23] TGA–DSC can be applied to determine the corresponding sublimation enthalpies, which are usually difficult to determine by conventional methods. The determination of sublimation enthalpies is notoriously difficult since with most volatile solids, the effusion process is rarely smooth and continuous and thus the use of STA for this purpose is a most welcome adjunct to many less reliable analytical techniques which rely on an ''ideal'' sublimation process. For sublimation studies, the sample is sealed in a container with a small pin-hole in the lid. The TGA curve shows a progressive mass loss until the sample is exhausted. The corresponding DSC curve shows a deviation from the base-line equivalent to the sublimation enthalpy which can be correlated with the rate of mass loss. Calibration of the system with a substance of known sublimation enthalpy, such as benzoic acid or ferrocene, allows the derivation of absolute sublimation enthalpies. With certain restrictions, this type of STA system can be applied to determine vaporization enthalpies of liquids. Overall, TGA–DSC is a valuable adjunct to the family of thermal analysis techniques particularly with respect to the specialist applications described herein.

CONCLUSIONS

Differential scanning calorimetry is the most sophisticated member of the family of thermal analysis techniques and bridges the nexus between ''thermal analysis'' and ''calorimetry.'' DSC essentially combines the principles of adiabatic calorimetry with those of differential thermal analysis and is essentially a ''quantitative DTA.'' DSC is of paramount importance in the characterization of the thermal behavior of synthetic polymers and polymer blends. It is also of major significance in the study of resin curing phenomena. DSC is recognized as the primary technique for the determination of heat capacity, particularly at subambient temperatures. DSC has also been applied to determine the percentage purity of a wide range of materials and in this context it is a primary analytical technique in pharmaceutical and medicinal chemistry. DSC is also of major significance in metallurgy in terms of the derivation of alloy phase diagrams and for the purity determination of metals and metalloids associated with the electronics industry. The recently derived technique known as temperature modulated DSC further enhances the precision and accuracy of DSC as a quantitative thermoanalytical technique and further refines the application range of DSC. The particular advantage of tmDSC is that samples are essentially maintained in an environment of thermal equilibrium during the modulated heating program and thereby, the thermodynamic data obtained are reliable, reproducible and relate to defined processes. DSC has been combined with thermogravimetric analysis TGA to form simultaneous thermal analysis TGA–DSC. Although the instrumental challenges are significant, this type of STA system is invaluable for the determination of the thermodynamic parameters associated with solid-state phase changes and the processes of sublimation and vaporization. Since the sublimation process of most volatile solids is complex and rarely complete, the TGA profile for a volatile solid indicates the extent of sublimation and the corresponding DSC profile indicates the sublimation enthalpy over the same temperature range. Overall, DSC, in all of its configurations is the most versatile and most significant thermal analysis technique and its application range in materials science is limitless particularly with respect to materials of technological importance.

Dimethyl Ether

Abhay Sardesai
Department of Chemical Engineering, University of Missouri–Columbia, Columbia, Missouri, U.S.A.

INTRODUCTION

The driving force for developing alternative fuels is no longer solely to reduce oil dependence on select oil exporting countries. Noxious exhaust emissions generated by combustion of fossil fuels as well as increasing levels of carbon dioxide, a major contributor toward global warming, have necessitated the need to develop alternative fuels that address clean-burning as an important criterion. Dimethyl ether (DME) is identified as a multisource, multipurpose fuel that can effectively allay both of these concerns by establishing stable indigenous fuel supply and alleviating environmental concerns. Dimethyl ether can be readily produced from natural gas and coal, renewable resources, such as biomass and wood, as well as waste matter. It can be used as a clean-burning fuel in diesel engines, a household fuel [liquefied petroleum gas (LPG) alternative] for heating and cooking, a fuel for gas turbines in power generation, a fuel for fuel cells, a feedstock for producing chemicals and oxygenates, and a propellant in the aerosols market. Applications of DME as a fuel in various industries have been successfully tested by a number of leading companies. Feasibility studies on producing DME from syngas have been carried out by NKK Corporation at their 5 ton/day facility and by Haldor Topsoe at their 50 kg/day facility. In addition, commercial plants have been planned and/or are under way, such as India DME project of 5000 MTPD, DME International Corporation, Japan, of 2500–4500 MTPD, and Japan DME Inc. of 5000 MTPD. Although studies indicate that DME will become economical when oil prices are at or above a threshold price per barrel, it is clear that recent strides in DME synthesis technology show that it holds tremendous promise with a realistic aspiration to develop into an alternative transportation and domestic fuel. It is apparent that DME production costs will get even lower when its production capacities increase as more and more countries start embracing the idea of utilizing this fuel as a viable alternative.

BACKGROUND

Dimethyl ether is gaining worldwide recognition as a multisource, multipurpose clean fuel and chemical feedstock for the 21st century. It is a technically mature, environmentally friendly, and market acceptable alternative fuel. As shown in Fig. 1, DME can be produced from a variety of sources, and its end use includes a number of important applications. Dimethyl ether can be manufactured in large quantities from coal, natural gas, biomass, and municipal solid waste. Current technologies for producing DME on a large scale include those of NKK Corporation, Haldor Topsoe, Air Products, and Toyo Engineering Corporation (TEC).

The simplest ether compound, DME has been shown to be both nontoxic and environmentally benign. Dimethyl ether has a variety of uses in the fuel and the chemical industries. Currently, the major use of DME is as a propellant in the aerosols industry. Its cetane number (a quantitative indicator of the ignition quality of diesel fuel) is high, ranging from 55 to 60, so that it can be used in diesel engines. Its flame is a visible blue flame similar to that of natural gas, and it can be used just as it is in an LPG cooking stove, and it does not produce any aldehydes. The toxicity of DME is low, about the same as that of LPG, and even lower than that of methanol.[1] Because of DME's restrictive use, current world capacity is only 150,000 metric tons/yr.[2] Future mega-plant technology providers include NKK, Haldor Topsoe, Lurgi, Toyo Engineering, Mitsubishi Gas Chemicals, Kvaerner, Synetix, etc.

There have been a number of joint efforts between companies at a multinational level to gather and disseminate know-how about DME properties, DME synthesis processes, and DME applications. These associations have furthered DME's cause by jointly conducting testing studies on DME applications as an automotive fuel, an LPG substitute, and a fuel for power generation. The International DME Association (IDA) plays a significant role in enhancing knowledge about DME to the general public and is a central source of comprehensive DME related information (www.aboutdme.org). Institutional members of this association include BP, Carbinol Technologies, AVL Powertrain Engineering, Inc., Air Products, Renault, Snamprogetti, Lurgi, Akzo Nobel, Shell Global Solutions, Haldor Topsoe, Volvo, Atrax Energi AB, Mitsui, Japan DME Forum (JDF), etc. It is an excellent source of comprehensive information about DME synthesis,

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007739

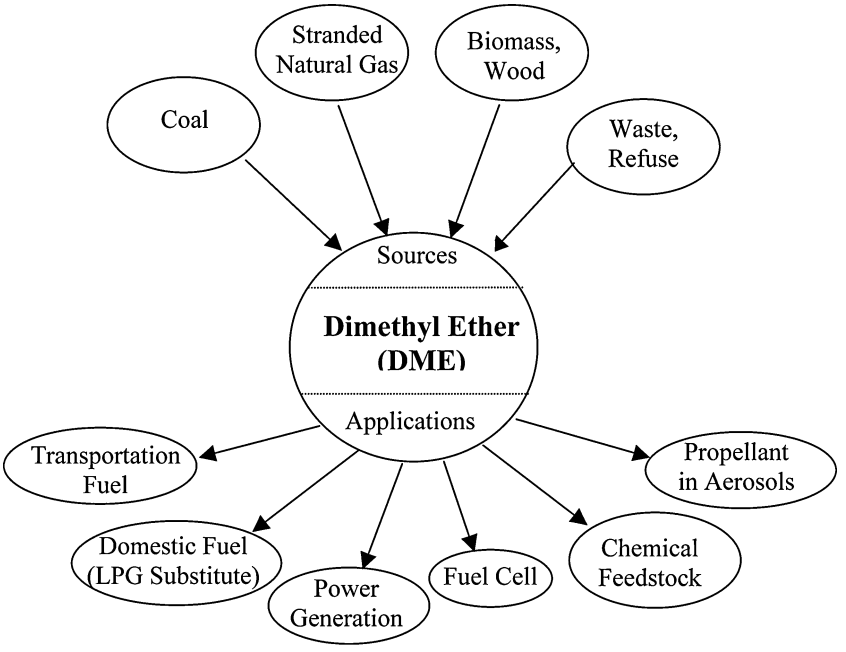

Fig. 1 Dimethyl ether—a multisource, multipurpose chemical.

applications of DME as a fuel in various sectors, as well as the economic, environmental, and commercial aspects of DME utilization. DME International Corporation was established in Tokyo and Japan by a consortium of eight companies to commercialize and market DME as a new source of alternative energy. NKK Corporation, Toyota Tsusho Corporation, and Hitachi, Ltd. are the leading participants. Other participants include a trading company, Marubeni Corporation; two energy-related firms, Idemitsu Kosan Co., Ltd. and INPEX Corporation; an industrial gas supplier, Nippon Sanso Corporation; LNG Japan Corporation; and one non-Japanese company, TotalFinaElf, which is the world's fourth largest petroleum company. The objective of this corporation is to produce DME by a low-cost direct synthesis route by taking advantage of stranded reserves of low-grade coal and smaller gas fields present in Asia. Japan DME Forum was formed by an alliance of 37 Japanese companies, two universities, and several trade organizations tasked with the development of large-scale DME technology. It is also a member of the IDA.

PROPERTIES OF DME

Dimethyl ether, the simplest form of ether, is a colorless gas at room temperature and pressure. It is noncarcinogenic, virtually nontoxic, and also noncorrosive in nature. Dimethyl ether is a liquid at the moderate pressure of approximately 496 kPa. Its handling characteristics are very similar to LPG. It is stored in conventional atmospheric pressure tanks as a refrigerated liquid (−25°C) or in pressurized tanks (5 bar) at 20°C. Dimethyl ether can be ocean transported in LPG tankers. While its net calorific value of 28.88 kJ/kg is lower than that of propane, butane, and methane, it is higher than that of methanol. In gaseous state, its net calorific value is 59,413 kJ/Nm^3, which is higher than that of methane. With regard to the combustion properties, its explosion limit is wider than that of propane and butane, but almost identical to that of methane and narrower than that of methanol. Table 1 compares the properties of DME with those of methane and propane.

USES/APPLICATIONS

High-purity DME is currently used as an aerosol propellant owing to its environmentally benign characteristics. In addition, it can be widely used as an

Table 1 Comparison of DME properties with methane and propane

Property	DME	Methane	Propane
Normal boiling point (°C)	−24.9	−161.5	−42.1
Vapor pressure at 25°C (atm)	6.1	246	9.3
Liquid density (g/cm^3)	0.668	–	0.501
Net heating value (kcal/kg)	6,900	12,000	11,100
Flammability limits in air (vol%)	3.4–17	5–15	2.1–9.4

ultraclean fuel for compression ignition and diesel engines (buses, taxis, trucks, and off-road vehicles such as construction equipment), a household fuel for heating and cooking, a power generation fuel in gas turbines, a hydrogen source in fuel cell cars, and a chemical feedstock for fuel additives and chemicals.

Dimethyl Ether as a Transportation Fuel

The need to develop alternative fuels is motivated by two important issues. Self-reliance in meeting fuel demands is the first factor, as fossil fuel supply is controlled by a small number of oil exporting countries. Second, the deleterious effect of fossil fuel combustion on the environment has prompted urgent use of clean-burning alternative fuels. Harmful exhaust emissions of internal combustion engines, such as nitrogen oxides (NO_x), carbon monoxide, volatile organic compounds, and carbon particulates, as well as high levels of carbon dioxide, a greenhouse gas contributing toward global warming, are causing irreparable harm to the environment. Use of DME, a cleaner burning oxygenate, has a very positive impact on these problems. Properties of DME are compared with those of diesel in Table 2.

Dimethyl ether has attractive advantages as an ultraclean transportation fuel alternative, most notably as follows:

- Dimethyl ether molecules have no carbon-to-carbon bonds, which diminish the tendency to form solid carbon particulates during combustion.
- Dimethyl ether has a low autoignition temperature.
- Dimethyl ether has a high cetane number of 55–60, compared to about 45 for diesel. Molecular bonds of DME break up to form radicals at reasonable activation energy, which leads to high cetane numbers.
- The normal boiling point of DME is −25°C. This provides fast fuel/air mixture formation, reduces ignition delay, and imparts excellent cold start properties.

Table 2 Comparison of DME properties with diesel

Property	DME	Diesel
Normal boiling point (°C)	−25.1	180–370
Liquid density (g/cm^3)	0.67	0.84
Ignition temperature (°C)	235	250
Explosion limit (%)	3.4–17	0.6–0.65
Cetane number	55–60	40–55
Net heating value (kcal/kg)	6,900	10,000

- Oxygen content of DME is 35 wt%, which suppresses the formation of soot and facilitates smokeless combustion.
- Dimethyl ether combustion produces low engine noise or quiet combustion and ultralow exhaust emissions, especially those of NO_x compounds.
- Dimethyl ether qualifies as a renewable fuel, as it can be produced from biomass and wood.

Dimethyl ether economics are comparable to those of diesel fuel, especially at low NO_x regulations, in terms of thermal efficiency. This is possible without major engine modifications, and as such end-user economics could be quite favorable for DME as compared to the costs of converting diesel engines to run on spark-ignited alternative fuels.[3] NKK Corporation, Japan, has been working on a novel process for mass-production and application technology for DME. The company aims to encourage development of DME-fueled vehicles, and is also researching applied technology for DME-fired gas turbine and diesel engine generator systems as well as DME fuel cells. They have tested DME on diesel engines with only minor modifications to the fuel injection system, with regard to engine performance and exhaust gas composition. No black soot or smoke was generated, ignition was quiet, generation of NO_x was reduced by 20–30% as compared to that of diesel fuel at the same cylinder pressure, and combustion time was shorter, translating into higher thermal efficiency.

The Combustion Laboratory at Pennsylvania State University has successfully developed a project involving conversion of a faculty–staff campus shuttle bus to operate on DME. The conversion of the Penn State shuttle bus was a collaborative effort between the Pennsylvania Department of Environmental Protection, Air Products, the Federal Energy Technology Center, Navistar International, Champion Motor Coach, Penn State's Combustion Lab, Fleet Services, and Pennsylvania Transportation Institute. The Combustion Laboratory will eventually convert the shuttle bus engine to operate on blends of DME, diesel fuel, and a lubricity agent.

Dimethyl Ether as a Household Fuel

Dimethyl ether has the capability to substitute LPG as a household fuel for heating and cooking purposes, especially in Asian countries such as Japan, China, and India where the demand for LPG is growing. Utilization of DME as a household fuel can also reduce the burden on developing countries that use solid fuels like coal and firewood, which in turn have harmful effects on the environment. Dimethyl ether can be produced indigenously in developing countries by taking

advantage of stranded natural gas fields in their vicinity. Dimethyl ether is a clean fuel and the total investment cost would be small because existing LPG infrastructures could be used with minor modifications.[4]

Dimethyl ether flame is a visible blue flame similar to that of natural gas, and it can be used in an LPG cooking stove without producing any aldehydes. Its lower explosion limit is higher than that of propane, indicating higher safety than propane in case of leakage. Combustion tests on DME have been conducted with mass-produced household cooking stoves in Japan, and have passed the Japan Industrial Standard combustion test.[4] This study showed that stoves designed to burn city gas (85% methane, 15% propane) could burn DME well with only an adjustment of the variable air dampers.

Dimethyl Ether for Power Generation

Dimethyl ether is a promising new gas turbine fuel. Roughly speaking, 1 bcf/day of gas, converted into about 20,000 tpd of DME, can generate about 10,000 MW of power. Utilization of DME for power generation offers tremendous environmental benefits, in terms of CO_x, SO_x and NO_x emissions.[5] It burns in conventional gas turbines without modifications to the turbine or the combustors. Emissions produced by combustion of conventional fuels in gas turbines include nitrogen oxides, carbon monoxide, unburned hydrocarbons, and sulfur oxides. Dimethyl ether produces no sulfur oxide emission, as the fuel is sulfur free. It generates the least amount of NO_x, CO, and unburned hydrocarbons as compared with natural gas and distillate, and lower CO_2 emissions than the distillates.

BP has introduced a turbine-grade DME fuel that contains 88.0–89.8 wt% DME, 2.9–3.5% water, 7.0–8.0 wt% methanol, and 0.3–0.5 wt% of other oxygenates (with no metals or nitrogen, and with only a trace of sulfur). BP and GE power systems are currently implementing a project in India to use DME as a fuel for power generation.[6] Test results of the BP-introduced fuel at General Electric show that its emission properties and other key combustor operating parameters, including dynamic pressures and metal temperatures, are comparable to those of natural gas. The power generation efficiency (D) is expressed in terms of a heat rate number that corresponds to the amount of thermal energy needed to generate one unit of electrical energy. A lower heat rate number reflects higher power generation efficiency. The estimated performance of a nominal 700 MW combined cycle power plant based on the GE 9E machine indicates that the heat rate using refrigerated DME would be about 1.6% lower than that using natural gas, and about 6.3% lower than that using liquid naphtha. GE is prepared to pursue commercial offers, including standard commercial terms and guarantees, of DME-fired B/E class (diffusion and DLN burners) and F class (diffusion burners) heavy-duty gas turbines.

NKK Corporation has developed a process for DME production, which will greatly enhance the use of DME in power plants in Asia, especially in Japan, which typically use liquefied natural gas (LNG), LPG, fuel oil, and coal. Fuel oil and coal are subject to environmental concerns, most notably the emission of carbon dioxide and treatment or disposal of ash. A possible solution to circumvent this problem would be to generate DME at the mine, which can be shipped and used in a more energy-efficient and environmentally conscious manner. Liquefied natural gas and LPG are cleaner burning fuels, albeit at a much higher investment cost. Japan imports LNG, as fuel for electric power generation. Again, it would be economical to import DME produced from natural gas at medium- and small-scale gas fields considered too small for LNG development for thermal power generation. The supply source for LPG is limited mainly to the Middle East for countries in Southeast Asia and the Far East. Dimethyl ether can substitute LPG in power generation applications, just like in household applications.

Dimethyl Ether for Fuel Cells

Fuel cells can be powered by DME. Daimler Chrysler A. G. has studied the feasibility of using DME as a fuel in a polymer electrolyte membrane (PEM) fuel cell, in collaboration with Ballard Power Systems and University of Technology RWTH Aachen, Germany. Direct oxidation fuel cells, including the ones using methanol as fuel, are hindered by efficiency losses. The effect of methanol fuel crossover oxidation reaction at the cathode is the most significant efficiency loss, the others being use of parasitic fluid pumps, and mild toxicity of methanol vapor. An advantageous finding of the study is that DME is typically not oxidized at the cathode of the fuel cell. This minimizes the unwanted effects of fuel crossover, leading to improved fuel cell efficiencies when compared to direct methanol fuel cells, especially at low to medium current densities.

Researchers at the Electrochemical Engine Center at the Pennsylvania State University have identified additional advantages of using DME as a fuel in PEM fuel cells. It must be noted that DME molecules do not have a carbon–carbon double bond, enabling nearly complete oxidation in low-temperature PEM fuel cells. Also, DME can be stored in high-density liquid phase at modest pressures of around 5 atm, and delivered as a gas-phase fuel in a pumpless operation. Therefore, use of DME can potentially combine

the advantages of easy fuel delivery of pressurized hydrogen and the high energy density storage of liquid fuel.[7]

Hydrolyzing DME with steam can produce hydrogen, carbon oxides being the by-products. This method utilizes an essentially alkali-metal free catalytic composition of copper or nickel in elemental form, which catalyzes the hydrolysis reaction. A water–gas shift reaction converts carbon monoxide, which is usually present in the hydrolysis product, to relatively inert carbon dioxide. The hydrolysis and shift reactions take place in a single reaction zone, or alternatively, in separate reaction zones where reaction conditions can be individually optimized. When separate zones are provided, the heat is essentially transferred from the water–gas shift reaction zone to the hydrolysis reaction zone. The hydroshifted product stream can be utilized as fuel to power a turbine, and an integrated heat transfer scheme can be used to recover heat from the turbine exhaust stream. The reactions are carried out at temperatures between 150 °C and 800 °C, with better results obtained when operating in the range of 350–400 °C. Dimethyl ether conversion of 88.5% and hydrogen to carbon oxide ratio of 2.44 in the product stream were obtained by operating at 350°C and 2°/hr.[8]

Catalytic reaction of steam reforming of DME to hydrogen-rich gas was studied in a fixed-bed continuous-flow reactor at a temperature of 200–360°C under atmospheric pressure over a mechanical mixture of catalysts for DME hydration and for methanol steam reforming. Two catalysts, namely, 12-tungstosilicoheteropolyacid deposited on γ-Al_2O_3 and copper deposited on SiO_2, were used in the study to perform the reactions of DME hydration to methanol and methanol steam reforming, respectively. Mechanical mixtures of these two catalysts were used to perform the steam reforming of DME to produce hydrogen-rich syngas. Dimethyl ether conversion increased with increasing temperature, and so did the concentrations of H_2, CO, and CO_2. Dimethyl ether conversion of 100% and hydrogen outlet concentration of ~71°vol% were obtained at 290°C and GHSV of ~1200/hr.[9]

Dimethyl Ether as a Propellant

Dimethyl ether has been increasingly used as a propellant in aerosol formulations to replace chlorofluorocarbons, which are found to destroy the ozone layer of the atmosphere. Dimethyl ether is nontoxic and easily degrades in the troposphere. Although about 90% of the major current U.S. aerosol industry uses hydrocarbon-based propellants (mostly isobutane and propane), DME could become a more widely used propellant in the coming years. Several aerosol-based household products include colognes, hair sprays and dyes, personal care mousses, antiperspirants, and room air fresheners.

Current suppliers for the DME propellant market include DuPont, Akzo Nobel, and Mitsubishi Gas Chemicals. Demeon D, a DME-based product from Akzo Nobel, is used as a propellant in cosmetic formulations, foam blowing, and paint or other aerosol sprays.

Dymel® A, a product based on DME manufactured by DuPont, is a medium- to high-pressure propellant for general aerosol use, including personal products. It has extremely low toxicity, its lower explosive limit in air is higher than that of propane and isobutane, and it is a chemically stable compound. In aqueous solutions, the propellant is hydrolytically stable over a wide pH range. Dymel A is unique among aerosol propellants in that it has high solubility in both polar and nonpolar solvents. It is completely miscible with most organic solvents, and is by itself a very good solvent for many types of polymers, e.g., hair spray and paint resins. Dymel A has 35 wt% solubility in water, which facilitates formulation of single-phase products with large amounts of water, and is the only liquefied gas aerosol propellant to do so.

Dimethyl Ether as a Chemical Building Block

Dimethyl ether is an essential intermediate in the synthesis of hydrocarbons from coal or natural gas derived syngas. Dimethyl ether is a building block for the preparation of many important chemicals, including methyl sulfate.[10] Dimethyl sulfate is an important commercial commodity as a solvent and also as an electrolyte in high-energy-density batteries. Lower olefins like ethylene and propylene or downstream products, such as gasoline and range boiling hydrocarbons, are produced from syngas using DME as an intermediate.[11,12] A variety of specialty industrial chemicals such as oxygenates, acetaldehyde, acetic acid, ethylene glycol precursor like 1,2-dimethoxyethane, etc. can be formed using DME as a feedstock. Air Products has programs under way to use DME as a chemical building block for higher-molecular-weight oxygenated hydrocarbons.[13] Some of the chemicals that can be synthesized using DME as a building block are shown in Fig. 2.

DIMETHYL ETHER SYNTHESIS

Dimethyl ether can be produced from natural gas, biomass, or other carbon containing materials. Using existing supplies of natural gas combined with current technology, DME can be economically produced on a large scale via synthesis gas. Syngas, or synthesis gas, is

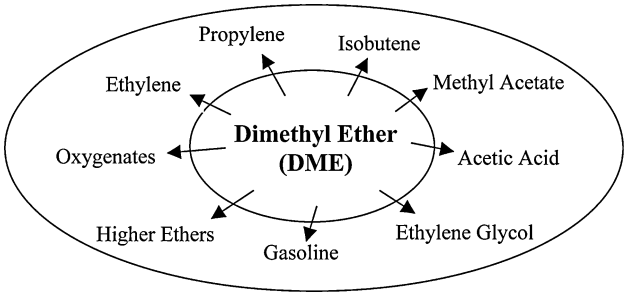

Fig. 2 Dimethyl ether—a building block for chemicals and oxygenates.

produced by coal gasification, biowaste gasification or by natural gas or hydrocarbon reforming. Dimethyl ether synthesis in the vapor phase suffers from low per-pass conversions, mandated in part by the debilitating effects of high temperature on the catalysts. Synthesis of DME in the gas phase has been studied in detail at Mobil Oil.[14,15] Gas-phase DME synthesis processes, in general, suffer from the drawbacks of low hydrogen and CO conversions per pass, along with low yield and selectivity of DME coupled with a high yield of carbon dioxide. These processes are typically expensive due to high capital costs for reactors and heat exchangers, and high operating costs due to inefficient CO utilization and high recycle rates.[13,16] Using an inert liquid as a heat sink for highly exothermic reactions offers a number of opportunities in syngas processing. Heat generated by the exothermic reactions is readily accommodated by the inert liquid medium. This enables the reaction to be run isothermally, minimizing catalyst deactivation, which is commonly associated with the more adiabatic gas-phase technologies.

The single-stage, liquid-phase DME synthesis process incorporates the sequential reaction of methanol synthesis and methanol dehydration in a slurry phase reactor system. Combining these reversible reactions in a single step drives each reaction thermodynamically by utilizing its inhibiting products as reactants in the subsequent reaction. Apart from the superior heat management allowed by the liquid-phase operation, the synergistic effect of these reactions occurring together yields higher quantities of DME than could be obtained from sequential processing.[13,16,17]

Commercial Processes

A number of processes have been developed to convert coal- or natural gas-based syngas into DME. The prominent ones include those by Haldor Topsoe, NKK Corporation, Air Products, Toyo Engineering Company, and the University of Akron, Electric Power Research Institute. A brief description of these processes is given below.

Haldor Topsoe Process

The chemical reactions involved in synthesis of DME from natural gas are as follows:

- Reforming:

$$CH_4 + 3/2O_2 = CO + 2H_2O$$
$$CH_4 + H_2O = 3H_2 + CO$$
$$CO + H_2O = CO_2 + H_2$$

- Dimethyl ether synthesis:

$$3H_2 + CO_2 = CH_3OH + H_2O$$
$$H_2O + CO = H_2 + CO_2$$
$$2CH_3OH = CH_3OCH_3 + H_2O$$

Haldor Topsoe has conducted a considerable amount of research for the purpose of developing DME as a diesel fuel from natural gas. They developed a new process, which is an integrated process for production of methanol from synthesis gas generated from various feedstocks ranging from natural gas to coal and biomass, followed by its subsequent conversion into DME in one single plant. The Haldor Topsoe process can produce neat DME or a raw fuel grade DME that can be specific blends of DME, methanol, and water. As shown in Fig. 3, the process consists of the following main steps: synthesis gas preparation, methanol and DME synthesis, and final purification unit. The synthesis gas preparation process uses autothermal reforming (ATR), consisting of a specifically designed burner (CTS burner). In this process, oxygen is added to desulfurize natural gas and steam. The steam to carbon ratio in the ATR is low (as low as 0.6) and the exit temperature is high. This ensures a favorable synthesis gas composition and low methane content. Synthesis of methanol and conversion of methanol into DME takes place in two separate reactors, which allows both parts of this sequential reaction to be carried out at optimal conditions. Methanol synthesis, which is a more exothermic reaction than DME synthesis, is carried out in a cooled reactor where reaction exotherm is continuously removed. Dimethyl ether synthesis takes place over a proprietary multiple-function methanol/DME catalyst in a loop comprising three adiabatic fixed-bed reactors in series. These have interstage cooling to achieve a high conversion of CO to CO_2. The product mixture of DME/methanol/water is then condensed and separated. The unconverted synthesis gas is split into a recycle stream and a purge stream, which is used as fuel and as hydrogen recycle. Dimethyl ether is purified by distillation in the final purification unit.[18,19]

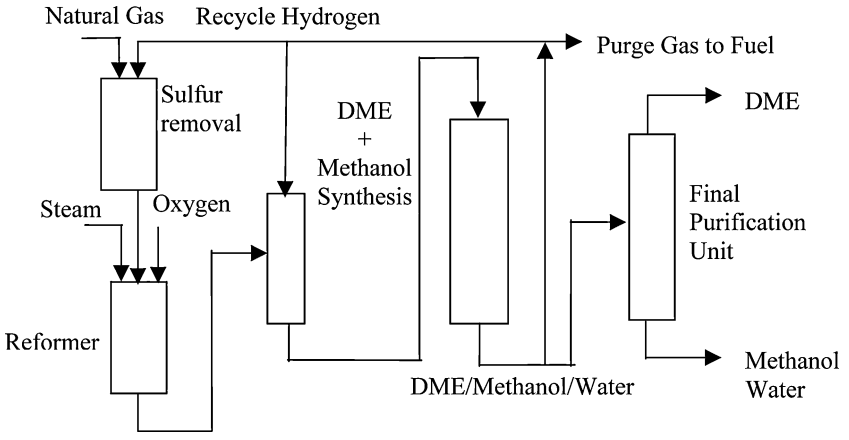

Fig. 3 Haldor Topsoe technology for DME synthesis.

NKK Process

Researchers at NKK Corporation have developed a process for DME synthesis from coal-bed methane using a slurry-bed reactor technology, utilizing a proprietary highly active catalyst for producing DME directly from the syngas at high yields. The success of this technology has been demonstrated in a 5 ton/day pilot plant, which is being operated since 1999.[20]

Chemical reactions involved in the synthesis of DME by NKK process are shown below

$$2CH_4 + O_2 + CO_2 = 3CO + 3H_2 + H_2O \quad (1)$$

Reforming reaction

$$2CO + 4H_2 = 2CH_3OH \quad (2)$$

Methanol synthesis

$$2CH_3OH = CH_3OCH_3 + H_2O \quad (3)$$

Methanol dehydration

$$3CO + 3H_2 = CH_3OCH_3 + CO_2 \quad (4)$$

DME synthesis

$$CO + H_2O = CO_2 + H_2 \quad (5)$$

Water–gas shift reaction

$$2CH_4 + O_2 = CH_3OCH_3 + H_2O \quad (6)$$

Overall process

Synthesis of DME from coal-bed methane consists of three reactions, namely, methane reforming, methanol synthesis, and methanol dehydration. Water produced by the methanol dehydration reaction participates in the water–gas shift reaction, which in turn produces hydrogen that can be utilized for methanol synthesis. In case the CO shift conversion reaction is slow, DME is synthesized by the methanol synthesis reaction and the methanol dehydration reaction.

The technology developed by NKK Corporation in Japan to produce DME from coal-bed methane is shown in Fig. 4. The process scheme consists of four sections: syngas reformer, carbon dioxide removal, DME synthesis, and DME separation/purification. Because the H_2/CO ratios of synthesis gas obtained by the coal gasification range from 0.5 to 1.0, the gas composition is adjusted by the shift reaction so that

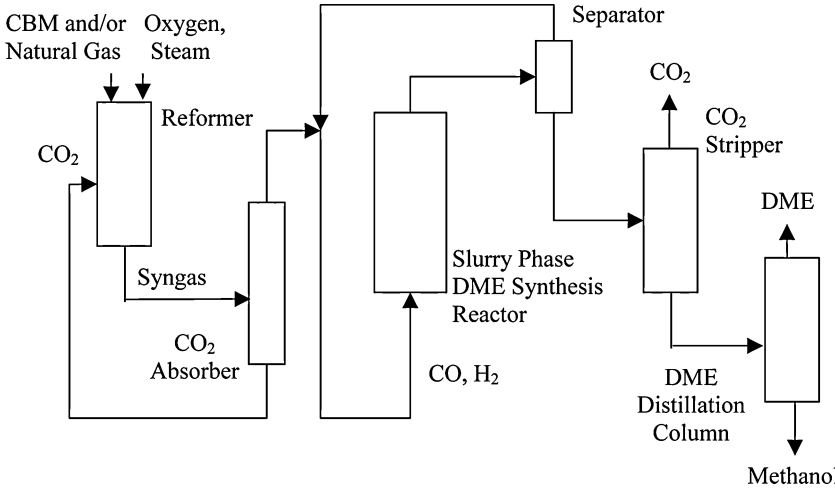

Fig. 4 NKK slurry phase DME synthesis.

$H_2/CO = 1$, and it is then supplied for DME synthesis. The effluent from the slurry reactor is cooled and chilled to separate the liquid phase containing DME, CO_2, and small amounts of methanol and water from the gaseous phase containing unreacted H_2 and CO. Most of the separated gas is recycled to the reactor. After CO_2 removal, the product DME of required purity is obtained by removing the impure water and methanol.

Air Products Process

Air Products has developed a single-step process for the direct synthesis of DME from synthesis gas with or without coproduct methanol in the liquid phase. This process can handle syngas with higher than 50 vol% CO, as is the syngas composition from advanced coal gasification. This process gives higher syngas conversion per pass than can be achieved by methanol synthesis alone. Selectivity of DME and methanol is optimized by varying reaction conditions, catalyst compositions, and/or ratios to suit specific process applications. Conversion of syngas to DME involves three separate reactions. All three reactions are equilibrium limited and exothermic in nature. Based on what they claim, the reaction chemistry is

$$xCO + xH_2O = xCO_2 + xH_2$$

Water–gas shift reaction

$$yCO + 2yH_2 = yCH_3OH$$

Methanol synthesis

$$2CH_3OH = CH_3OCH_3 + H_2O$$

Methanol dehydration

$$(x + y)CO + (2y - x)H_2 = CH_3OCH_3 + CO_2 + (y - 2)CH_3OH + (1 - x)H_2O$$

Net reaction

The single-stage synthesis of DME is carried out in a slurry-phase reactor, equipped with six-bladed draft-tube impellers. The catalysts used are powdered commercial catalysts BASF S3-85 and BASF S3-86 for methanol synthesis, γ-alumina catalysts for methanol dehydration, and copper-based BASF K3-110 as a shift catalyst. These catalysts are slurried in either degassed Witco-70 or DRAKEOL-10 mineral oils with slurry concentrations in the range of 15–30 wt% catalyst.

As shown in Fig. 5, three potential commercial modes of operation to produce DME have been investigated by Air Products. The first operating mode uses an oxygen-blown coal gasifier with recycle of the synthesis gas. The coproducts of this process mode are methanol and DME, which have applications in the fuel and petrochemical industry. Per-pass CO conversion was 70% at 1200 L/kg of catalyst per hour. The second operating mode uses the once-through approach of coal-derived syngas. Dimethyl ether and methanol are recovered, and unreacted gas is fired to a turbine. The third operating mode also uses the once-through process, but uses basic oxygen furnace (BOF) off-gas as the feed stream. The hydrogen to carbon monoxide ratio of BOF off-gas is essentially zero, thereby making it imperative for steam to be cofed to the reactor. This process enables the use of off-gases with unfavorable compositions, which are currently recovered only for their fuel value, and upgrading them into more valuable liquid products.[13,16]

Toyo Engineering Corporation Process

Toyo Engineering Corporation has developed a jumbo DME plant from natural gas using existing proven technologies.[21] Toyo Engineering Corporation has developed a number of large-scale methanol synthesis plants in the world. Chemical reactions involved in DME synthesis by TEC's process, as claimed, are shown below:

$$CO + 2H_2 = CH_3OH$$
Methanol synthesis

$$CO_2 + 3H_2 = CH_3OH + H_2O$$
Methanol synthesis

$$2CH_3OH = CH_3OCH_3 + H_2O$$
Methanol dehydration

$$CO + CO_2 + 5H_2 = CH_3OCH_3 + 2H_2O$$
Overall reaction

The configuration of a 7000 MTPD DME plant is based on the combination of methanol synthesis and methanol dehydration. Attractive features of this process include lesser total investment cost and lesser oxygen consumption when compared with the methanol/DME coproduction route or direct DME synthesis route. Also, carbon dioxide is not produced in the DME synthesis step of this process. As shown in Fig. 6, this process utilizes a steam reformer, TEC's TAF-X reactor, oxygen reformer, TEC's MRF-Z® methanol reactor, and TEC's DME reactor.

University of Akron, Electric Power Research Institute (UA-EPRI) Process

Researchers at the University of Akron, in conjunction with the Electric Power Research Institute, have developed a novel liquid-phase process that produces DME in a single stage from CO-rich syngas.[22,23] A process schematic of the DME minipilot plant is shown in Fig. 7. The process chemistry for the novel one-step

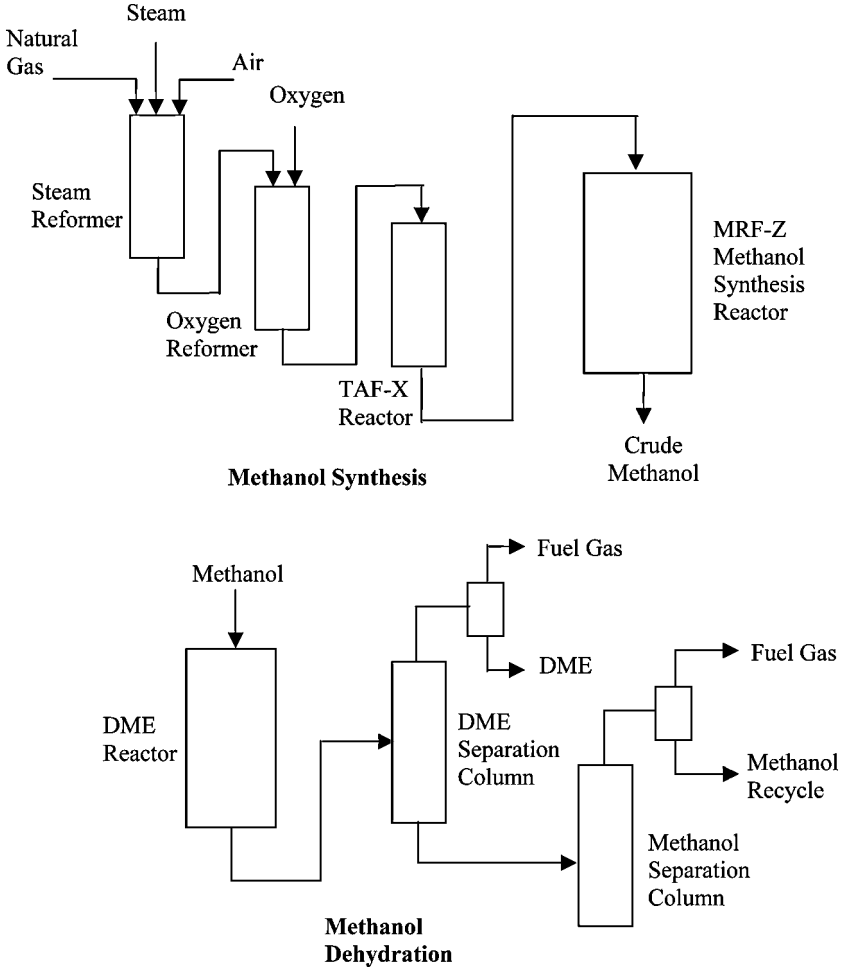

Fig. 6 Toyo Engineering Corporation DME process.

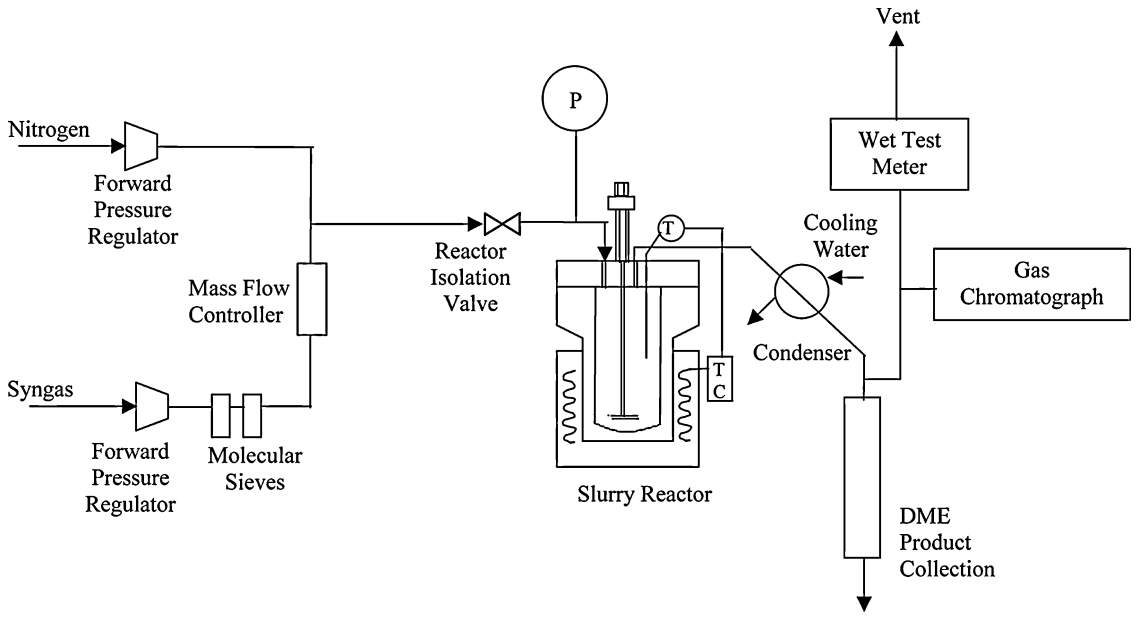

Fig. 7 Process schematic of the UA-EPRI liquid-phase DME experimental process unit.

synthesis of DME in the liquid phase is as follows

$$CO_2 + 3H_2 = CH_3OH + H_2O$$
Methanol synthesis

$$CO + H_2O = CO_2 + H_2$$
Water–gas shift reaction

$$2CH_3OH = CH_3OCH_3 + H_2O$$
Dimethyl ether synthesis

The methanol synthesis reaction and water–gas shift reaction take place over the coprecipitated $Cu/ZnO/Al_2O_3$ catalyst, and the methanol dehydration reaction takes place over a γ-alumina catalyst. The reactions are carried out at 250°C and 70 atm in a liquid phase involving inert oil, such as Witco-40, Witco-70, or Freezene-100 oil.

The single-stage reactor productivity was increased by as much as 60% when the coproduction of methanol and DME was used, as compared to methanol synthesis alone. Per-pass syngas conversion when using the coproduction of methanol and DME approach was increased by as much as 50% over that of methanol synthesis only. At high slurry ratios, when methanol concentration in the liquid phase is very high, the percent increase in single-stage reactor productivity could be as high as 80%. The above fact is very significant from a commercial perspective as almost all the commercial reactors in the liquid-phase synthesis are operated in the gas-to-liquid mass transfer limited region. The process is capable of coproducing methanol and DME in any fixed proportion, at significant synthesis rates of both methanol and DME. The process feasibility has been well demonstrated on their minipilot plant system.[17,22]

CONCLUSIONS

Dimethyl ether is a versatile multisource, clean-burning fuel. It can be readily produced from natural gas and coal, from renewable resources, such as biomass and wood, as well as from waste matter. Production of DME by combining methanol synthesis, methanol dehydration, and water–gas shift reactions in a single stage results in a synergistic effect with favorable thermodynamics, thereby creating a driving force for the overall reaction with very high syngas conversion in a single pass. Dimethyl ether can be used as a clean-burning fuel in diesel engines and fuel cells, as a household fuel (LPG alternative) for heating and cooking, as a fuel for gas turbines in power generation, as a feedstock for producing chemicals and oxygenates, and as a propellant in the aerosols market. Use of DME as a transportation fuel results in lower NO_x, CO_x, and hydrocarbon emissions, and also eliminates soot particulates and evaporative emissions. Acceptance of DME as a clean fuel in terms of public perception is facilitated by the fact that it is nontoxic and noncorrosive and it can be transported, stored, and dispensed as a liquid fuel in the same manner as LPG or propane. In the short term, DME can be easily manufactured from methanol. Meanwhile, commercial production plants are being designed and set up in different parts of Asia, Europe, South America, and the

United States to produce DME directly from natural gas and coal-based syngas in the near future.

Dimethylcarbonate

Byung Gwon Lee
Environment and Process Technology Division, Korea Institute of Science and Technology, Cheongryang, Seoul, Korea

INTRODUCTION

Dimethylcarbonate [DMC, $(CH_3O)_2CO$] is a versatile chemical substance, which has been used mainly as a carbonylating, methylating, or methoxycarbonylating agent. It can be effectively used as an environmentally benign substitute for phosgene in polycarbonates and isocyanates synthesis, and for dimethyl sulfate in various methylation reactions.[1,2]

Dimethylcarbonate has two carbon centers at which a nucleophile may react: the carbonyl and the methyl group. When a nucleophile attacks the carbonyl carbon of DMC, the cleavage of acyl–oxygen bond results in a methoxycarbonyl product. Therefore, DMC can replace phosgene as a safe source for carbonic acid derivatives. On the other hand, when a nucleophile attacks at the methyl carbon of DMC, the methylation product is produced by the alkyl–oxygen bond cleavage. As a methylating agent, DMC is a safe substitute for dimethyl sulfate.[2]

Phosgene and dimethyl sulfate are highly reactive chemicals, used since the beginning of the chemical industry. The cost of their utilization, however, is dramatically increasing owing to the growing safety concerns and measures during their production, transportation, storage, and use. Their use in carbonylation and methylation reactions brings about the formation of stoichiometric amounts of by-products such as inorganic chlorides of sulfates, generally in the form of organically contaminated aqueous streams. Dimethylcarbonate does not have this kind of problem at all in its various applications. In addition, DMC is being considered as a component of reformulated fuels owing to its high oxygen content and good blending properties.[3] Dimethylcarbonate has about three times higher oxygen content than methyl *tert*-butyl ether (MTBE) and its synthesis is not dependent on isobutylene feed like MTBE.

PROPERTIES

Dimethylcarbonate is a transparent liquid with a melting and boiling point of 277 and 363 K, respectively, and the specific gravity is close to unity. Thus, in a sense, the physical properties are close to those of water. Dimethylcarbonate is sparingly soluble in water and miscible with the most organic solvent, particularly polar solvents such as esters, ketones, ethers, and alcohols. Dimethylcarbonate is extremely stable to pyrolysis up to at least 623 K. Dimethylcarbonate undergoes base- or acid-catalyzed hydrolysis to produce methanol and carbon dioxide.[1] One of the most important properties of DMC is low toxicity compared with conventional methylating agents or carbonylation agents. Table 1 summarizes the physical and toxicological properties of DMC.

Some data are available in the open literature on the hazards and toxicity of DMC.[3,4] These toxicology studies performed by IITRI (Illinois Institute of The Technology Research Institute) involved eye and skin irritation studies and dermal sensitization studies, along with dermal, oral, and inhalation studies for acute toxicity. The results indicate that DMC is a nonirritant, nontoxic chemical. Dimethylcarbonate is listed in the "Hazard Rating 3"(HR3) category. Hazard rating (HR) is a number between 1 and 3. Ratings are assigned on the basis of low [1], medium [2], or high [3] toxic, fire, explosive, or reactivity hazard. HR3 means the substance has an LD_{50} (lethal dose, 50% of population) below 400 mg/kg and an LC_{50} (lethal concentration, 50% of population) below 100 ppm, or that the material is explosive, spontaneously flammable, or highly reactive. Hazard Rating 2 (HR2) means the substance has an LD_{50} between 400 and 4000 mg/kg, and an LC_{50} between 100 and 500 ppm, or that the material is either highly flammable or reactive. Hazard Rating 1 (HR1) means the substance has an LD_{50} between 4000 and 40,000 mg/kg and an LC_{50} between 500 and 4000 ppm, or that the material is combustible. Hexane and cyclohexane fall into the HR3 category, the same as DMC.[3] In addition, recently it has been found that the photochemical ozone creation potential (POCP) of DMC is the lowest among common volatile organic compounds (2.5, ethylene = 100).[4]

MANUFACTURE

The traditional synthesis of DMC used to require toxic, hazardous phosgene as a reagent. Nonphosgene alternative routes for DMC production basically have

relied on the reaction of methanol with carbon monoxide (oxidative carbonylation) or with carbon dioxide (direct carboxylation with CO_2, or indirect carboxylation, using urea or alkene carbonates as CO_2 carriers), as depicted in Fig. 1.

Phosgene Alcoholysis

The conventional method for synthesizing DMC employs phosgene.[3] Phosgene will react with methanol to form methyl chloroformate.

$$CH_3OH + COCl_2 \rightarrow CH_3COCl + HCl \quad (1a)$$

Methyl chloroformate reacts with an additional mole of methanol to form DMC.

$$CH_3COCl + CH_3OH \rightarrow CH_3OCOOCH_3 + HCl \quad (1b)$$

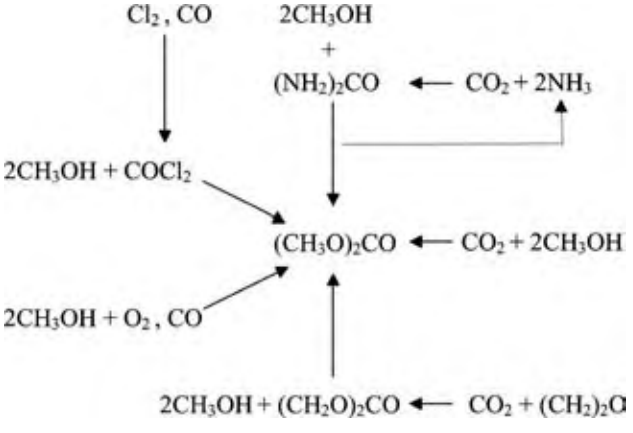

Fig. 1 Dimethylcarbonate synthesis routes.

Reaction (1a) occurs quite easily, whereas reaction (1b) is slower and can be accelerated using an acid scavenger such as a tertiary amine or an inorganic base, e.g., NaOH.[5] While making the carbonate, the amount of alcohol and the reactor residence time are increased. The continuous production of methyl carbonate has been reported in a 1973 French patent.[3] Here, methyl chloroformate and methanol are fed continuously into a packed-bed reactor operating with a bottom to top temperature gradient of 72–127°C. HCl is drawn off the head and dimethylcarbonate (99%) is withdrawn from the base.

Oxidative Carbonylation of Methanol

Liquid-phase synthesis

The methods of DMC preparation that are based on the catalytic reaction of methanol with carbon monoxide and oxygen, according to reaction (2), have been the subject of intensive studies.

$$2CH_3OH + CO + 1/2O_2 \rightarrow (CH_3O)_2CO + H_2O \quad (2)$$

EniChem set up a project aimed at the development of a nonphosgene synthesis of DMC for large volume usage; as a result, a new industrial process was established, based on a liquid-phase methanol oxidative carbonylation in the presence of copper chlorides as catalysts.[6] This catalytic system was highly effective in DMC production: the reaction was carried out by feeding at the same time methanol, carbon monoxide, and oxygen to the suspension of the catalyst in a mixture of water, methanol, and DMC and recovering DMC by distillation after the catalyst separation. Besides, the process

was not influenced by the carbon monoxide purity: diluents such as hydrogen did not interfere with the catalytic system. The first industrial plant, based on the developed technology, went onstream since 1983.

Modification of the copper chloride catalyst has been sought by different research groups in the effort to improve the catalyst performance; examples are: 1) the use of a CuCl/KCl eutectic mixture as catalyst combined with the pressure swing technique; and 2) the introduction of high-boiling cosolvents/ligands in the reaction mixture.[6]

Methanol oxy-carbonylation is a redox two-step reaction. According to a simplified scheme, the reaction proceeds through CuCl oxidation by oxygen to cupric methoxychloride [reaction (3)].[6]

$$2CuCl + 2CH_3OH + 1/2O_2 \rightarrow 2Cu(OCH_3)Cl + H_2O \quad (3)$$

The latter is reduced by carbon monoxide to DMC [reaction (4)], restoring CuCl and allowing the setup of the catalytic cycle.

$$2Cu(OCH_3)Cl + CO \rightarrow (CH_3O)_2CO + 2CuCl \quad (4)$$

This scheme does not appear fully adequate because it was observed that the reduction of cupric methoxychloride under carbon monoxide hardly proceeds under strictly anhydrous conditions, but it is promoted by the addition of even small amounts of soluble cupric species, such as $CuCl_2$. The same effect is obtained by the addition of some water, bringing Cu(II) in solution, by hydrolysis. Moreover, diethylcarbonate is produced when $Cu(OCH_3)Cl$ is reacted in ethanol under CO. Therefore, polymeric, insoluble cupric methoxychloride cannot be considered the true reaction intermediate. As a matter of fact, a methanol dispersion of $Cu(OCH_3)Cl$ synthesized by CuCl oxidation with oxygen in methanol presents an electron spin resonance spectrum with a resolved signal typical of a cupric ion in solution over the enlarged signal particular to the insoluble, polymeric species.

In systems containing high water concentrations, as generated by direct oxygen reoxidation under technical conditions, exhaustive hydrolysis of copper methoxychloride leads to a number of soluble and insoluble cupric species containing chloride and hydroxide anions such as $CuCl_2$ and $Cu_4Cl_2(OH)_6$ (atacamite). This reaction system brings about, by reduction under CO, DMC and cuprous chloride formation, provided that copper and chloride are balanced. Halide anions appear to be very important to establish the catalytic cycle.

In the presence of amine ligands, such as pyridine, dipyridyl, and tetramethylethylene diamine, the catalytic effectiveness increases, but the practical use of this system is hampered because it fails to produce DMC under technical conditions, mainly owing to water sensitivity. In the amine–copper system, catalysis of DMC formation by Cu(I), through the carbonyl complex CuCl(CO), was observed, this feature being reminiscent of the mechanism of CO to CO_2 oxidation by Cu(II) in aqueous solutions.[6]

Other redox metallic systems are able to perform the alcohol oxy-carbonylation to carbonates. Palladium(II) chloride complexes stoichiometrically give carbonates in the presence of a base such as Na_2CO_3 or $N(Et_3)$ under very mild conditions.[7] In the methanol oxy-carbonylation with palladium(II) acetate complexes, dimethyl oxalate is produced along with DMC.[8] The selectivity toward DMC could be driven by the choice of the phosphine ligand, by increasing the carbon monoxide pressure and by the addition of a base. A lot of effort has been put in with the aim of making the oxy-carbonylation catalytic with respect to palladium, by addition of some cocatalyst for palladium(0) reoxidation. When using air or oxygen as oxidants, water is coproduced. It is known that the system Pd(II)–CO in the presence of water easily brings about carbon dioxide formation. It was reported that the addition of phosphonium salts or nitriles as cosolvents/ligands to the reaction mixture improves carbon monoxide selectivity to DMC, ranging from 50% to 80%, according to the reaction conditions.[6] Besides, by addition of alkali earth metal salts and 2-hydroxypyridine to the palladium–copper salts system, the CO selectivity toward DMC could be increased up to 90%. To prevent the formation of water in the reaction medium, use of dialkyl peroxides as oxidants, in the presence of a copper–pyridine complex as cocatalyst, or an electrochemical oxidation has been proposed.[9]

Cobalt(II) complexes bearing ligands with nitrogen and oxygen donors, such as Schiff bases, acetylacetonate, or picolinate, produce DMC with high selectivity in methanol under carbon monoxide and oxygen, especially in the presence of weakly coordinating solvents such as nitriles, amides, or ureas. These cobalt-based systems appear very attractive because they are halogen-free and noncorrosive compared with systems containing chloride, especially copper chlorides. In contrast to palladium and copper, simple cobalt salts, such as chlorides, are inactive as catalysts.[6]

Gas-phase synthesis

A lot of effort has been put in to develop a gas-phase oxy-carbonylation process. First, EniChem described gas-phase DMC production using CuCl dispersed on alumina.[6] Dow Chemical studied $CuCl_2$, alone or in combination with alkali and alkali earth halides, and the pyridine complex of $Cu(OCH_3)Cl$, both supported

on active carbon, as catalysts. The catalyst activity was not high and decreased during the tests in a relatively short time (20–40 hr), depending on the catalyst loading; it was restored by in situ regeneration of the catalyst by addition of HCl. It was reported that both high selectivity and DMC productivity are obtained when using a $CuCl_2$ catalyst supported on active carbon and modified by treatment with alkaline hydroxides; a stable catalytic activity was claimed after 100 hr. Recently, a study of the structural change in a $CuCl_2$ active carbon supported catalyst used in the DMC synthesis was reported.[10]

Cuprous chloride supported on a Y-type zeolite by high-temperature anhydrous reaction gave a DMC productivity as good as the active carbon supported catalyst.[11] Addition of tetraalkyl ammonium chlorides to copper chlorides on zeolites or alumina increased the DMC productivity and the catalyst life. In any case, active carbons are the most preferred supports for this reaction, compared to zeolites or alumina, because of higher DMC productivity when working with copper(II) chlorides.

The DMC productivity increases by addition of palladium salts to copper salts supported on active carbon. It is worth pointing out that, although copper salts without halides are practically inactive in the reaction, the use of halogen-free palladium/copper salts supported on active carbon reportedly gives high DMC productivity and CO selectivity.[6]

When palladium salts are used for methanol oxy-carbonylation to DMC, reaction conditions are milder than using copper only; however, methanol and CO selectivities are lower owing to the formation of DMO as a by-product and to the higher ratio between CO_2 and DMC production rates. Despite the large amount of work on the catalytic systems, no process based on gas-phase direct methanol oxy-carbonylation to DMC has been established.

Carbonylation of Methylnitrite

Recently, two reviews on the synthesis of DMC via methylnitrite (MN) appeared.[12] Starting from methanol, carbon monoxide, and oxygen as raw materials, the process takes place in two steps in the gas phase: in the first, methanol reacts at about 50°C with nitrogen oxides and oxygen to give MN and water, without any catalyst, according to reactions (5) and (6), which involve N_2O_3 as an intermediate species.

$$2NO + 1/2O_2 \rightarrow N_2O_3 \quad (5)$$

$$2CH_3OH + N_2O_3 \rightarrow 2CH_3ONO + H_2O \quad (6)$$

In the second, MN reacts with carbon monoxide to produce DMC at 100–120°C and 0.5–1 MPa, in the presence of a palladium supported catalyst, in a fixed-bed reactor according to reaction (7).

$$2CH_3ONO + CO \rightarrow (CH_3O)_2CO + 2NO \quad (7)$$

In the catalytic process, the NO produced in the latter reaction is converted back to MN according to reactions (5) and (6).

The above DMC synthesis using MN was discovered at UBE, and a plant based on this technology has recently gone onstream with a capacity of about 6000 ton/yr.[13] Reaction (7) is catalyzed by supported palladium(II) halide complexes, which allow high (90–95%) CO selectivity. The addition of a cocatalyst such as copper chloride is required to prevent the reduction of Pd(II) to Pd(0) because Pd(0) tends to accelerate the formation of DMO.

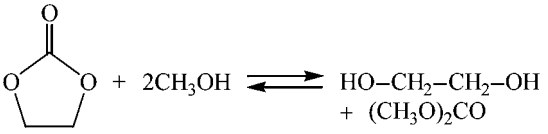
Many different catalytic systems based on palladium with various cocatalysts and supports were studied.[6] The nature of the support influences the catalyst performance; it is important to avoid the presence of both acid sites, to avoid MN decomposition to methylformate and methylal, and basic sites that increase the DMO production. The catalyst must contain chloride anions to be effective and to keep the oxidation state of palladium(II). Therefore, the loss of chlorides in the outlet stream of the reactor as organic or inorganic compounds must be counteracted by addition of chlorinated organic compounds or HCl in the feed, to maintain the catalyst performances.

Surprisingly, palladium(II) salts supported on NaY zeolite produce DMC, even without halogens.[6] The preferred support seems to be active carbon compared to zeolites because of higher DMC selectivities based on both MN and carbon monoxide, >95% in the case of active carbon and 80–90% in the case of zeolites. Palladium chloride/copper chloride on active carbon is likely used as a catalytic system in the industrial process. Because the carbonylation of MN to DMC occurs without water coproduction, the use of palladium salts as catalysts does not adversely affect selectivity. In the carbonylation reactor outlet some amount of methylchloroformate is present, as expected because it is known that palladium(II) chloride supported on alumina or silica catalyzes the reaction between MN, CO, and HCl to give methylchloroformate.[14] The presence of halide ions in the catalytic system and the methylchloroformate generation likely raise some corrosiveness issues.

The methyl nitrite process, studied both at UBE and at Bayer, is a new and valuable process for the DMC synthesis; nevertheless, there are some concerns about the toxicity and handling of MN.[6]

Transesterification of Ethylene Carbonate or Urea

An alternative to the oxy-carbonylation processes is the transesterification of ethylenecarbonate (EC) with methanol. In this process, DMC is cogenerated with ethylene glycol (EG), according to reaction (8).

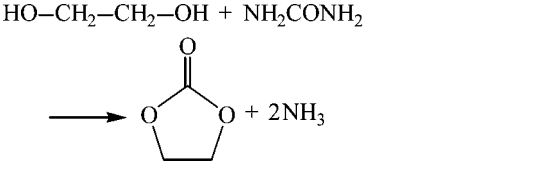


(8)

Ethylene carbonate can be prepared by a well-known process, from ethylene oxide and carbon dioxide with a catalyst such as a quaternary ammonium halide at 150–175°C. Addition of a cocatalyst such as zinc chloride to a quaternary ammonium iodide allows milder reaction conditions (50–100°C).[6]

Reaction (8) takes place in the presence of a catalyst at about 100–150°C at moderate pressure, for example, by working in a homogenous phase in the presence of tin, zirconium, or titanium complexes. Both homogenous and heterogenous basic or acid catalysts can also be used for the reaction; however, the base catalyzed reaction appears to be the most effective for the synthesis of DMC.[15] Recently, a new heterogenous catalyst based on potassium carbonate treated titanium silicate (TS-1) molecular sieve was reported.[16] Unfortunately, the transesterification reaction of EC with methanol is an equilibrium reaction and the formation of DMC is thermodynamically not favored. Several methods have been suggested to improve the low yield of DMC, for example, by removal of the reaction product as DMC/CH_3OH azeotrope from the reaction mixture by distillation or by selective solvent extraction of the DMC produced.[6] In this reaction, EC and methanol conversion are typically in the range 50–60% and 15–20%, respectively, whereas the DMC selectivity, based on both converted EC and methanol, is about 98%.

This process also suffers from the complications associated with the cogeneration of two compounds. This problem could be overcome by recycling ethylene glycol to produce EC, for example, via urea transesterification according to reaction (9).



(9)

The driving force for reaction (9) is ammonia removal. By using an adequate catalyst such as zinc oxide, 95–98% EC selectivities based on ethylene glycol and urea have been reported, at total urea conversion, when using a small excess of ethylene glycol.[6]

Although the direct synthesis of DMC starting from urea and methanol would be very attractive, its thermodynamics is not favorable, the calculated ΔG° for the direct transesterification reaction being about $\cong$3 kcal at 100°C.[3] The reaction involves two steps: first, urea is converted to methylcarbamate by reaction with methanol at relatively low temperatures (ca. 100°C in the presence of a catalyst or ca. 150°C without catalyst); then, the carbamate is further reacted with methanol at 180–190°C in the presence of a catalyst to produce DMC, according to the reactions (10a) and (10b).

$$NH_2CONH_2 + CH_3OH \rightarrow NH_2COOCH_3 + NH_3 \quad (10a)$$

$$NH_2COOCH_3 + CH_3OH \rightarrow (CH_3O)_2CO + NH_3 \quad (10b)$$

As above, the driving force for both reactions is ammonia removal. Both reactions (10a) and (10b) are catalyzed by a combination of a weak Lewis acid and a weak Lewis base, such as equimolar amounts of Al(*i*-Bu)$_2$H and PPh_3. These bifunctional catalysts reduce the formation of by-products from carbamate decomposition. The above reactions could be carried out in two separate steps or in one pot when in the presence of tin(IV) compounds as catalysts for the second reaction.[6]

In a recent development of this route, the reactions take place at the same time in a reactor with a distillation column at about 180°C and 0.5 MPa, in the presence of a tin(IV) alkoxide in a high-boiling solvent such as triglyme, feeding methanol and urea in the reactor containing the catalyst and the solvent and removing DMC and methanol overhead.[17] Dimethylcarbonate selectivity based on methanol is excellent (97–98%), and the DMC yield is higher than previously reported. However, the urea selectivity and conversion are more difficult to estimate. Some products of urea alkylation are produced in 1–3% yields, whereas the formation of urea decomposition products (such as biuret $NH_2CONHCONH_2$ and other high molecular weight by-products) cannot be ruled out because their presence was not checked.

Synthesis of DMC from urea is attractive. In fact, by this process the synthesis of a carbonate starting from an alcohol and carbon dioxide would be achieved, because in principle the evolved ammonia can be recycled to the synthesis of urea.

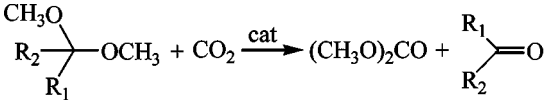
Direct Synthesis of DMC Starting from CO_2

Conversion of carbon dioxide to useful industrial compounds has recently raised much interest in view

of the so-called ''Sustainable Society'' and ''Green Chemistry.'' The direct synthesis of carbonates starting from alcohols and carbon dioxide, studied since the 1980s, fulfils this approach.[6] In particular, the catalytic DMC synthesis starting from carbon dioxide and methanol is currently studied intensively. The reaction occurs at 140–190°C and 5 MPa in the presence of zirconia (ZrO_2) with a very high (ca. 100%) methanol selectivity to DMC.[10] Unfortunately, the methanol conversion is very low because the equilibrium of the reaction (11) is largely shifted to the left as shown:

$$CO_2 + 2CH_3OH \rightarrow (CH_3O)_2CO + H_2O \qquad (11)$$

To avoid the formation of water as by-product, the reaction could be carried out using dehydrated derivatives of methanol, such as acetals [reaction (12)]. The carbonyl compound, formed along with DMC, can be recycled to prepare the corresponding acetal:



(12)

This reaction occurs at 190°C under supercritical CO_2 (30 MPa) via the carbomethoxy methoxy bridged dialkyl tin dimer intermediate. Yields, based on this tin intermediate, are ca. 60%. Dimethylcarbonate appeared to be formed by an intramolecular pathway. Further efforts in this very promising area are necessary to discover more efficient catalytic systems.

Other Routes to DMC

A few other routes to DMC have been studied. Alkylation of metal carbonates with organic halides could be a method to prepare complex, functionalized carbonates under mild conditions, but it is unattractive for the synthesis of DMC from many points of view, both economic and ecological.[6]

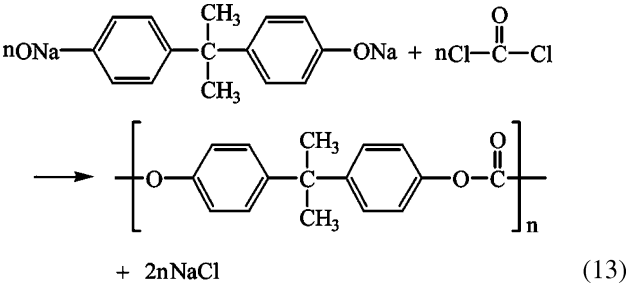
Dimethylcarbonate was prepared by decarbonylation of DMO in the presence of sodium methoxide or tetraphenyl phosphonium chloride as catalyst at 100°C without solvent. Under these conditions, DMO is totally converted and the selectivity to DMC ranges between 85% and 95%.[18] The method could be also used to prepare DMC starting from the corresponding oxalate.

APPLICATIONS

Dimethylcarbonate characteristics, coupled to its nontoxicity, are very attractive for the chemical industry. Dimethylcarbonate applications are sorted according to its use as a chemical intermediate (carbonylating or methylating reagent), solvent, and fuel additive.

Polycarbonate Production

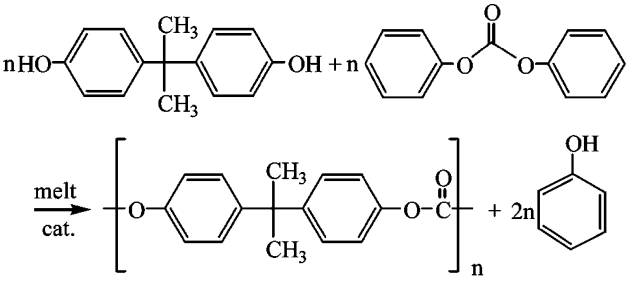
Polycarbonate resins are important engineering thermoplastics with good mechanical and optical properties as well as electrical and heat resistance, useful for many engineering applications. Polycarbonates have been commercially produced by the interfacial polycondensation between a bisphenol-A salt in an aqueous caustic solution and phosgene in an organic solution as follows [reaction (13)]:



(13)

The main disadvantages of this phosgene process are: 1) The high toxicity and corrosiveness of phosgene; 2) The use of copious amounts of methylene chloride solvent (10 times the weight of the product); This solvent is water soluble, so it contaminates the wash water; and 3) The complex cleanup to remove ionic materials.

The most practical nonphosgene process for manufacturing polycarbonates is the transesterification of diphenylcarbonate (DPC) with bisphenol-A. A nonphosgene process for the melt polymerization production of aromatic polycarbonates [reaction (14)], making use of EniChem technologies for the production of DMC and DPC as intermediates, has been commercially established and will account in a short time for about 300,000 ton/yr polycarbonates.



(14)

This process avoids at the same time the use of phosgene as a reactant, and methylene chloride as a solvent, and thus eliminates the coproduction of NaCl salt. Avoiding these drawbacks is a common feature

of DMC-based processes, matching the guidelines for a clean chemistry: besides exploiting the use of a harmless reagent, they avoid the use of solvents and the coproduction of salts or HCl, and generate only easily disposable or recyclable by-products.

The DMC-based route to aromatic polycarbonates takes place via production of DPC as intermediate and successive melt polymerization between DPC and bisphenol-A, overcoming the previous technology, based on interfacial polymerization with phosgene.[6]

The transesterification reaction between DMC and phenol is carried out in the liquid phase in the presence of a variety of homogenous catalysts.[19] According to the process developed by EniChem, DPC is obtained from DMC in two steps [reactions (15a) and (15b)]: in the first, DMC and phenol are reacted in the presence of a titanium alkoxide catalyst to give methylphenylcarbonate (MPC); in the second, MPC is disproportionated to DPC and DMC.[20]

$$PhOH + (CH_3O)_2CO \rightarrow PhO(CO)OCH_3 + CH_3OH \quad (15a)$$

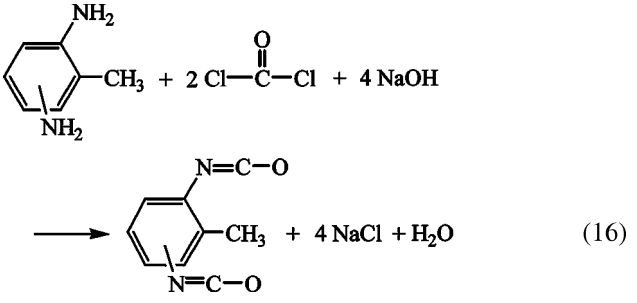
$$2PhO(CO)OCH_3 \rightarrow (PhO)_2CO + (CH_3O)_2CO \quad (15b)$$

There were two critical aspects on the road from DMC to DPC. The first was related to obtaining DPC with high selectivity, because it was known that DMC is a powerful methylating agent toward phenol with the formation of anisole. EniChem first disclosed the DMC to DPC route through the use, as catalysts, of a number of Lewis acids and metal alkoxides, especially titanium tetraphenoxide, allowing selective DPC formation. By the use of titanium compounds, selectivity well over 99.5% to DPC is obtained. Afterward, many other catalysts were found suitable, like Sn, Pb, Mo derivatives, and others.[21] The second critical aspect of DPC production was related to the highly unfavorable equilibrium of the reaction, the equilibrium constant being as low as 7.9×10^{-10} at 25°C. Performing the transesterification reaction only to produce mainly the intermediate MPC and, instead of the second transesterification step from MPC to DPC, carrying out a disproportionation of MPC to DPC and DMC partially overcomes the equilibrium constraints. Still, a very unfavorable equilibrium has to be dealt with in MPC formation. Even if a positive effect of raising the temperature on the equilibrium is observed, because of the slight endothermicity of the reaction, and the use of titanium tetraphenoxide as catalyst allows to carry out the reaction with high selectivity up to at least 200°C, the gain on the equilibrium constant value is not so pronounced as to relieve the problems raised by the reaction thermodynamics: at 200°C, an equilibrium constant of 1.7×10^{-3} still holds for the formation of MPC. Therefore, good process engineering design was required to successfully carry out the reaction to MPC on a large industrial scale, with a reasonable energy consumption. As there are many equilibrium reactions, the process is best carried out in a reactive column with countercurrent phenol/DMC feeds, using optimized operation conditions, to guarantee an isothermal temperature profile in the column, and adopting an excess of feed DMC over phenol. Under the selected conditions, phenol conversion per pass in the range of 25–35% is obtained.

Another well-established application of DMC in the field of polycarbonates relates to the production of polydiethyleneglycol bis(allylcarbonate), a thermosetting resin used in the production of optical glasses and lenses. The nonphosgene process involves the intermediate formation of diallylcarbonate from DMC, whereas the traditional process was based on the use of diethyleneglycol bis(chloroformate), obtained from phosgene, and allows high flexibility in terms of customer tailored products.

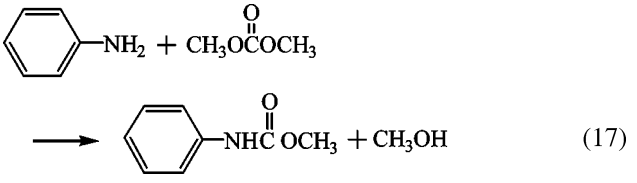
Carbamate and Isocyanate Production

One of the most important uses of phosgene is the production of isocyanate for polyurethane. For example, toluene diisocyanate is produced by the reaction of diaminotoluene with phosgene [reaction (16)].



(16)

The obvious drawbacks of this method are high toxicity of phosgene and handling of a large amount of hydrogen chloride. Therefore, several methods for synthesizing isocyanates (or carbamate ester as a precursor) without using phosgene have been sought.



(17)

The reaction between DMC and primary or secondary amines yields carbamates [reaction (17)]. Suitable catalysts are needed to achieve good reaction rates

and high selectivities. When aliphatic amines are reacted, strong bases, such as alkali alkoxides, can be used to afford quantitative yields under mild conditions.[22] Interestingly, carbon dioxide has also been proved to be an effective catalyst in the reaction. Lewis acids, such as $AlCl_3$ or AlI_3 and mercuric salts, zinc acetate, or lead oxides, and salts are required in the case of anilines.[23] By these methods it is possible to obtain both mono- and dicarbamates.

The nonphosgene production of isocyanates takes place through the thermolysis of the corresponding carbamate. The carbamate synthesis may involve a number of possible alternative ways, such as the reaction of a nitrocompound with CO, or the reaction of an amine with CO and O_2, with urea and alcohol, or with a carbonic ester. Among these routes, the reaction of DMC or DPC with aliphatic amines is a very efficient way to produce carbamates.

A nonphosgene process for the production of methyl isocyanate, starting from methylamine and DPC as raw materials, has been established by EniChem, resulting in the commercialization of two production units in the United States (1988) and China (1994).[24] Selective formation of *N*-methyl *O*-phenyl urethane (MPU) is achieved by the reaction, in nearly stoichiometric amounts, of methylamine and melt DPC. This reaction is quickly and easily performed continuously at 50°C and atmospheric pressure. The resulting liquid product, consisting of an equimolar mixture of MPU and phenol, is thermally treated at 210°C to decompose MPU, then the isocyanate and phenol produced are separately recovered. The latter, after distillation, can be eventually recycled to DPC production. Not only is the use of phosgene avoided by this process, but also CH_3NCO is safely generated as a controlled vapor stream by MPU decomposition in the pyrolysis step, according to the heat provided to the endothermic reaction. The stream of isocyanate can be directly reacted to the finally desired product, which is normally a carbamate pesticide or pharmaceutical, avoiding the need for any risky accumulation or storage of CH_3NCO. By using suitable catalysts, the stationary concentration of CH_3NCO in the reacting solution is kept very low during the entire addition of the isocyanate and reaches negligible concentration values at the end of the addition in short intervals, allowing efficient production under highly safe conditions. 1,8-Diazabicyclo[5.4.0]undec-7-ene (DBU) behaves as a particularly useful catalyst.[25] Also in this process, it is worth noting the absence of coproducts and solvents.

The efficient production of *O*-methyl carbamates from aliphatic amines and DMC requires, as a rule, the use of catalysts such as basic compounds. With such catalysts the reaction is selectively performed under very mild conditions and an excellent hourly productivity is obtained, in the production of both monocarbamates and dicarbamates. The following isocyanate forming decomposition step can be performed in several ways: through purely thermal processes or through the aid of catalysts to improve the performance; in liquid phase, by diluting the carbamate in an inert high-boiling solvent, or in the gas phase; and in continuous or in batch processes. The required temperatures are, as a rule, in excess of 250°C because *O*-alkyl,*N*-alkyl carbamates are more resistant to decomposition than the aryl substituted counterparts. A relevant example is the process for hexamethylene diisocyanate (HDI) production studied and patented by EniChem.[26] Hexamethylenediamine (HDA) is transformed into the corresponding hexamethylene diurethane (HDU) in excess DMC, acting as a reactant and solvent at the same time 99% yield is obtained after a 0.5 hr reaction at 65°C in the presence of $NaOCH_3$ as catalyst. In a second step HDU undergoes a noncatalytic vapor phase thermolysis in a tubular reactor at 420–460°C, 30 torr residual pressure, and 1–3 sec contact time, to afford HDI with a 95% overall process yield, based on the amine.

A process for the nonphosgene production of aromatic isocyanates, like the largely produced commodity isocyanates TDI and MDI, would be of outstanding industrial interest. This goal will require solving formidable chemical and technological problems, to stand the competition with the existing phosgene processes. EniChem is currently actively pursuing the development of a DMC based production process for TDI and, following promising results obtained on the laboratory scale, further activity advancement involving design and operation of a pilot plant has been scheduled.

Dimethylcarbonate as Methylating Reagent

Dimethylcarbonate is a versatile reagent for methylation reactions at C, N, O, and S centers, behaving as a good substitute for dimethylsulfate or methylhalides that are toxic and corrosive.[1] For the mono-methylation of activated methylene groups in substrates such as arylacetonitriles, useful intermediates for antiinflammatory drugs, DMC is better than other methylating agents for selectivity to mono-methylated derivatives. Methylation of amines, amides, imide dyes, phenols, and thiols can be achieved by the reaction with DMC in liquid phase, in the presence of basic catalysts (e.g., carbonates of cesium or potassium) and phase transfer agents, or in gas phase, by gas–liquid phase transfer catalysis in the presence of polyethylene glycol (PEG 6000) or zeolites supported carbonates. Finally, gas-phase methylation of substituted phenols on alumina supported alkali metal salts was recently reported.[6]

Quaternary ammonium salts are obtained by exhaustive methylation of aliphatic tertiary amines.

An important application is the preparation, from trimethylamine and DMC, of electronic-grade tetramethylammonium hydroxide, free from chloride ion, by electrolysis of the hydrogen carbonate.

Dimethylcarbonate as Solvent

Dimethylcarbonate, represents a viable alternative to acetate esters and ketones in most applications, from paints to adhesives, taking advantage of its good solvency power. It should also be reminded that DMC is the file leader of many derived carbonic esters, available by transesterification reactions, whose properties can be tailored according to the target applications, like in the field of lubricating oils. Dimethylcarbonate, as a nonaqueous electrolyte component, is finding increasing application in the field of lithium rechargeable batteries, as witnessed by the number of patents in the area (more than 200 in the last 3 yr). A further example of DMC application is as a blowing agent in polyurethane foam after the ban on CFC.[27]

Dimethylcarbonate as Fuel Additives

In recent years, DMC has been taken into consideration as oxygenate to reduce vehicle emissions associated to environmental and health risks. The reasons are the outstanding oxygen content in the DMC molecule (53.3 wt%) combined with its good blending properties.[2]

In addition to its blending properties, there is one physical characteristic of DMC that is of paramount significance. The distribution of DMC in a gasoline/water two-phase system is much more favorable than for the C_1–C_3 light alcohols. Another characteristic of DMC that is a concern is its freeze point. Pure DMC freezes at 1°C (34°F). However, at 3–4 wt% in gasoline, DMC remains in solution without becoming cloudy or hazy below −40°C (−40°F).

Another characteristic of DMC that is important is hydrolysis. Dimethylcarbonate can react with water to produce methanol and CO_2. Conditions that favor this reaction are elevated temperature, excess free water, and alkali metal carbonates. Under normal circumstances, in gasoline without any free water, the reaction does not proceed at all. With a small amount of free water and adequate time and temperature, some of the DMC will enter aqueous phase and hydrolyze. In a completely aqueous system with an alkali carbonate catalyst present and elevated temperature, DMC hydrolyzes slowly. For example, DMC in water held at 70°C (158°F) for 1 week with ample K_2CO_3 present was hydrolyzed to methanol and CO_2 with a conversion of 50%.[2]

CONCLUSIONS

One of the most important goals of the chemical industry with respect to environmental issues is a reduction in the use of toxic materials and in the amount of waste generated. Industrial development of nonphosgene route to DMC production has resulted in DMC playing a significant role as a nontoxic versatile chemical and as a component of reformulated fuels. It is expected that the future will show a growing expansion of the current and new DMC applications.

Distillation Column Design: Packing

Andrew W. Sloley
VECO USA, Inc., Bellingham, Washington, U.S.A.

INTRODUCTION

Fractional distillation is the most widely used operation in the process industries. Applications cover the range from petroleum refining, gas processing, chemicals, to pharmaceuticals and foods. Process and mechanical design requirements must merge for successful application. Distillation column internal design meshes both mechanical and process requirements in a careful selection of packing and supporting internals.

The objective of mechanical layout and design of a distillation column is to construct and install equipment that creates the conditions that will meet the process design objectives of a distillation service. However, mechanical design considerations and process design objectives interact. Balancing mechanical convenience vs. process needs minimizes investment for any given process. Process design must take equipment limitations into account. It cannot require physically impossible equipment performance. Mechanical design must meet the process objectives. Mechanical convenience cannot override process necessities.

The general design guidelines here apply to liquid–vapor packing for heat-transfer and mass-transfer services. In addition to fractional distillation this includes many stripping, absorption, and other services. This discussion covers a range of common equipment situations. The objective of the discussion is to allow for a design sizing (overall height and diameter) of a straightforward, new distillation column. Complex columns and modified columns present many challenges requiring specialized application of design criteria. The references included direct the engineer to in-depth discussions on special design requirements.

WHEN TO USE PACKING

The main distillation devices are the tray and packing. Both trays and packing come in different types. Device selection requires balancing many competing factors. Table 1 lists the factors that favor each type of equipment. Final equipment selection is usually service specific.

For new tower design, packing is the favored choice in 1) low-pressure operation; 2) low-pressure drop operation; 3) high liquid-to-vapor ratios; 4) low liquid-to-vapor ratios; 5) ceramic and polymer materials of construction; and 6) weight and size critical installations.

PACKING SYSTEM DESIGN

Introduction

A wide variety of random packing and structured packing are available. For new construction, except for especially corrosive services, pressure drop critical applications, and special cases, economics drives fractionation equipment selection toward trays. Special cases include applications of very low liquid rates, and where equipment size is critical. Examples of critical equipment size include units on offshore platforms, towers in severe earthquake zones, and towers to be housed inside buildings.

Severely corrosive services that require ceramic or special polymer materials favor packing design as tray fabrication in anything but metal is extremely difficult and expensive. Packing, with its low pressure drop, is also the equipment of choice in most systems operating under vacuum.

The majority of packing installations go into existing tray towers for new operating conditions. Some combination of capacity increase, product quality improvement, or energy reduction may be the target. Revamp packing installations require critical attention to integration of the packing system with the existing equipment. Many unit failures have occurred from reusing distributors, feed devices, and draw pans designed for tray towers with packed towers.

The complexities of packing refits into an existing tower are well beyond the current scope of discussion. Here, we will concentrate on the simplest element of packed tower design, selection and verification of packing hydraulic performance, along with an introductory discussion of packing efficiency.

When faced with a packed tower, always keep in mind that packing involves an entire system, not just some mass-transfer surface. Packed towers include packing supports, packing, packing hold-down, feed distributors, internal redistributors, and other equipment. Fig. 1 shows a generic packed tower system.

Similar to trays, packing flooding has no clearly defined and commonly accepted definition. Different

companies will choose definitions that favor specific marketing approaches. Literature values often define flooding based on very subjective factors. Even the same engineer may observe different flooding points for the same packing during different tests because of dynamic behavior of system hydraulics and the subjective definitions in use.

When quoting packing percentage of flood two different numbers are referenced: 1) percentage of flood at constant vapor-to-liquid (V/L) ratio and 2) percentage of flood at constant liquid (L) load. These concepts come from graphical methods of packing selection. Fig. 2 shows a packing flooding curve. Flooding vapor load is shown vs. liquid load. The Souders–Brown coefficient (c_{SB}) represents the vapor load:

$$c_{SB} = V_s\sqrt{\frac{\rho_V}{\rho_L - \rho_V}} \quad (1)$$

where V_s is the superficial velocity of the vapor across the cross section of the tower (in ft/sec). For the example shown, the constant V/L flood is $AB/AC = 20/25.2 = 0.784 = 78.4\%$. The constant L flood is $DB/DE = 0.2/0.278 = 0.719 = 71.9\%$. V/L flood is most applicable to distillation applications where increases in capacity are handled at constant V/L, equipment constraints permitting. Constant L flood is most applicable to absorption applications where increased vapor may not have a corresponding increased liquid rate. A constant vapor (V) load flood can also be stated; however, by common usage this is rarely, if ever, used.

Across the usable loading range, packing hydraulics go through two major zones. First, as vapor load increases the packing pressure drop increases close to proportionally to the square of the vapor rate. In this zone, the unloaded region, liquid holdup is essentially constant and the liquid volume fraction in the packing is low. The pressure drop comes from the vapor head losses as it flows through the packing. Once the loading point is reached, liquid holdup varies with gas flow rate. This is the loading region. Vapor kinetic energy is now being used to support the extra liquid retained in the packing, hence the pressure drop varies with gas flow rate to some power greater than 2. Fig. 3 shows a typical packing pressure drop curve. In this case the pressure drop is shown as inches of fluid per foot of packing vs. c_{SB} for parametric flow rates.

Eventually, higher gas rates prevent liquid from flowing down the packing. Visually, a continuous liquid surface forms across the top of the packed bed. This is another classical definition of flooding. Translation of the classical definition to observed system behavior is difficult and subjective. Most available packing capacity data come from vendor tests. Typically, each vendor uses a definition suitable for the best presentation of their product. Vendors have had few incentives to clarify equipment comparisons. Caution should be used in comparing flooding predictions based on different data.

Design Basis

The most commonly used design procedure is based on the Sherwood–Leva–Eckert packing correlation curve, commonly referred to as the general pressure drop (GPD) correlation curve. Multiple versions of the curve and associated correlations have been developed. They differ in the correlation parameters used in

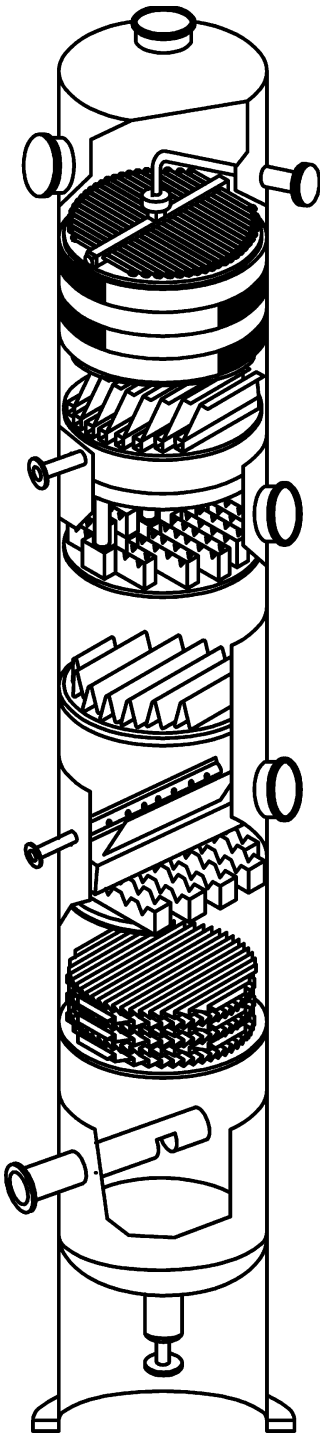

Fig. 1 Packed tower system. (Modified from Binkley, M.J.; Thorngren, J.T.; Gage, G.W.; Bonilla, J.A.; Beckman, D.H. Method of Downcomer-Tray Vapor Venting. U.S. Patent 5,106,556, Apr 21, 1992.)

defining the GPD curve axis. The GPD curve does not directly produce a ''flood'' load prediction. Rather, it predicts a pressure drop for a given loading. Then, the pressure drop is compared to a flooding pressure drop to get an approach to flooding.

The design method shown is a combination of the alternate form of the Norton method[1] for determining pressure drop coupled with the Kister and Gill[2] correlation for defining pressure drop at flood. The method works well for random packing. Limitations of the method and on the range of applicability are discussed at the end of the procedure. For structured packing, the apparent packing factor used in the equation varies with liquid and vapor load. Vendor curves should be obtained and used for proper evaluation of structured packing systems.

Both the design curve shown and the Kister and Gill correlation use a packing factor as the key definition of the packing's hydraulic capacity. Many researchers have attempted to define the packing factor by geometric analysis. However, the best definition of packing factor is that it is a correlating number that fits the packing performance to a pressure drop correlation curve. Because different pressure drop correlation curves are in use, packing factors reported from different sources may vary.[3–8] Test data are required to make fine distinctions between packing types.[9] Simple comparisons based on packing factors may be misleading.

Design Outline

The general design procedure for a new tower is:

1. Set design basis.
2. Selection of the packing type.
3. Detailed tower sizing for diameter and height: iterate on packing selection until overall design criteria are met.

Set design basis

Before starting work on the packed tower design obtain the following data:

1. Internal liquid and vapor traffic inside the column.
2. Vapor and liquid density, liquid viscosity, and surface tension.

The method shown does not take into account surface tension affects on capacity. Other detailed methods may include these.

The required liquid and vapor rates are the amount of liquid and vapor traversing the same plane through the packed bed. Owing to separation affects and heat transfer occurring concurrently with mass transfer the most loaded region of the packed bed may be at any point in the bed. Standard practice is to check

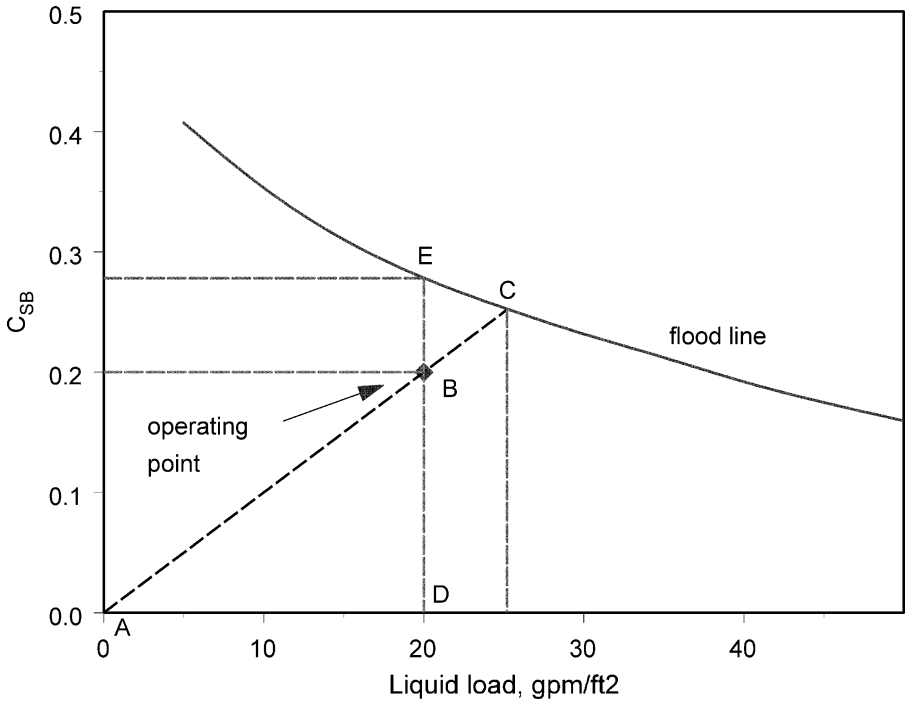

Fig. 2 Flooding capacity and constant V/L vs. constant L flood evaluation (graphical).

loading values from the bottom, middle, and top of the bed.

Today, engineers most often use simulation packages to calculate the vapor and liquid traffic. Care should be taken to extract the appropriate total stream rates and densities at operating conditions from the simulation. Many columns have failed as a result of taking incorrect flow rates or properties from the simulation.

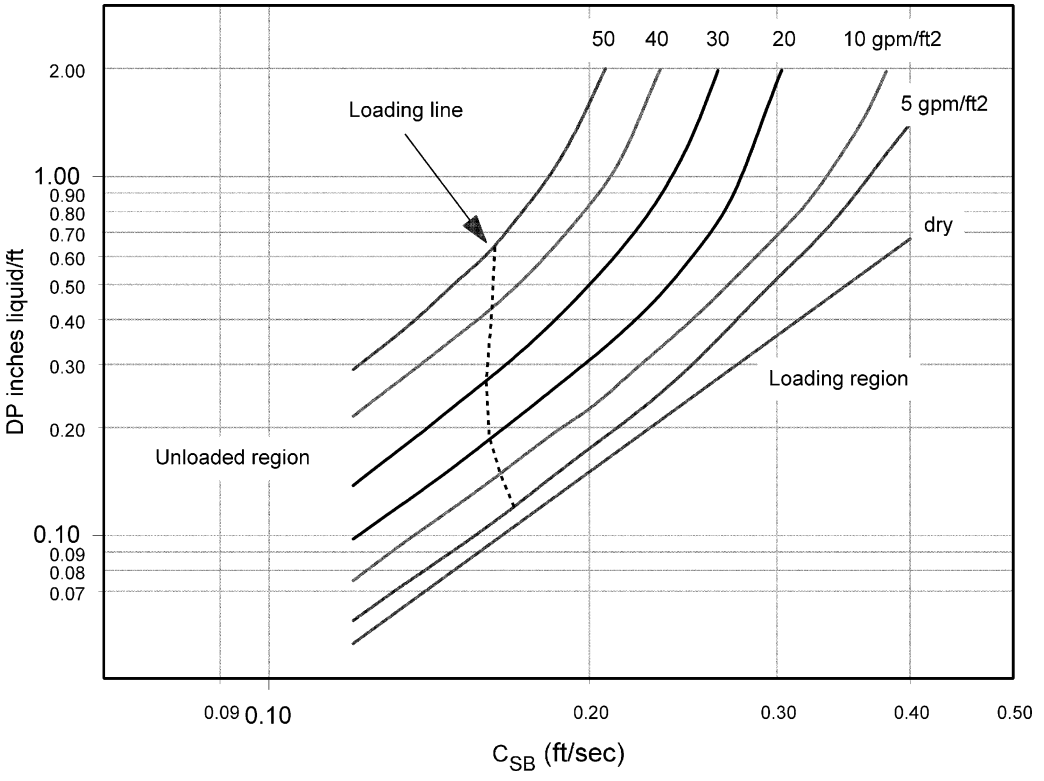

Fig. 3 Typical packing pressure drop curve.

Selection of packing type

Packing includes random packing, structured packing (sheet), grid, and wire-mesh packing. Fig. 4 shows the typical random packing available. Fig. 5 shows a typical structured packing brick. Fig. 6 shows a grid-type packing. Packing selection depends on balancing a variety of factors. Table 2 lists major packing selection criteria. Generally, most applications will call for either random packing or structured packing.

Type selection includes more than just hydraulic and efficiency evaluation. Other important factors include fouling resistance,[10] corrosion resistance, liquid holdup, ease of installation, ease of removal, and operability range.

Fouling arises from two mechanisms: introduction of foreign material in the unit feed streams and internal behavior and system characteristics. Packing is subject to fouling from both particulate and system sources. Liquid distributors are especially sensitive to particulate. Wire basket strainers should always be installed upstream of liquid feeds to packed columns. Fouling on the packing arises from materials being caught or sticking or is due to reactions at stagnant points in the packing. Random packing has more stagnant areas than structured packing or grid. In any given packing family, the more efficient the packing, the greater the tendency to foul. This is an important consideration in process selection of equipment for fouling services.

Packing is available in metal, polymers, and ceramics. In rare circumstances glass and wood packing has also been used. Materials selection depends on process requirements.

Metal packing is usually made of alloy material rather than carbon steel. The main reason for this is the susceptibility of carbon steel to corrosion during transport, storage, and installation. Unless the process requires carbon steel for specific reasons, it should never be used for packing.

Because of the thinness of the material, packing is very susceptible to damage during installation and inspection. Structured packing is extremely susceptible to handling damage. Damage to other internals may require removal of packing for access and support replacement. For this reason, in services where packing may need to be removed and reinstalled periodically, use of higher-grade materials and thicker materials in distributors and supports may be called for. Also, a minimum structured packing thickness of 0.008 in. (0.203 mm) should be specified if removal and reinstallation are required.

Random packing can be classed into first- through fourth-generation packing types. Raschig rings are the most widely known first-generation packing. The packing is a tube section. Second-generation random packing opens the interior of the tube to allow higher vapor flows. Pall rings are a traditional second-generation random packing. Third-generation random

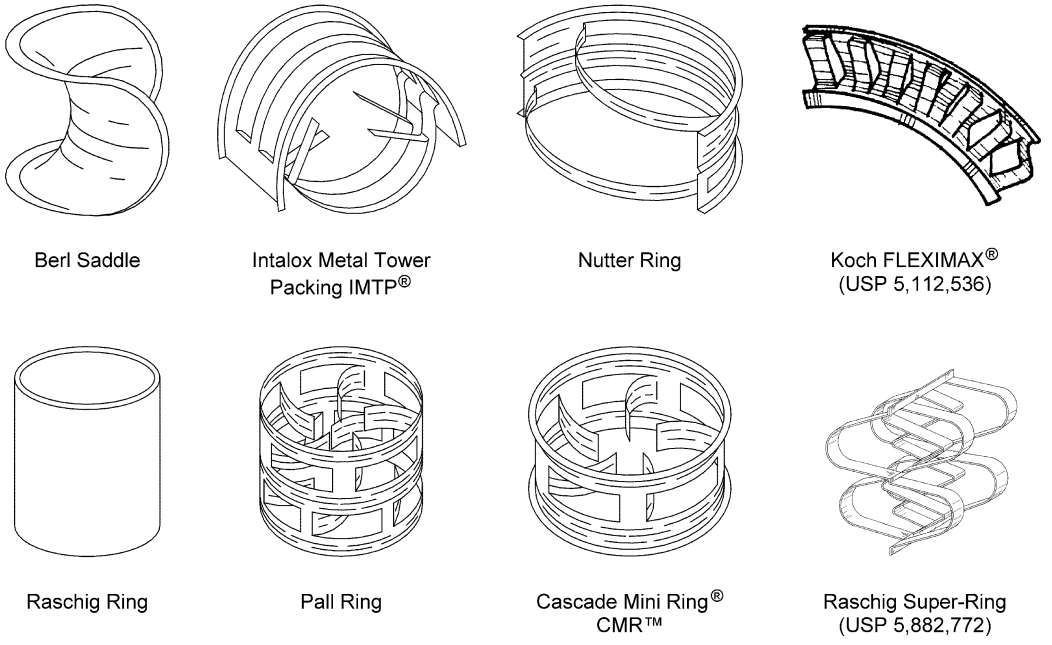

Fig. 4 Selection of random packing. (Illustration of Koch FLEXIMAX® from McNulty, K.J.; Yeoman, N.; Li-Hsieh, C. Random Packing Element and Method. U.S. Patent 5,112,536, May 12, 1992. Illustration of Raschig Super-Ring from Schultes, M. Packing Element for Use, in Particular, in Mass Transfer and/or Heat Transfer Columns or Towers. U.S. Patent 5,882,772, Mar 16, 1999.)

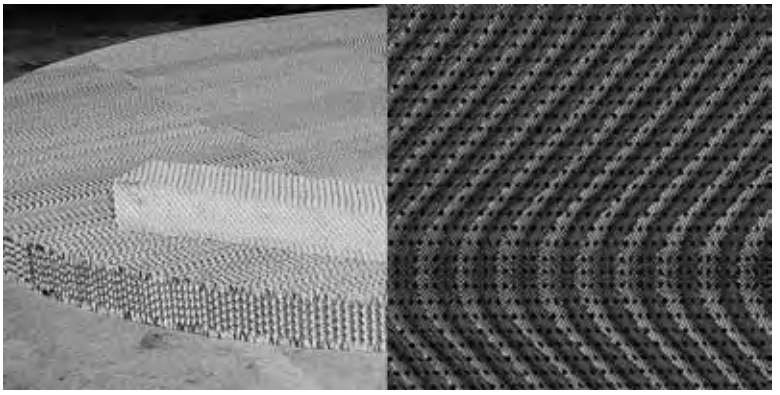

Fig. 5 Structured packing (Sulzer Mellapak® 252Y, courtesy of Sulzer Chemtech). Left shows overall packing layer. Right shows smooth flow direction change in center of packing layer used in this particular packing.

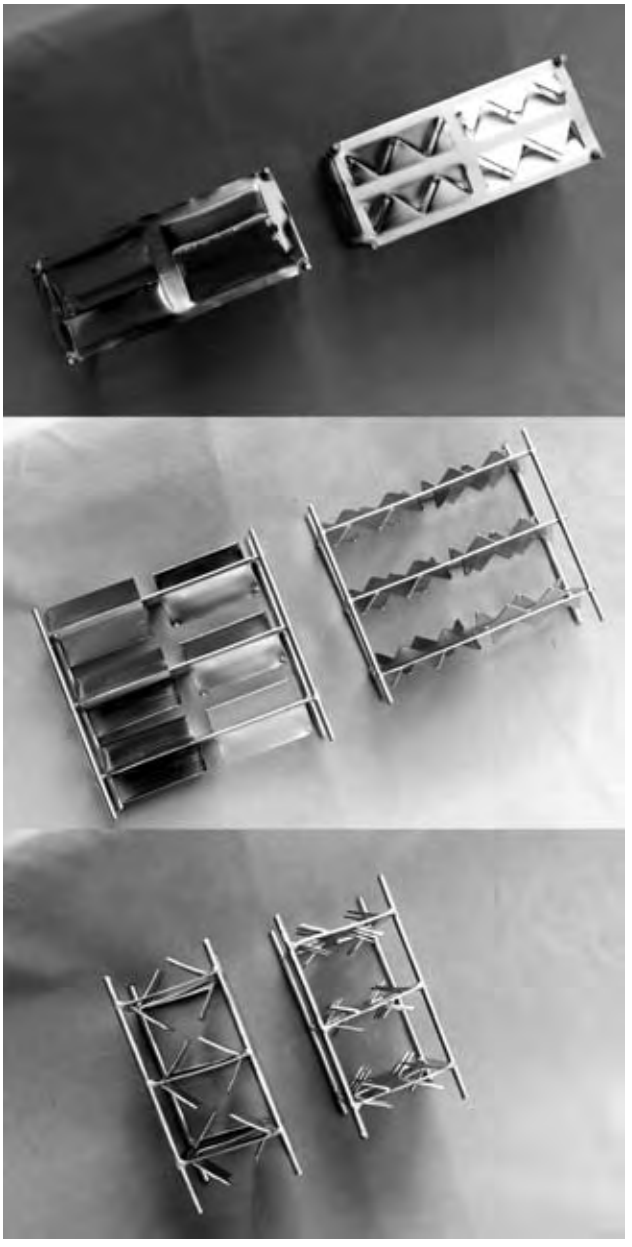

Fig. 6 Grid packing. Top, side, and end views of section of grid.

packing starts to use more complex shapes. The packing increases the number of potential drip points and film surface area for mass transfer. Third-generation random packing includes CMR™, Intalox® Rings, and Nutter Rings. Fourth-generation packing uses very complex shapes to optimize vapor and liquid mass transfer. These include the new Raschig SuperRing®. Overall, for any packing in a given generation, capacity and efficiency will be very similar for packing elements of the same dimension. Table 3 classifies commonly available packings.

At the present time, unless other factors are decisive, a third-generation random packing choice is the best starting point for packing installations. Situations where structured packing is the preferred choice include vacuum operation and where very high numbers of theoretical stages are required.

Detailed tower sizing

1. Determine the foaming tendency of the system. Pick a system factor, S_F, based on system experience or use typical values from Table 4.
2. Select a preliminary packing type. In general, select either a third-generation random packing or a structured packing.
3. For the desired packing, find its packing factor. Tables 5–8 list packing factors for some common packing types (author estimates[11–14]).
4. Calculate the pressure drop at flood for a nonfoaming system.

$$\Delta P_{\text{fnf}} = 0.115 F_{\text{PX}}^{0.7} \tag{2}$$

5. Calculate the pressure drop at flood for the actual system.

$$\Delta P_{\text{f}} = S_{\text{F}} \Delta P_{\text{fnf}} \tag{3}$$

Table 2 Initial packing selection

Factor	Favors	Reason
Liquid rate less than $0.5\,\text{gpm/ft}^2$ ($0.76\,\text{m}^3/\text{m}^2$)	Large-size packing	Liquid distributor design limits
Vacuum systems	Large-size packing Structured packing	Low-pressure drop
Expensive materials	Structured packing	Metal thickness
Fouling	Grid	Few dead spots in flow
High vapor rates	Large-size packing	Capacity vs. cost
High number of stages required	Small-size packing Structured packing	Minimize overall height
Low number of stages required	Large packing sizes	Minimum bed depth vs. height restrictions
High vapor–liquid density difference	Structured packing	Improved vapor–liquid separation
Low vapor–liquid density difference	Random packing	Known cause of structured packing hydraulic failures
Small diameter (revamps)	Small packing sizes Structured packing Woven wire-mesh packing	Natural distribution limits with random packing in small relative diameters

6. Determine the flow parameter

$$X = \frac{L}{V}\sqrt{\frac{\rho_V}{\rho_L}} \tag{4}$$

with L and V in consistent mass units and ρ_L and ρ_V in consistent units.

7. Using the modified GPD curve (Fig. 7), the flow parameter (X), and the flood pressure drop, find the allowable packing load parameter, L_F. Fig. 7 shows pressure drop isobars at flood for different flow parameters.
8. Determine the Souders–Brown coefficient at flood:

$$c_{SB} = \frac{L_F}{F_{PX}^{0.5}\ \nu_L^{0.05}} \tag{5}$$

with liquid kinematic viscosity, ν_L, in centistokes and with

$$\nu_L = \frac{\mu_L}{L_{SG}} \tag{6}$$

with μ_L in centipoise.

9. Determine the vapor superficial velocity V_s:

$$V_s = \frac{c_{SB}}{\sqrt{\frac{\rho_V}{\rho_L - \rho_V}}} \tag{7}$$

where V_s is in feet per second and densities are in consistent units.

10. Calculate the tower cross-sectional area required for operation at flood:

$$A_{CSF} = \frac{V}{\rho_V V_s} \tag{8}$$

where A_{CSF} is in square feet, V is in pounds per second, ρ_V is in pounds per cubic feet, and V_s is in feet per second.

11. Calculate the tower cross-sectional area required for operation at the design flooding fraction:

$$A_{CS} = \frac{A_{CSF}}{F_F} \tag{9}$$

The design flooding fraction is commonly 0.8 (80% of flood) for most new units. The value should never be higher the 0.95.

12. Find the tower diameter:

$$D = \sqrt{1.27 A_{CS}} \tag{10}$$

where A_{CS} is in square feet and D is in feet.

13. Calculate the design vapor velocity:

$$V_s = \frac{V}{\rho_V A_{CS}} \tag{11}$$

where V_s is in feet per second, V is in pounds per second, ρ_V is in pounds per cubic feet, and A_{CS} is in square feet.

14. Calculate the Souders–Brown coefficient for the design diameter:

$$c_{SB} = V_s\sqrt{\frac{\rho_V}{\rho_L - \rho_V}} \quad (1)$$

where c_{SB} is in feet per second, V_s is in feet per second, and density is in consistent units.

15. Calculate the design packing load factor, L_F:

$$L_F = c_{SB}F_{PX}^{0.5}\nu_L^{0.05} \quad (12)$$

Table 4 System factors

Service	System factor
General systems	
Nonfoaming	1.0
Low foaming	0.9
Moderate foaming	0.85
High foaming	0.70
Severe foaming	0.60
Foam stable	0.30
Specific systems	
C3–C6 hydrocarbons	1.0
Low-molecular-weight alcohols	1.0
Atmospheric crude petroleum	1.0
Oxygen stripper	1.0
Rectisol contactor	1.0
Halogens	0.90
Cryogenic gas plant absorbers	1.0–0.85
Oil absorbers	0.85
Amine regenerators	0.85
Glycol regenerators	0.85
Water strippers	0.70–0.80
Amine absorbers	0.70
Glycol absorbers	0.70
Methyl ethyl ketone (MEK) units	0.60
Caustic regenerators	0.30

with liquid kinematic viscosity ν_L in centistokes.

16. From Fig. 7 with the design packing load factor from Step 15 and the flow parameter X from Step 6 find the design pressure drop in inches of water.
17. Verify the packing size and diameter of the column. Column diameter should be a minimum of 10 times the packing size for random packing. Column diameters smaller than this criterion have a significant risk of excessive liquid and vapor channeling. Select a new packing size as needed.

LIMITATIONS AND APPLICABILITY

All packing correlation methods for hydraulics have systemic limitations. These limits arise from the underlying correlation forms and the difficulty in data interpretation. Table 9 lists applicability ranges for Fig. 7. Strigle and Kister and Gill both have excellent discussions of the limitations of the method shown. In summary, the limitations are:[1,2]

1. Over the entire range of data examined the pressure drop correlation fits ~40% of the data with an excellent fit, ~40% with a good fit, ~15% with a reasonable fit, and ~5% with a poor fit.
2. Flow parameters, X, from 0.05 to 0.3 give good fits. This is the normal operating range for atmospheric distillation systems.
3. At flow parameters greater than 0.3 with nonaqueous systems the pressure drop curves are optimistic. Actual pressure drops will typically be higher than that predicted for a given load. This operating region is typical of high liquid rates and high-pressure systems (vapor density >0.05 liquid density).
4. At flow parameters less than 0.05 the predicted pressure drop is nearly independent of the flow parameter. Pressure drop in this operating range tends to be higher than predicted. This operating range is typical of vacuum operation.

To correct for pressure drop at flow parameters greater than 0.3, the flooding pressure drop on the GPD correlation, the author modifies the predicted pressure drop at flood by:

$$\Delta P_{\text{fnfc}} = L_{\text{SG}}^{-0.33} 0.115 F_{\text{PX}}^{0.7} \tag{13}$$

This equation should be used in place of equation Eq. (2) and ΔP_{fnfc} is used in place of ΔP_{fnf} in Eq. (3). Care should be taken to understand this correction. The pressure drop at flood is actually the same [continue to use Eqs. (2) and (3) to determine the predicted pressure drop at flood]. The correction is to get a correlating factor that gives a more conservative definition of allowable vapor velocity from Fig. 7. This correction gives a good fit to hydrocarbon systems.

For conservative design at flow parameters less than 0.05, use the value of 0.02 for the flow parameter.

PACKING EFFICIENCY

Packing efficiency is even more difficult to predict than hydraulic capacity. For prudent design, data are mandatory from the actual operating system or a very similar system. Operating and test data have resulted in many, many surprises when comparing demonstrated vs. predicted efficiency.

Packing efficiency is an extremely complex function of system properties (density, diffusivity, relative volatility, surface tension, wetting tendency, composition, and other factors), packing geometry, and loading. No effective predictive method based on fundamentals is available. Even comparing different types of packing is difficult. In one service a specific packing may be more efficient than another. In a different service, the relative efficiency may be reversed. The only reliable general rule is that a physically smaller packing will have a higher efficiency than a geometrically identical, larger packing.

Table 5 Packing factors: random packing, metal

Packings are grouped into columns of similar size.

The following method for predicting efficiency is based on the Norton method for IMTP packing.[15] It should be used with extreme caution if system-specific performance data are not known. It is no worse than other methods and has the benefit of simplicity. The method should only be used for rough evaluation of packing for checking the general feasibility of a design.

Packing height can be evaluated with either the transfer-unit or the height equivalent theoretical plate (HETP) approach. Traditionally, the transfer-unit approach has been used with absorption and stripping systems and the HETP approach for fractionation services. The method used here is the HETP approach. The method is applicable to distillation and reboiled stripping services for nonaqueous, nonreacting, nonionizing, systems with a relative volatility less than 3:

$$\text{HETP} = K_{21}\left[\frac{\sigma}{20}\right]^{-0.16}(1.78)^{\mu_L} \tag{14}$$

for $\mu_L < 0.4$ cP.

$$\text{HETP} = K_{22}\left[\frac{\sigma}{20}\right]^{-0.19}\left[\frac{\mu}{0.2}\right]^{0.21} \tag{15}$$

for $\mu_L > 0.4$ cP.

Tri-pack			28	25	16	12

Packings are grouped into columns of similar size.

Tables 10–12 show K_{21} and K_{22} values for HETP (in in. and mm) and surface tension (in dyn/cm) for a selection of packings.

A design factor of 1.13 should be applied to these HETP values to account for the differences between HETP values found in test installations and those found in commercial units:

$$\text{HETP}_{\text{design}} = 1.13\text{HETP} \tag{16}$$

The total packing height needed for the service is then calculated by:

$$H_{\text{P}} = N_{\text{t}}\text{HETP}_{\text{design}} \tag{17}$$

The author's experience is that the HETP values calculated from this method tend to be systemically optimistic. A 10% extra safety margin should be applied to these values.

BED HEIGHT LIMITATIONS

Packing bed heights are limited for both process and mechanical reasons. Liquid maldistribution in packed beds reduces efficiency by having localized liquid ratios that differ from the average across the bed. The taller the bed, the more significant is the efficiency degradation. As a good practice, packed bed heights should be limited to 10 theoretical stages or less and 20 ft (6.1 m) or less.

All types of packing are subject to a limitation on bed height to avoid excessive crush loads on the bottom packing layers in a bed. The problem is most common in random packing and structured packing installations. To avoid crushing during installation and operation, aluminum materials should not be used in beds over 12 ft (3.66 m) deep or at operating temperatures in excess of 400°F (205°C). Ceramic packing should be limited to bed heights of 20 ft (6.10 m) or less. This avoids excessive breakage during installation and operation. Polypropylene packing

should be restricted to operation at temperatures of 200°F (93°C) or lower. Care should be taken when polypropylene packing is to be specified that the tower will not be steamed out during shut-down or start-up operations. Some engineering plastics have higher temperature-resistant capabilities but are significantly more expensive.

For a typical design 2 ft (0.61 m) of extra height is required for each redistributor when using pan-orifice distributors and 4 ft (1.22 m) of extra height is required for each redistributor when using trough-orifice distributors.

INTERNALS REQUIRED WITH PACKING

Auxiliary equipment in packing installations includes:

- Bed supports
- Bed hold-downs
- Liquid collectors
- Liquid distributors and redistributors
- Vapor distributors and redistributors.

Design of this equipment is specialized. Standard references for these equipment types are included in the References. The following discussion covers the general issues involved.

Bed supports provide for safe support of the packed bed while not interfering with the flow of vapor and liquid through the grid. Additionally, the support grid must have sufficient strength to support the weight of packing in the bed, the inspection personnel on the bed, the liquid retained on the packing during operation, and the upset forces possible during sudden foaming and vaporization incidents. Selection of load criteria must take all these factors into account.

Random packing support grids use holes small enough to prevent random packing pieces from falling through the grid and down the tower. The most effective design uses a vapor injection style. The support grid has large corrugations that increase the overall surface area available for vapor flow. The hole area open for liquid and vapor flow should be equal to or greater than the tower cross-sectional area. The corrugation size is set by the tower diameter and manway access size. Fig. 8 shows a vapor injection support.

Structured packing and grid packing support grids use a flat subway grate construction to allow for proper placement of the structured packing bricks on the support. This allows for a high degree of strength with a minimum reduction in the area available for vapor and liquid transport up and down the tower.

During upset operation with random packing, sudden load increases can lead to packing displacement or fluidization of a random packing bed. Standard designs use a mesh-type structure or a subway-grating-type grill. The holes in the mesh or grill must be smaller than the packing size. As little as possible of the tower cross-sectional area should be taken up by the hold-down.

Standard hold-downs (such as subway grating) can be used with structured packing. As an alternative, rods can be used to tie a hold-down grid and packing support grid together.

Liquid collectors provide for withdrawal of products, mixing of new feeds with the internal liquid traffic, and remixing to avoid composition gradients after a certain height of packed bed has been traversed. Liquid collectors are often designed as one item to be integral with vapor distributors and liquid redistributors.

Under normal service conditions, the liquid collector is a separate tray from any liquid distribution device. The basic collector is a chimney tray with a sump (Fig. 9). The chimneys provide passage for vapor rising through the tray. The sump(s) provides for liquid drainage into a draw nozzle (for product draw) or into transition piping to a redistributor. Unless fully welded, chimney trays will leak. In all critical services, chimney trays must be fully welded.

Passages on chimney trays should be designed so that liquid can easily flow into product draws and sumps. If blockage of liquid draws is a potential

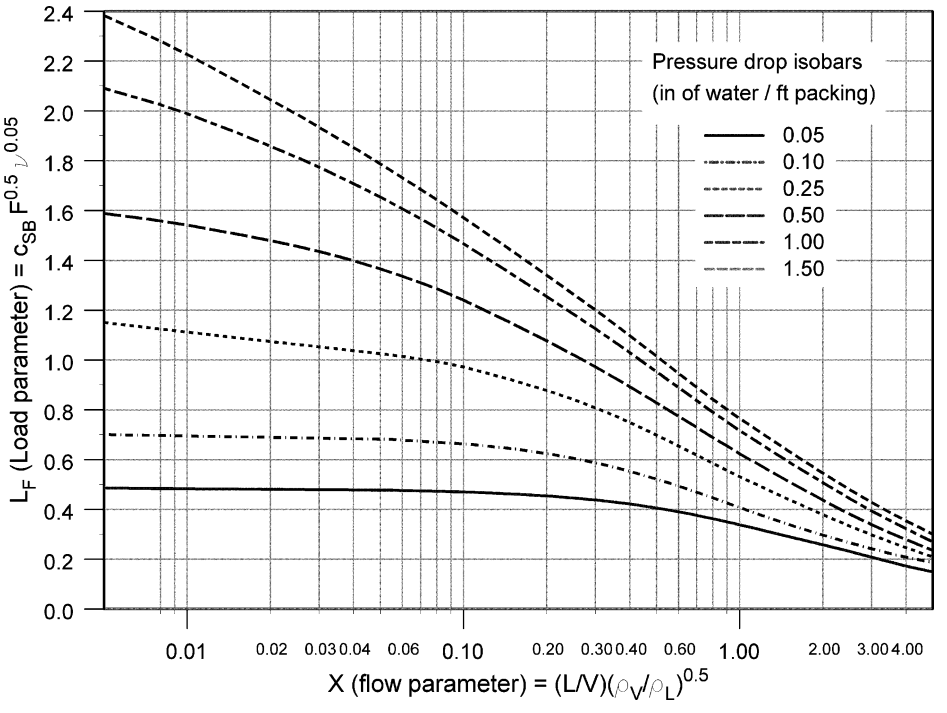

Fig. 7 General pressure drop curve.

problem, internal overflows can be added. This usually takes the form of emergency overflow down-pipes to prevent excessive buildup of liquid on the collector. Additionally, in fully welded designs, external draw nozzles and internal transfer piping should be located to enable full draining of the tray during shut-downs.

Liquid distributors function to spread an even distribution of liquid over the packing bed. Liquid distributors are commonly broken down by motive force into pressurized or gravity distributors. Pressurized distributors include pipe-orifice distributors and spray distributors. Gravity distributors include pan-orifice distributors and trough distributors.

Pressurized liquid distributors use pressure drop across an orifice to deliver a smooth liquid distribution to a packed bed. Two main types exist, pipe-orifice distributors and spray distributors. Of the two, spray distributors are the most common. In specifying either type, the main criteria to be set are the pressure drop available for use and the minimum orifice size. These must be set in conjunction with the definition of the flow rate required.

In pipe-orifice distributors, each orifice delivers a liquid stream to the packed bed. Pipe orifice distributors have the advantage that they are relatively compact and occupy a small vertical space in the tower. However, they tend to be very expensive. A separate orifice is needed for each drip point onto the packing. Typical designs call for between 5 and 15 drip points per square foot (50 and 150 drip points per square meter). The minimum orifice size is set by the fouling tendency of the system. Liquid velocities leaving the orifice should be kept to under 10 ft/sec (3 m/sec). This prevents excessive liquid splashing on the top of the packed bed.

In spray-header distributors (Fig. 10), a main header with a collection of spray nozzles is used to distribute liquid to the packed bed. Spray header distributors are well suited to liquid distribution at low liquid rates, of moderately fouling fluids, and for

Table 9 Sherwood–Leva–Eckert correlation data range

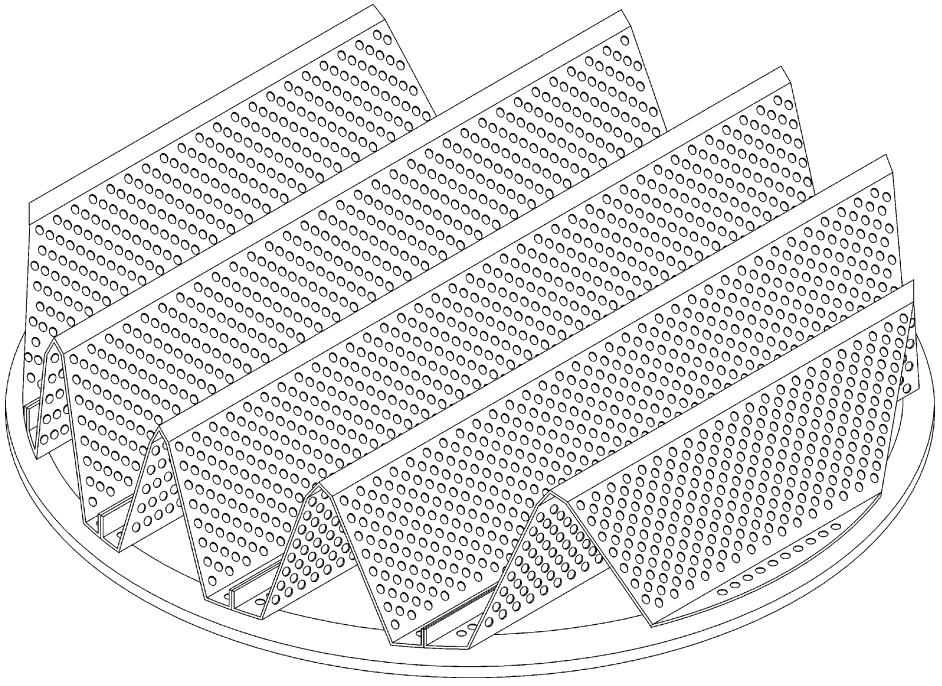

Fig. 8 Random packing vapor injection support.

heat-transfer services. Spray headers are much less expensive than pipe orifice headers because of the relatively small number of spray points. However, a spray nozzle tends to concentrate liquid along the outer periphery of the spray. For this reason, spray nozzles should never be used for distillation, absorption, or stripping services that require a large number of mass-transfer units per bed.

Spray nozzle spray angles and droplet size formation are functions of the pressure drop across a spray header. Effective pressure drop range for a spray nozzle distributor varies from 5 to 20 psi (from 34 to 138 kPa) for good design practice. Specific designs may operate outside this range.

Gravity liquid distributors use an internal head of liquid to flow through the distributor to the packed

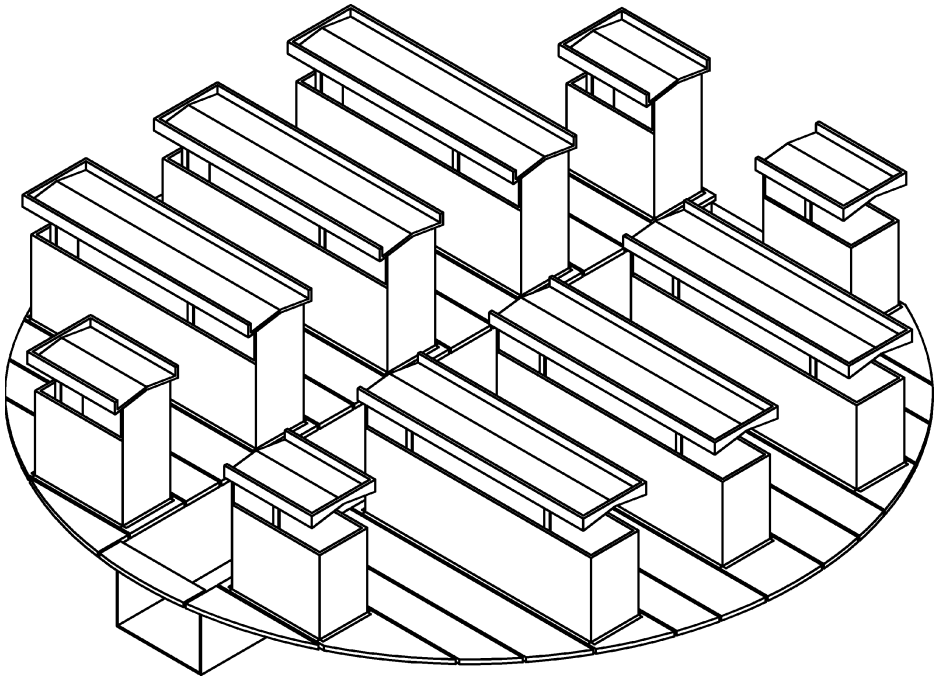

Fig. 9 Chimney collector tray.

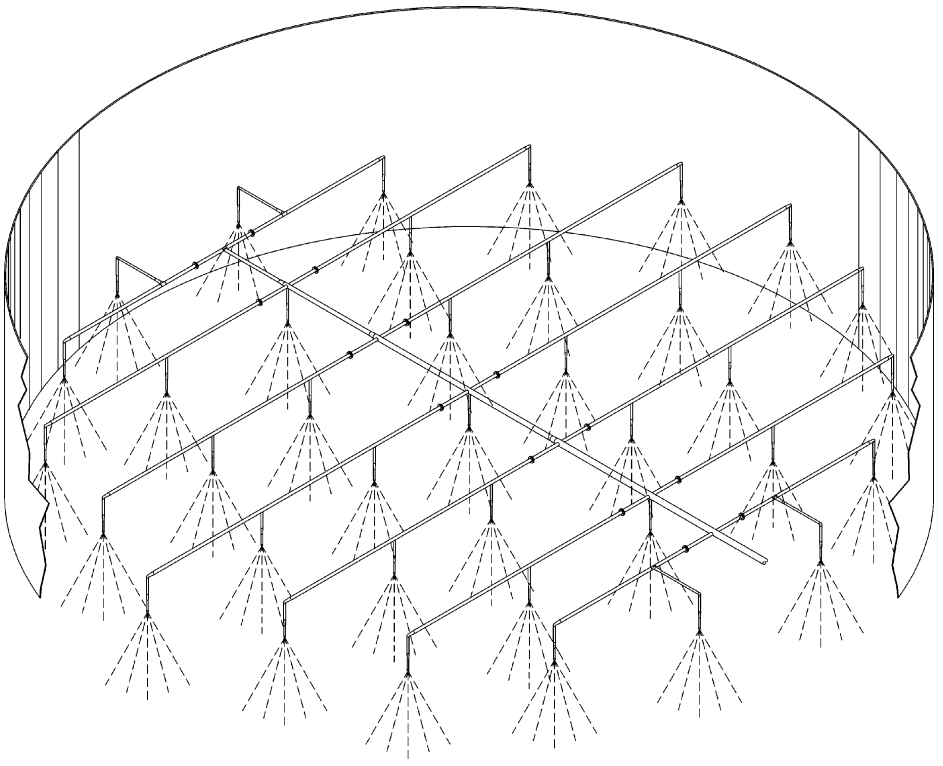

Fig. 10 Spray nozzle distributor.

bed. Two main types are available, pan-orifice distributors and trough distributors.

Pan-orifice distributors depend on liquid height on a pan to provide sufficient head for the liquid to flow through holes in the pan to the packed bed below. Pan-orifice distributors also include vapor chimneys for vapor to rise past the tray.

Of critical importance in deciding on the suitability of pan-orifice distributors is the degree of levelness expected in the installation and in the quality of distribution required. Flow through the orifice holes in the pan varies with the square root of the liquid height above the trap minus the pressure drop of the vapor through the distributor (expressed in height of liquid).[16] All liquid on the orifice pan is in one pool. When a liquid product is drawn from an orifice pan, a liquid gradient across the pan is set up. Moore and Rukovena[17] present the basic calculation methods for determining the liquid gradient on a pan-orifice distributor.

Whenever a product draw is taken from a collector pan, the liquid flow through any orifice hole depends on the local height. This guarantees that some degree of liquid maldistribution will take place. Additionally, orifice-pan distributors are installed on tray rings welded to the tower wall. If the tray ring is not level, the orifice pan will have liquid maldistribution caused by the out-of-level installation.

To avoid maldistribution due to out-of-level and by liquid draws, some manufacturers install tubes through the pan floor. This is intended to reduce flow maldistribution by guaranteeing a minimum liquid height for lateral flow toward the product draw on the pan during all operations. While this is an improvement, it is not an effective solution for the inherent limitations of this type of device.

Trough distributors (Fig. 11) use a preliminary distribution box (parting box) to meter a proportional flow to each of a series of troughs below the parting box. Each trough has a number of drip holes punched along the side. The liquid height required in both the parting box and the trough is a function of the flow range required. A typical flow range design for a trough distributor with round holes is a 2 : 1 turndown ratio. At a minimum height of 4 in. (100 mm) in the parting box (to avoid flow gradients along the box) a 2 : 1 flow range requires a 16 in. (400 mm) tall parting box. Hole areas above each trough are punched proportionate to the total area of the tower that the trough serves.

Slotted and v-notched distributor designs should be avoided. These designs are subject to large variations in local liquid distribution because of small manufacturing and installation errors.

Vapor distributors ensure a smooth vapor distribution before the vapor enters the packed bed. They fall into two classes. The first class consists of those that distribute the vapor flow profile by imposing a pressure drop on the vapor steam. The second class consists of devices that mechanically redistribute the vapor flow by means of vanes.

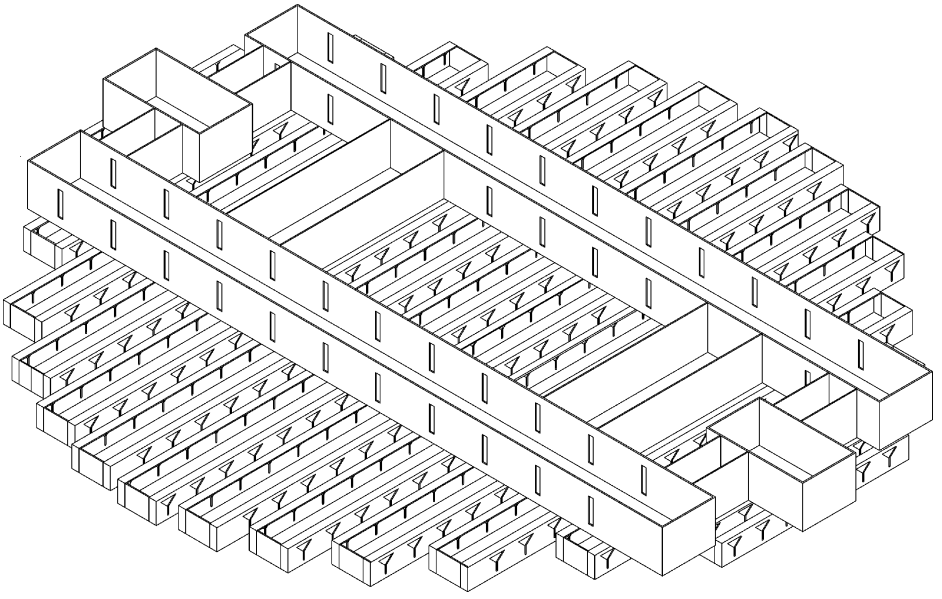

Fig. 11 Trough-orifice distributor.

Pressure vapor distribution devices are trays with orifice chimneys. They are usually constructed integrally with a liquid collector. The main difference between a liquid collector designed for liquid collection only and one designed for vapor redistribution as an additional function is in the open area available for vapor flow and the positioning of the vapor chimneys. Orifice plates welded to the tray deck under the vapor risers impose the specified pressure drop. Spacing between the top of the chimney hats and the packed bed above is set so that the angle from the hat to the bed required to give full diffusion of the rising vapor is 15° or less. Standard practice is to use chimney trays with a large number of small hats in vapor distribution service. This helps to ensure an even distribution of the vapor to the packed bed above.

Vane vapor distributors use directional vanes to ensure vapor distribution of a vapor stream. Vane-type distributors are commonly used for distribution of high-velocity, mixed-phase feeds. Various proprietary and patented designs are in use. Both radial entry and tangential entry designs are available. Tangential entry designs are the better choice for two-phase flows. However, radial entry designs will work acceptably for most applications.

CONCLUSIONS

Fractional distillation, absorption, and stripping are the most common separation unit operations. All these services can use packing to achieve their mass-transfer objectives. Effective hydraulic and mass-transfer design for packing involves selection of both the packing and the auxiliary internals. The other internals include packing supports, hold-downs, and liquid and vapor distributors. When properly selected, packing meets the combined process and mechanical requirements of the service. The process and mechanical requirements are not independent. The equipment must work, and it must work as part of a process to achieve plant objectives. Applications for packing cover the gamut of the petroleum refining, petrochemical, gas processing, and chemical industries. The general design criteria here cover standard design issues for new towers. Revamps often involve extremely complex balancing of mechanical possibilities vs. process risk to meet economic and operating targets.

NOMENCLATURE

A_{CS}	Total tower cross-sectional area
A_{CSF}	Tower cross-sectional area at flooded operation
c_{SB}	*c*-factor (Souders–Brown factor)
ΔP_f	Pressure drop at flood, packing
ΔP_{fnf}	Pressure drop at flood for a nonfoaming system, packing
F_F	Flooding fraction
F_{PX}	Factor, packing
H_P	Height of packing
L	Total liquid flow (mass or volume units as applicable)
L_F	Load parameter
L_{SG}	Liquid specific gravity
μ_L	Liquid absolute viscosity, (centipoises)

ν_L	Liquid kinematic viscosity, (centistokes)
N_t	Number of theoretical stages
ρ_L	Density, liquid
ρ_V	Density, vapor
σ	Surface tension (dyn/cm)
S_F	System factor
V	Total vapor flow (mass or volume units as applicable)
V_s	Velocity, superficial vapor velocity through the tower's entire cross section
X	Flow parameter

Distillation Column Design: Trays

Andrew W. Sloley
VECO USA, Inc., Bellingham, Washington, U.S.A.

INTRODUCTION

The objective of mechanical layout and design of a distillation column is to construct and install equipment that creates the conditions that will meet the process design objectives of a distillation service. However, mechanical design considerations and process design objectives interact. Balancing mechanical convenience vs. process needs minimizes investment for any given process. Process design must take equipment limitations into account. Process design cannot require physically impossible equipment performance. Mechanical design must meet the process objectives. Mechanical convenience cannot override process necessities.

The general design guidelines here apply to liquid–vapor trays for heat-transfer and mass-transfer services. In addition to fractional distillation this includes many stripping, absorption, and other services.

This discussion covers a range of common equipment situations. The objective of the discussion is to allow for design sizing (overall height and diameter) of a straightforward, new distillation column. Complex columns and modified columns present many challenges requiring specialized application of design criteria. The references direct the engineer to an in-depth discussion of special requirements.

WHEN TO USE TRAYS

The main distillation devices are the tray and packing. Both trays and packing come in different types. Device selection requires balancing many competing factors. Table 1 lists the factors that favor each type of equipment. Final equipment selection is usually service specific.

For new tower design, without overriding process factors, the cheapest overall system (tower, foundation, internals) is normally a sieve or a valve tray. Both have essentially the same capacity. The driving force behind valve tray selection is the flexibility benefit of the valve tray at little additional cost. However, for larger diameters and higher liquid rates, the flexibility advantage of the valve tray is more illusory than factual.[1]

TRAY OPERATION

Basic Tray Operation

Tray contacting devices include both downcomer trays and downcomer-less trays. Trays with downcomers constitute the vast majority of tray installations. Fig. 1 shows a typical downcomer tray.

Liquid from the tray above descends a downcomer to the tray below. In the downcomer, the vapor in the liquid leaving the active area de-entrains. The downcomer inlet panel deflects the liquid sideways to the active area. Mass-transfer contacting devices on the active area intimately mix the liquid and rising vapor. The aerated liquid leaves the tray by entering the downcomer. In the space above the active area, the entrained liquid falls out of the vapors and returns to the tray deck. Fig. 1 shows the function of the tray zones.

The mass-transfer devices may be sieves (holes), fixed valves, moveable valves, or bubble caps. Fig. 2 shows a selection of mass-transfer devices.[2,3] The purpose of the device is intimate mixing of the vapor and liquid on the tray deck. An ideal device has high capacity, high flexibility, low leakage, low pressure drop, and low cost.

Vapor mixing into the liquid through the mass-transfer device creates the tray's active area. The active area may have either liquid as the continuous phase (froth regime) or vapor as the continuous phase (spray regime).

TRAY LIMITATIONS

Depending on tray type, at least 10 different operating modes can limit tray operation. Entrainment flood (jet flood) and downcomer filling set the upper capacity limit. Weeping and dumping set the lower operating limit. Other limits, including downcomer choking, system limit, blowing, and downcomer sealing constraints, restrict operation in specific situations.

Jet flooding includes situations where the rising vapor velocity is sufficient to prevent liquid droplets from disengaging from the vapor above the tray deck. Jet flooding can be reduced by increasing tray spacing.

Downcomer flooding includes situations where the liquid cannot get down the downcomer. Depending on the cause it can be reduced by increasing tray

spacing, increasing downcomer volume, and reducing tray pressure drop.

Weeping and dumping set the lower operating limit of most tray designs. Weeping is liquid droplets bypassing the tray active area by falling through the contacting devices.

TRAY DESIGN

Introduction

Bubble-cap trays are rarely used in modern tower installations unless service specific reasons dominate the selection criteria. Based on the author's experience, valve tray installations outnumber sieve trays by approximately three to one. For these reasons, the tray design procedure given here is for valve trays. The most common valve tray methods are based on the Glitsch, Koch Engineering, and Nutter Engineering correlations.[4–6] Other, less commonly used methods are also available.[7]

For entrainment flooding (jet flood), all the correlations give useable results though the Glitsch correlation appears to be slightly more accurate than the Koch method. Both the Glitsch and the Koch correlations have a tighter fit to the data than the Nutter correlation. Given the subjective nature of judging the flood point, most statistical differences between the correlations are

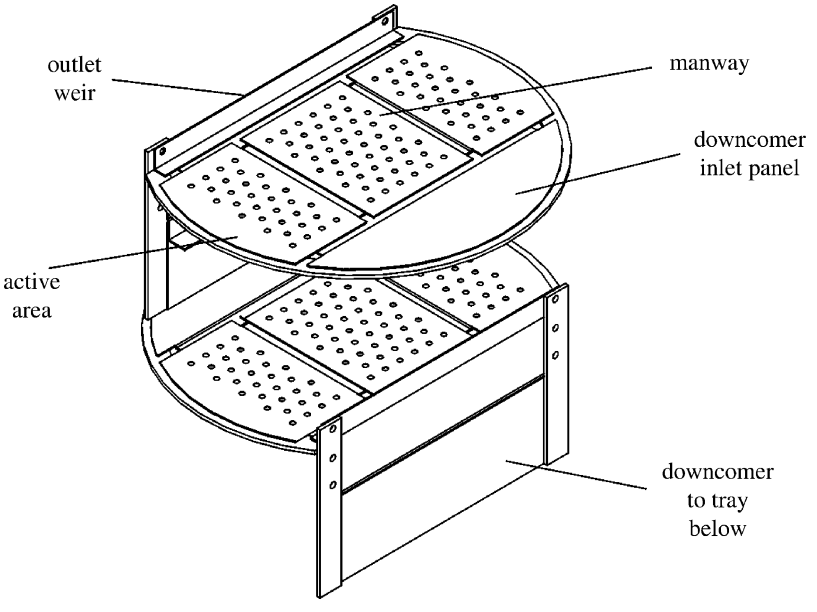

Fig. 1 Typical downcomer tray and functional areas.

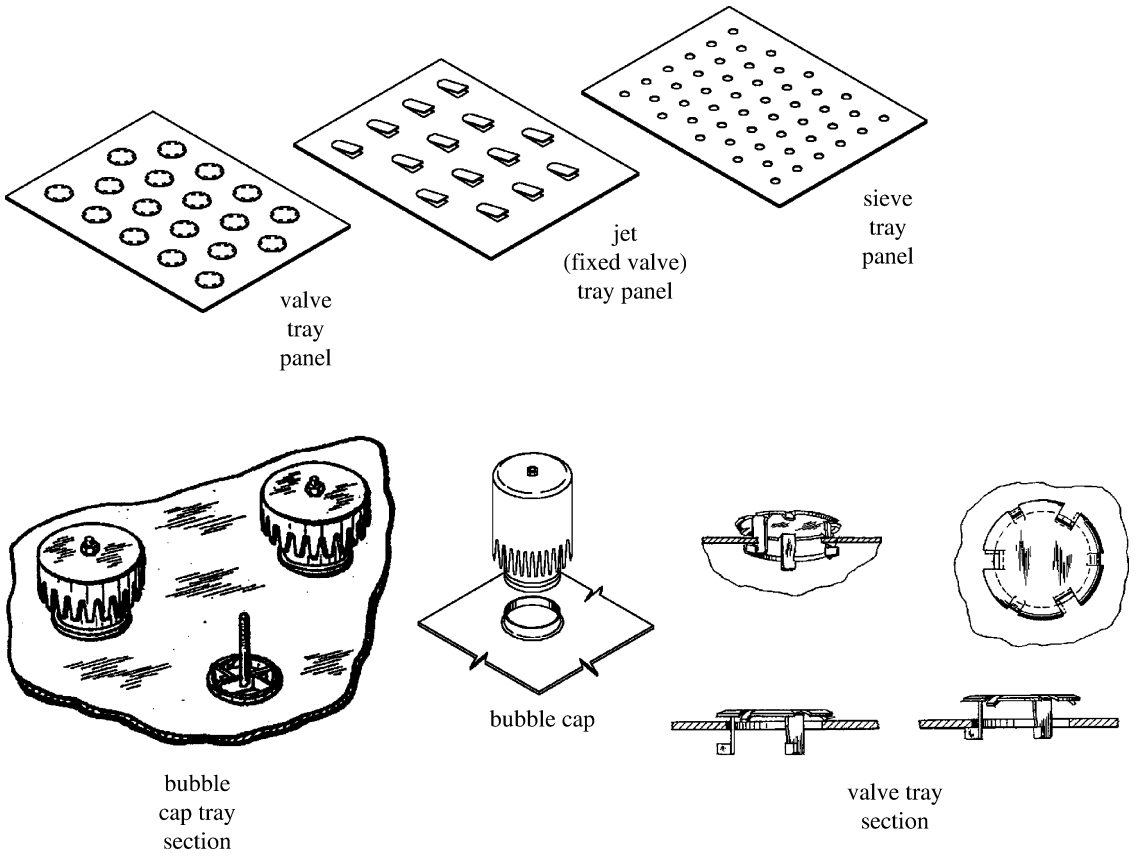

Fig. 2 Mass-transfer devices: bubble caps and valve sections. (From Refs.[2,3].)

not significant. Capacity differences between the different standard valve types are minimal.

In contrast, the literature methods for downcomer flooding have poor accuracy. Error bands for correlation results show poor results. Proprietary methods, including the FRI and TZF methods, give excellent results but are not generally available.[8]

The method shown is a modified version of the Glitsch method. Jet flood results for low-vapor-density operation ($<1.5\,lb/ft^3$, $<24\,kg/m^3$) are generally accurate. Application of the method is valid for tray spacing between 12 and 48 in. (30–122 cm).

Tray design is complex and design optimization involves many steps and decisions. Entire books have been written on the subject. The procedure here is for a general system with no special features. For those investigating the subject in detail the standard references are only a starting point for detailed discussions.[9–11]

Design Outline

The general design procedure for a new tower is:

1. Set design basis
2. Preliminary design of the tower: set diameter, tray spacing, and tray passes
3. Detailed design and pressure balance: iterative procedure using the preliminary design as a starting point.

Set Design Basis

Before starting work on the tray design obtain the following:

1. Internal liquid and vapor traffic inside the column
2. Vapor and liquid density.

The method shown does not take into account surface tension and viscosity effects. Other detailed methods may require these.

The required liquid and vapor rates are the amount of vapor entering the tray and the amount of liquid leaving the tray. This combination gives the correct pressure balance for the liquid inventory in the downcomer and the vapor pressure drop loss through the tray (Fig. 3). Today, engineers most often use simulation packages to calculate the vapor and liquid traffic. Care should be taken to extract the appropriate

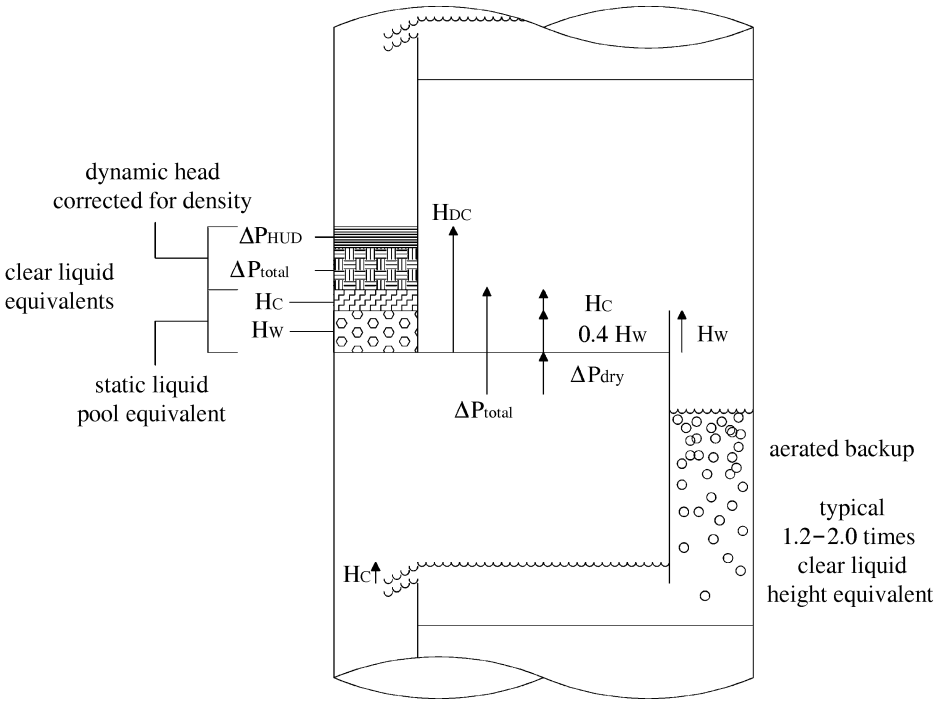

Fig. 3 Tray pressure balance—vapor entering the tray and liquid leaving the tray.

total stream rates and densities at operating conditions from the simulation. Many columns have failed as a result of taking incorrect flow rates or properties from the simulation.

Most columns use a 24 in. (61 cm) tray spacing for access room during inspection and installation. Use 24 in. (61 cm) as the starting point unless the column is expected to be very tall (over 100 stages), use very expensive materials of construction, or have a very large diameter. For tall columns made of expensive materials consider a shorter tray spacing and for columns with a very large diameter consider a taller tray spacing.

Preliminary Design

1. Determine the foaming tendency of the system. Pick a system factor, S_F, based on system experience or use typical values from Table 2. This factor will apply to both the downcomer and the active area design.
2. Estimate a design downcomer velocity using the following three equations and take the lowest value:

$$V_{DD} = K_1 S_F \quad (1)$$

$$V_{DD} = K_2 \sqrt{\rho_L - \rho_V} \quad (2)$$

$$V_{DD} = K_3 \sqrt{T_S} \sqrt{\rho_L - \rho_V} \quad (3)$$

Where V_{DD} is in feet per second, ρ is in pounds per cubic feet, T_S (tray spacing) is in inches, then $K_1 = 0.557$, $K_2 = 0.0914$, and $K_3 = 0.0167$. Where V_{DD} is in meters per second, ρ is in kilograms per cubic meter, T_S (tray spacing) is in centimeters, then $K_1 = 0.170$, $K_2 = 0.00696$, and $K_3 = 0.000799$.

3. Select a downcomer target flooding fraction, F_D. A typical design value for a new column would be 0.80 (80%). This value does not have to be the same as the jet flood design value.
4. Determine the minimum design downcomer area:

$$A_{DM} = \frac{L}{V_{DD} F_D} \quad (4)$$

where L and V_{DD} have consistent units of cubic feet per second and feet per second or cubic meters per second and meters per second, respectively. If L is in gallons per minute (gpm), multiply L by 0.00223 to convert to cubic feet per second.

5. Calculate the column vapor load:

$$V_{load} = V \sqrt{\frac{\rho_V}{\rho_L - \rho_V}} \quad (5)$$

where V_{load} and V are in cubic feet per second or cubic meters per second, and ρ is in consistent units.

Table 2 System factors

Service	System factor
General systems	
Nonfoaming	1.0
Low foaming	0.9
Moderate foaming	0.85
High foaming	0.70
Severe foaming	0.60
Foam stable	0.30
Specific systems	
C3–C6 hydrocarbons	1.0
Low-molecular-weight alcohols	1.0
Atmospheric crude petroleum	1.0
Oxygen stripper	1.0
Rectisol contactor	1.0
Halogens	0.90
Cryogenic gas plant absorbers	1.0–0.85
Oil absorbers	0.85
Amine regenerators	0.85
Glycol regenerators	0.85
Water strippers	0.70–0.80
Amine absorbers	0.70
Glycol absorbers	0.70
Methyl ethyl ketone (MEK) units	0.60
Caustic regenerators	0.30

6. Calculate the dry tray capacity factor:

$$c_{AFO} = T_S^{1/2}(K_4 - K_5\rho_V) \quad (6)$$

or

$$c_{AFO} = K_6 T_S^{0.65}\rho_V^{1/6} \quad (7)$$

if vapor density is less than $0.17\,lb/ft^3$ ($2.72\,kg/m^3$). Where c_{AFO} is in feet per second, T_S is in inches, and ρ is in pounds per cubic feet, then $K_4 = 0.0933$, $K_5 = 0.00293$, and $K_6 = 0.0833$. Where c_{AFO} is in meters per second, T_S is in centimeters, and ρ is in kilograms per cubic meter, then $K_4 = 0.0178$, $K_5 = 0.0000350$, and $K_6 = 0.00873$.

7. Select an active area target flooding fraction, F_A. A typical design value for a new column would be 0.80 (80%). This value does not have to be the same as the downcomer flood design value. Optimized designs use the same value, F_F, for both jet flood and downcomer flood.
8. Estimate a required active area using the following two equations and taking the highest value:

$$A_{AM} = K_7\frac{V_{load}}{S_F} \quad (8)$$

$$A_{AM} = \frac{V_{load} + K_8 L}{c_{AFO}F_A S_F} \quad (9)$$

Where A_{AM} is in square feet, c_{AFO} is in feet per second, and V_{load} and L are in cubic feet per second, then $K_7 = 4.00$ and $K_8 = 0.828$. If L is in gallons per minute, multiply L by 0.00223 to convert to cubic feet per second. Where A_{AM} is in square meters, c_{AFO} is in meters per second, and V_{load} is in cubic meters per second and L is in cubic meters per hour, then $K_7 = 13.1$ and $K_8 = 0.828$.

9. Check the minimum downcomer area. If A_{DM} is less than $0.11A_{AM}$ then modify the minimum downcomer area to the smaller of:

$$A_{DM} = 0.11A_{AM} \quad (10)$$

$$A_{DM} = 2A_{DM} \quad (11)$$

[from Eq. (4)].

10. Calculate the tower cross-sectional area.

$$A_{TM} = A_{AM} + 2A_{DM} \quad (12)$$

Calculate the tower diameter:

$$D = \sqrt{1.27A_{TM}} \quad (13)$$

Detail Design and Rating

This procedure is for approximate design and rating of one-pass or two-pass valve trays. Again, the procedure is based on the Glitsch design method. In design, tray sizes can be restricted by mechanical considerations for valve pattern and layout and minimum panel sizes for internal man-ways. Steps 1–3 establish the basic layout of the downcomer for designing cases. This starts with the areas calculated in the preliminary design procedure. For rating an existing tray, skip to Step 4 and use the existing tray dimensions.

1. Select the general pass configuration, one-pass or two-pass. Fig. 4 shows the tray layout and terminology. Higher liquid loads favor two-pass design. Acceptable liquid load ranges are 2–10 gpm/in. of weir length ($0.0267–0.134\,ft^3/sec/ft$, $8.94–44.7\,m^3/h/m$). Rates below 1 gpm/in. ($0.0134\,ft^3/sec/ft$, $4.47\,m^3/h/m$) and above 18 gpm ($0.240\,ft^3/sec/ft$, $80.5\,m^3/h/m$) should be strenuously avoided. Straight, chordal weir lengths can be determined from downcomer widths (rises) by:

$$W = 2\sqrt{2RH_1 - H_1^2} \quad (14)$$

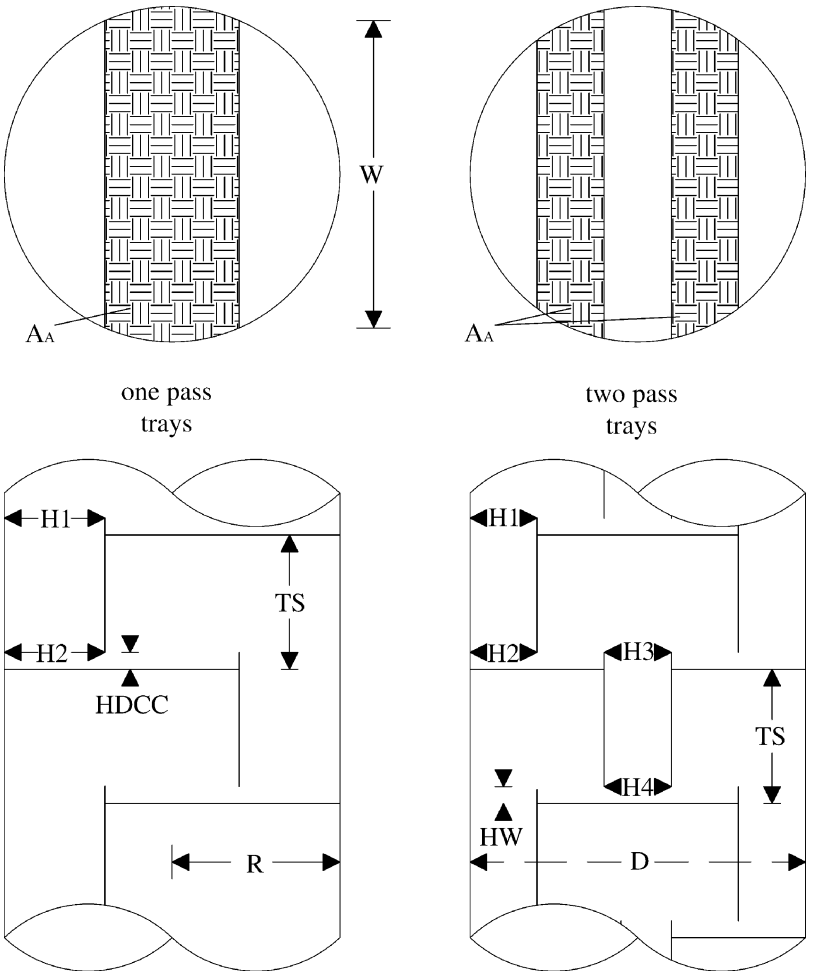

Fig. 4 Tray layout and terminology. One-flow-path and two-flow-path trays.

or downcomer areas by:

$$S - \sin S = \frac{2A_{DC}}{R^2} \tag{15}$$

and then

$$W = 2R \sin\left(\frac{S}{2}\right) \tag{16}$$

where S is in radians.

Eqs. (14–16) are for one-pass trays. For two-pass trays the total downcomer area is halved before calculating the weir length. The weir length is then doubled to account for both downcomers. Two-pass tray weir loads are limited by the liquid flow into the downcomers on the tower edge (outboard downcomers).

2. Dimension downcomers: Based on the areas and the downcomer, active areas and total areas determine the dimensions H_1, H_2, and L_{FP} for one-pass trays as:

$$S - \sin S = \frac{2A_{DC}}{R^2} \tag{15}$$

where S is in radians. Then,

$$H_1 = H_2 = R\left(1 - \cos\frac{S}{2}\right) \tag{17}$$

($H_1 = H_2$ for straight, vertical downcomers.)

$$L_{FP} = D - H_1 - H_2 \tag{18}$$

For two-pass trays, Eqs. (14) and (16) define H_1 for the outboard downcomer and half the total downcomer area A_{DC} is used. H_3, the center downcomer width, can be calculated by assuming the center downcomer is a rectangle. This gives good results for nearly all towers:

$$H_3 = H_4 = \frac{A_{DC}}{D} \tag{19}$$

($H_3 = H_4$ for straight, vertical downcomers.)

$$L_{FP} = \tfrac{1}{2}(D - H_1 - H_1 - H_3) \tag{20}$$

3. Check the downcomer and flow path length dimensions. Internal man-ways inside the tower require a minimum flow path length of 16 in. (40.6 cm). If the flow path length is less than

16 in. (40.6 cm) and internal man-ways are required, increase the tower dimensions to get a 16 in. (40.6 cm) F_{PL}. If the downcomer widths are less than 6 in. (15 cm) consider increasing the tower size to get a 6 in. (15 cm) wide downcomer. Update the flow path length, L_{FP}, and downcomer dimensions, and tower diameter as required.

4. Calculate the downcomer area. For outboard (side downcomers):

$$A_{DC1} = R^2 \cos^{-1}\left(\frac{R - H_1}{R}\right) - (R - H_1)\sqrt{2RH_1 - H_1^2} \quad (21)$$

An alternate approximation gives areas with a less than 1% error:

$$W = 2\sqrt{2RH_1 - H_1^2} \quad (14)$$

$$A_{DC1} \approx \frac{2}{3}WH_1 + \frac{H_1^3}{2W} \quad (22)$$

Use the entire area for one-pass trays; for two-pass trays, use half the total area for A_{DC}. For the inboard (center) area of two-pass trays use the approximation:

$$A_{DC3} = H_3 D \quad (23)$$

5. Calculate the active area:

$$A_A = A_{CS} - 2A_{DC1} \quad (24)$$

for one-pass trays or

$$A_A = A_{CS} - 2A_{DC1} - A_{DC3} \quad (25)$$

for two-pass trays.

6. Calculate vapor load:

$$V_{load} = V\sqrt{\frac{\rho_V}{\rho_L - \rho_V}} \quad (5)$$

where V_{load} and V are in cubic feet per second or cubic meters per second, and ρ is in consistent units.

7. Calculate the tray capacity factor, c_{AF}:

$$c_{AFO} = T_S^{1/2}(K_4 - K_5\rho_V) \quad (6)$$

or

$$c_{AFO} = K_6 T_S^{0.65}\rho_V^{1/6} \quad (7)$$

if vapor density is less than 0.17 lb/ft^3 (2.72 kg/m^3). Where c_{AFO} is in feet per second, T_S is in inches, and ρ is in pounds per cubic foot, then $K_4 = 0.0933$, $K_5 = 0.00293$, and $K_6 = 0.0833$. Where c_{AFO} is in meters per second, T_S is in centimeters, and ρ is in kilograms per cubic meter, then $K_4 = 0.0178$, $K_5 = 0.0000350$, and $K_6 = 0.00873$.

$$c_{AF} = c_{AFO}S_F \quad (26)$$

8. Calculate the jet flooding fraction and jet flooding percentage. This is equivalent to the Glitsch Equation 13[4] for flooding:

$$F_F = \frac{V_{load} + (LL_{FP}/K_9)}{A_A c_{AF}} \quad (27)$$

$$F_P = 100F_F \quad (28)$$

Where c_{AF} is in feet per second, V_{load} and L are in cubic feet per second, L_{FP} is in feet, A_A is in square feet, then $K_9 = 2.42$. Where c_{AF} is in meters per second, V_{load} is in cubic meters per second, L in cubic meters per hour, L_{FP} is in centimeters, A_A is in square meters, then $K_9 = 0.738$. Where c_{AF} is in feet per second, V_{load} is in cubic feet per second, L is in gallons per minute, L_{FP} is in inches, A_A is in square feet, then $K_9 = 13{,}000$.

9. Estimate the number of valves. Valve density varies between 12 and 14 per square foot depending on tray layout and geometry. Use an average of 13 valves per square foot (140 valves per square meter) or the actual number of standard valves ($1\frac{17}{32}$ in., 39 mm diameter) to rate a tray:

$$N_u = K_{10}A_A \quad (29)$$

Where A_A is in square feet, then $K_{10} = 13$. Where A_A is in square meters, then $K_{10} = 140$.

10. Calculate hole area in valves:

$$A_H = \frac{N_u}{K_{11}} \quad (30)$$

Where A_H is in square feet, then $K_{11} = 78.5$. Where A_H is in square meters, then $K_{11} = 845$.

11. Calculate hole vapor velocity:

$$V_H = \frac{V}{A_H} \quad (31)$$

12. Calculate dry tray pressure drop. The pressure drop is calculated for two cases, assuming valves full open and assuming valves part open. Use

the larger value of the two.

$$\Delta P_{\text{dry}} = K_{12} V_{\text{H}}^2 \frac{\rho_{\text{V}}}{\rho_{\text{L}}} \tag{32}$$

for valves full open

$$\Delta P_{\text{dry}} = K_{13} t_{\text{m}} \frac{\rho_{\text{M}}}{\rho_{\text{L}}} + K_{14} V_{\text{H}}^2 \frac{\rho_{\text{V}}}{\rho_{\text{L}}} \tag{33}$$

for valves part open.

Most trays are 10–14 gage for stainless steel and 12–16 gage for special alloys. Table 3 lists values of K_{12} for various tray deck thicknesses. Table 4 lists a selection of tray material densities and Table 5 lists conversions for gage in millimeters.

Where ΔP_{dry} is in inches of liquid at conditions, V_{H} is in feet per second, t_{m} is in inches, and ρ_{L}, ρ_{M}, and ρ_{V} are in consistent units, then the value of K_{12} is as given in Table 3, $K_{13} = 1.35$, and $K_{14} = 0.20$. Where ΔP_{dry} is in millimeters of liquid at conditions, V_{H} is in meters per second, t_{m} is in millimeters, and ρ_{L}, ρ_{M}, and ρ_{V} are in consistent units, then K_{12} is as given in Table 3, $K_{13} = 1.35$, and $K_{14} = 54.7$.

60. Check dry tray pressure drop. The dry tray pressure drop should be less than 20% of the tray spacing ($\Delta P_{\text{dry}} < 0.2 T_{\text{S}}$). If not, increase the tray spacing or increase the active area. In some cases, increasing the valve density may be acceptable.
61. Calculate the liquid crest over the outlet weir:

$$H_{\text{C}} = K_{15} \left(\frac{L}{W} \right)^{2/3} \tag{34}$$

Where H_{C} is in inches, L is in cubic feet per second, and W is in feet, then $K_{15} = 4.47$. Where H_{C} is in millimeters, L is in cubic meters per second, and W is in meters, then $K_{15} = 554$. Where H_{C} is in inches, L is in gallons per minute, and W is in inches then $K_{15} = 0.4$.

This is a version of the Francis weir formula without modification for weir height.[12]

Table 3 Dry tray pressure drop coefficients

Tray thickness (in.)	0.074	0.104	0.134	0.187	0.250
K_{12}	1.18	0.95	0.86	0.67	0.61
Tray thickness (mm)	1.88	2.64	3.40	4.75	6.35
K_{12}	323	260	235	183	167

Table 4 Metal densities

	Density

Aluminum	168	2,690
Copper	560	8,970
Lead	708	11,340

Fig. 3 illustrates the pressure balance locations for the tray.

62. Calculate the total tray pressure drop. The total tray pressure drop is the dry tray pressure drop plus the height of the liquid on the tray deck. Aeration is assumed to reduce the tray liquid density to 40% of the nonaerated liquid density.

The weir height, H_{W}, usually varies from 1 to 3 in. (2.5–7.5 cm). Two inches (5 cm) is a typical value. For heights above 15% of the tray spacing reduce the effective tray spacing for jet flood by the excess over 15%:

$$\Delta P_{\text{total}} = \Delta P_{\text{dry}} + H_{\text{C}} + 0.4 H_{\text{W}} \tag{35}$$

ΔP_{total} is the height of liquid at conditions. To convert to other units:

$$\Delta P_{\text{total psi}} = \frac{\Delta P_{\text{total in. of liquid}} \rho_{\text{L}}}{1728} \tag{36}$$

$$\Delta P_{\text{total mmHg}} = \frac{\Delta P_{\text{total in. of liquid}} \rho_{\text{L}}}{33.3} \tag{37}$$

$$\Delta P_{\text{total kPa}} = \frac{\Delta P_{\text{total mm of liquid}} \rho_{\text{L}}}{101,900} \tag{38}$$

Table 5 Tray deck thickness

	t_{m}	
Gage	**(in.)**	**(mm)**
20	0.037	0.940
18	0.050	1.27
16	0.060	1.52
14	0.074	1.88
12	0.104	2.64
10	0.134	3.40

16. Calculate the downcomer escape area:

$$A_{DCE} = H_{DCC}W \tag{39}$$

For sloped downcomers adjust W (weir length) to the correct value for the downcomer bottom edge. Downcomer clearance, H_{DCC}, is typically a minimum of 1 in. (25.4 mm) and is usually 0.5 in. (12.7 mm) less than the outlet weir height to maintain a positive seal on the downcomer.

17. Calculate the velocity under the downcomer:

$$V_{UD} = \frac{L}{A_{DCE}} \tag{40}$$

18. Calculate the head loss under the downcomer:

$$\Delta P_{HUD} = K_{16}V_{UD}^2 \tag{41}$$

Where ΔP_{HUD} is in inches of liquid at conditions and V_{UD} is in feet per second, then $K_{16} = 0.65$. Where ΔP_{HUD} is in millimeters of liquid at conditions and V_{UD} is in meters per second, then $K_{16} = 178$. Alternately, ΔP_{HUD} may be calculated directly from liquid load and tray dimensions by:

$$\Delta P_{HUD} = K_{17}\left(\frac{L}{WH_{UD}}\right)^2 \tag{42}$$

Where ΔP_{HUD} is in inches of liquid at conditions, L is in gallons per minute, W and H_{UD} are in inches, then $K_{17} = 0.06$.

19. Calculate the downcomer backup:

$$H_{DC} = H_W + K_{18}\left(\frac{L}{W}\right)^{2/3} + (\Delta P_{total} + \Delta P_{HUD})\left(\frac{\rho_L}{\rho_L - \rho_V}\right) \tag{43}$$

Where H_{DC}, ΔP_{total}, and ΔP_{HUD} are in inches, L is in cubic feet per second, ρ is in consistent units, and W is in feet, then $K_{18} = 4.47$. Where H_{DC}, ΔP_{total}, and ΔP_{HUD} are in millimeters, L is in cubic meters per second, ρ is in consistent units, and W is in meters, then $K_{18} = 554$. Where H_{DC}, ΔP_{total}, and ΔP_{HUD} are in inches, L is in gallons per minute, ρ is in consistent units, and W is in inches, then $K_{18} = 0.4$.

The downcomer backup (clear liquid height basis) should be 40% or less of the tray spacing for high-vapor-density systems (>3.0 lb/ft^3, 48.1 kg/m^3), 50% or less for medium-vapor-density systems, and 60% or less for low-vapor-density systems (<1.0 lb/ft^3, 16.0 kg/m^3).

One of the major weaknesses in the method is that it does not account for varying vapor entrainment into the downcomer with changes in vapor rate.

20. Check design flexibility. The minimum vapor for no leakage through the tray is defined by the vapor kinetic energy to liquid density ratio, E:

$$E = V_H^2\frac{\rho_V}{\rho_L} \tag{44}$$

The acceptable value of E depends on the liquid height on the tray.

$$H_L = H_C + H_W \tag{45}$$

Table 6 shows the lower value of E for different liquid heights on the tray. This is the point at which liquid leakage through the valves begins. Values lower than that shown indicate leakage. This check does not calculate direct leakage rates.

Many trays function well even with some leakage. Leakage rates of up to 10% have a negligible effect on tray efficiency. Leakage up to 25% typically reduces tray efficiency by approximately 10%. Various strategies can be used to reduce leakage. These include changing valve types, using a mix of valves of different densities, and increasing tray spacing and using fewer valves (increase the hole velocity).

ADDITIONAL TRAY FEATURES

Specific service requirements may require additional tray features to improve operation. Many features result from either very high or very low liquid and vapor rates. High-liquid-rate design choices include

Table 6 Tray lower flexibility

Liquid level (in.)	1.0	1.5	2.0	2.5	3.0	3.5	4.0
E (ft^2/sec^2)	0.122	0.202	0.281	0.348	0.476	0.562	0.672
Liquid level (cm)	2.5	3.75	5.1	6.4	7.6	8.9	10.
E (m^2/sec^2)	0.0113	0.0188	0.0261	0.0323	0.0442	0.0522	0.0624

antijump baffles, modified arc and multichordal downcomers, and swept-back weirs. Low-liquid-rate design choices include picket fence weirs and splash baffles. High-vapor-rate choices include sloped downcomers and hanging downcomers. Low-vapor-rate trays may require careful allocation of holes or valves to prevent bypassing. Large flexibility range and solids handling also require many special design features.[13,14]

Multiple-pass trays use antijump baffles at high liquid rates to prevent downcomer choking (Fig. 5). On the center and offside downcomers for multiple-pass trays, large liquid jumps and vapor expansion in the outlet liquid can cause downcomer inlet choking. Deflecting the entering liquid prevents flooding. If the specific vapor load exceeds a tray liquid loading factor, then antijump baffles should be used.

$$W_{FP} = \frac{A_A}{L_{FP}} \tag{46}$$

If

$$\frac{V_{load}}{A_A} > K_{19} - K_{20}\left(\frac{L}{W_{FP}}\right) \tag{47}$$

use antijump baffles.

Where V_{load} is in feet per second, A_A is in square feet, L is in cubic feet per second, and W_{FP} is in feet, then $K_{19} = 0.336$ and $K_{20} = 7.18$. Where V_{load} is in cubic meters per second, A_A is in square meters, L is in cubic meters per second, and W_{FP} is in meters, then $K_{19} = 0.102$ and $K_{20} = 23.6$. Where V_{load} is in cubic feet per second, A_A is in square feet, L is in gallons per minute, and W_{FP} is in inches, then $K_{19} = 0.336$ and $K_{20} = 0.0192$.

Multichordal downcomers can increase weir length (Fig. 6). Fig. 6 shows a combined multichordal and stepped downcomer. The increased weir length decreases the liquid crest height over the weir. This decreases total tray pressure drop. The stepping is a variation of a sloped downcomer. The step increases the downcomer inlet area with a minimum decrease in tray active area.

Swept-back weirs increase the weir length and decrease the active area of the tray (Fig. 7). They are often the lowest-cost method to decrease weir load as long as sufficient vapor handling capacity is available.

Picket fence weirs are used in low-liquid-rate applications (Fig. 8). Picket fence weirs can serve two purposes at low liquid rates. First, they reduce the effective length of the weir for liquid flow increases the liquid height over the weir. This makes tray operation less sensitive to out-of-level installation. Second, pickets can prevent liquid loss (blowing) into the downcomer by spraying. This occurs at low liquid rates when the vapor is the continuous phase on the tray deck.[15] Picket fence weirs should be considered if the liquid load is less than 1 gpm per inch of weir ($0.0267\,ft^3/sec/ft$, $0.00248\,m^3/sec/m$). At liquid rates lower than 0.25 gpm per inch of weir ($0.00668\,ft^3/sec/ft$, $0.000620\,m^3/sec/m$) even picket fence weirs and splash baffles have a mixed record in improving tray efficiency. Operation at liquid rates this low strongly favors the selection of structured packing.

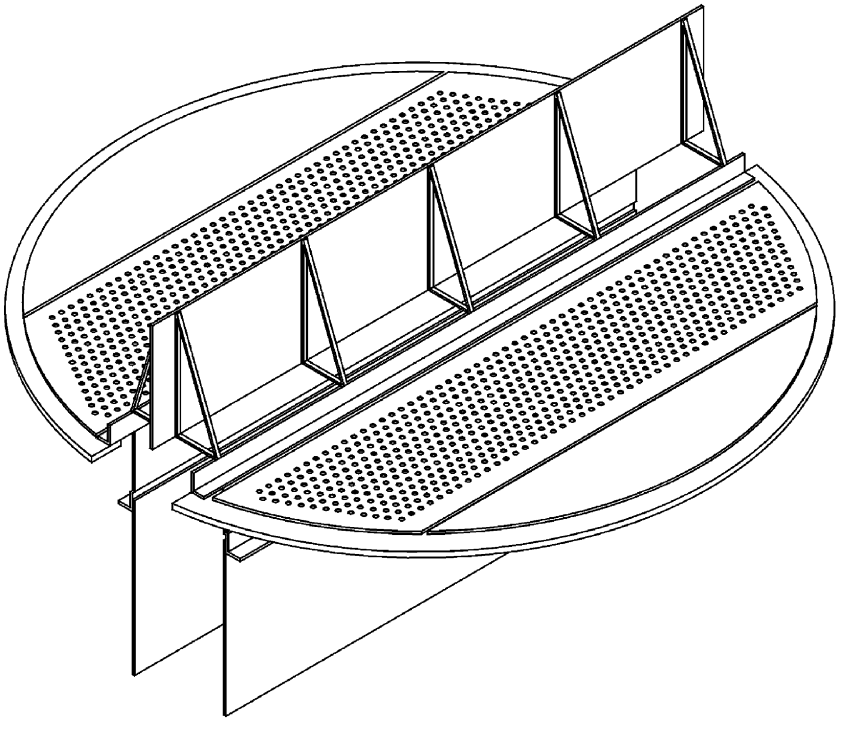

Fig. 5 Antijump baffle on sieve tray.

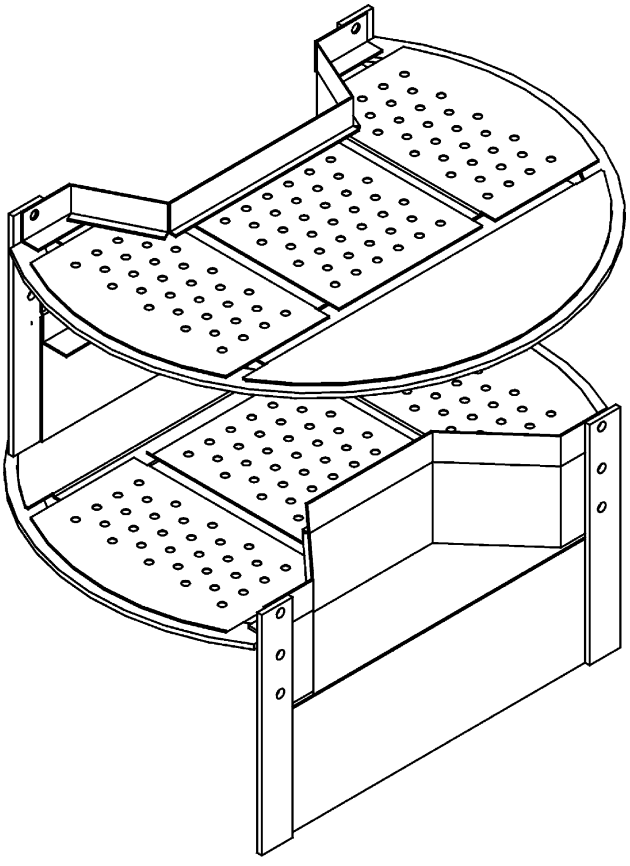

Fig. 6 Multichordal, stepped downcomer.

Picket fence weirs are also used to balance flow to the different passes on trays that have more than two flow paths. Splash baffles are an alternative to picket fence weirs when the major problem is blowing.

Sloped downcomers and modified arc-downcomers are traditional choices to increase the effective area of the tray for vapor–liquid contacting and increase vapor handling capacity (Fig. 9). In the last decade hanging downcomer trays have reached wide acceptance under the generic grouping of ''high-capacity'' trays. These trays can dramatically increase the capacity but are subject to more stringent design and operating limits.[16,17]

PASS SELECTION

Design criteria may force selection of multiple flow pass trays. Increasing the number of flow paths increases the weir length, hence decreasing the liquid load per length of weir. This reduces overall tray pressure drop for high-liquid-rate applications. Multiple flow pass trays also reduce the flow path length. Flow path lengths over 6 ft (1.83 m) start to create significant liquid gradients. Large liquid gradients have caused tower failures. No clearly accepted method for flow gradient prediction is available. Flow path lengths over 9 ft (2.74 m) should be avoided.

At the other extreme (small towers), mechanical limits constrain tray pass selection. Flow paths need to be long enough to install internal man-ways in the trays. Table 7 shows minimum tower diameters for different pass configurations.

TRAY EFFICIENCY

Tray efficiency is required to convert the number of theoretical stages identified as necessary to a number of real plates for installation in a tower. Many

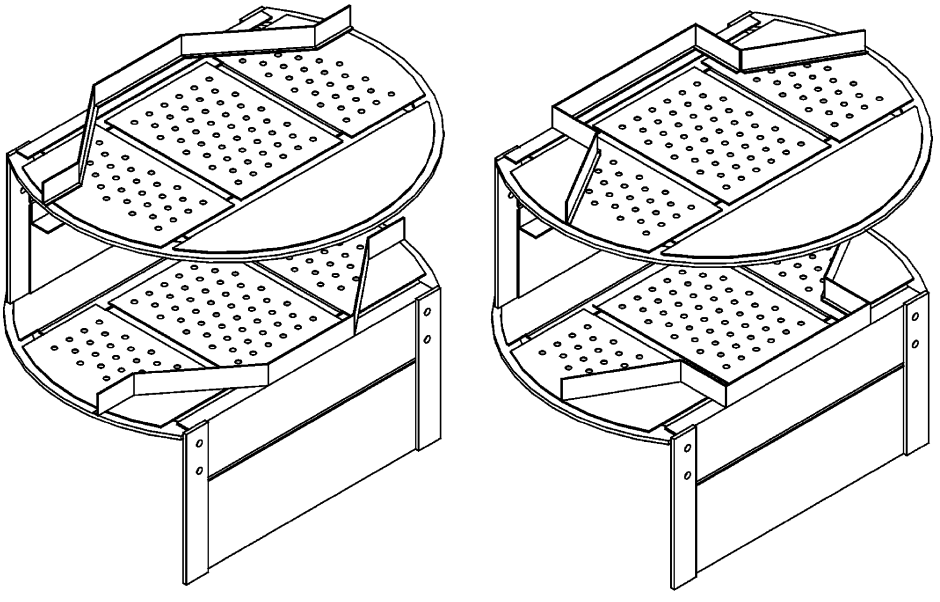

Fig. 7 Swept-back weirs.

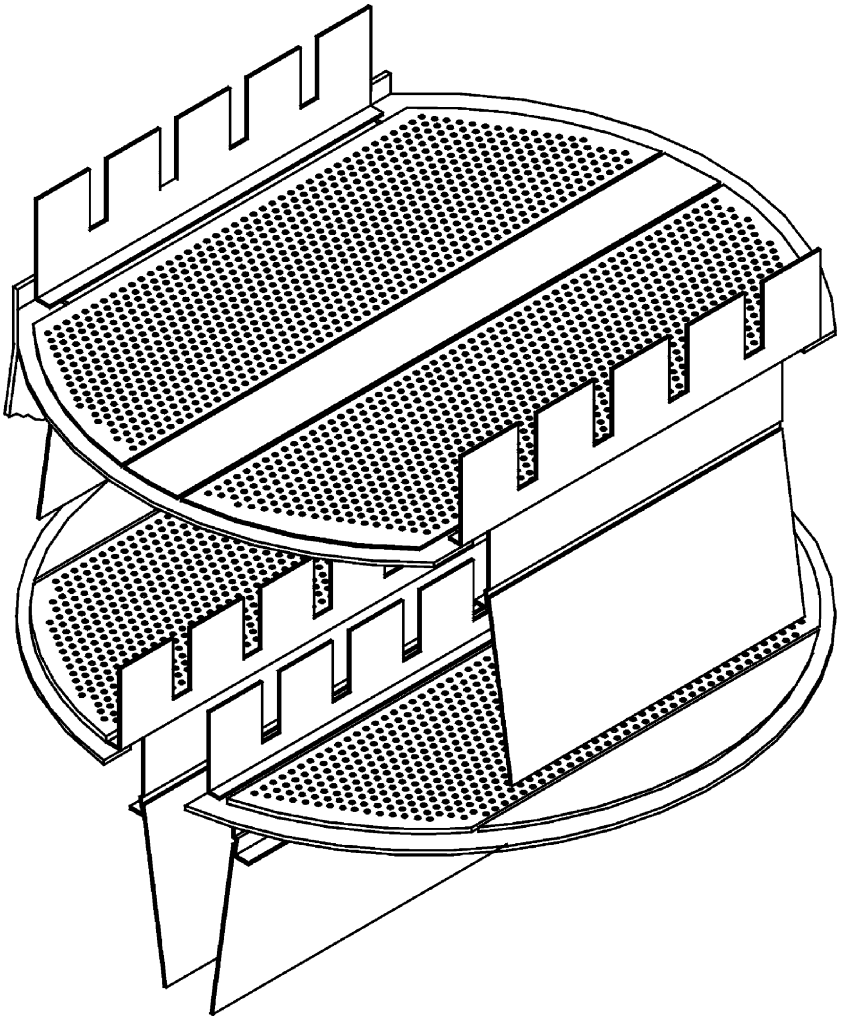

Fig. 8 Picket fence weirs.

theoretical and empirical methods have been proposed.[18–20] Apart from the O'Connell method, few have had wide acceptance for use in constructing towers.[12] The author's experience and the anecdotal experience of others shows the O'Connell method to give reasonable results, when used with a 10% safety factor, for a wide range of systems.

Multiple factors influence tray efficiency. These include the physical properties of the system, operating conditions, vapor and liquid loads, compositions, tray type, fabrication details of the tray, and many others. A range of experimental studies have examined tray efficiency under different conditions. These studies show often conflicting results for the influence of the mechanical and process conditions involved. Study results reveal few useful engineering guidelines for tray design and efficiency.

Two efficiency definitions are in common use for engineering design: overall tray efficiency and Murphree tray efficiency. Murphree tray efficiency basis can be set on either the vapor phase or the liquid phase. Most literature reports data on a vapor phase basis. Tray efficiency relations included here are on the vapor phase basis. Murphree point efficiencies are rarely used. However, some authorities recommend their use for specific situations and some literature includes point efficiency values.[21]

Overall tray efficiency is defined as the number of theoretical trays required for a service divided by the number of actual trays.

$$E_o = \frac{N_a}{N_t} \tag{48}$$

Murphree tray efficiency is defined as the approach to equilibrium on an individual tray by:

$$E_M = \frac{y_o - y_i}{y^* - y_i} \tag{49}$$

For an ideal separation at equilibrium and with straight operating lines, E_o and E_M are related by:

$$\lambda = m\frac{G_m}{L_m} \tag{50}$$

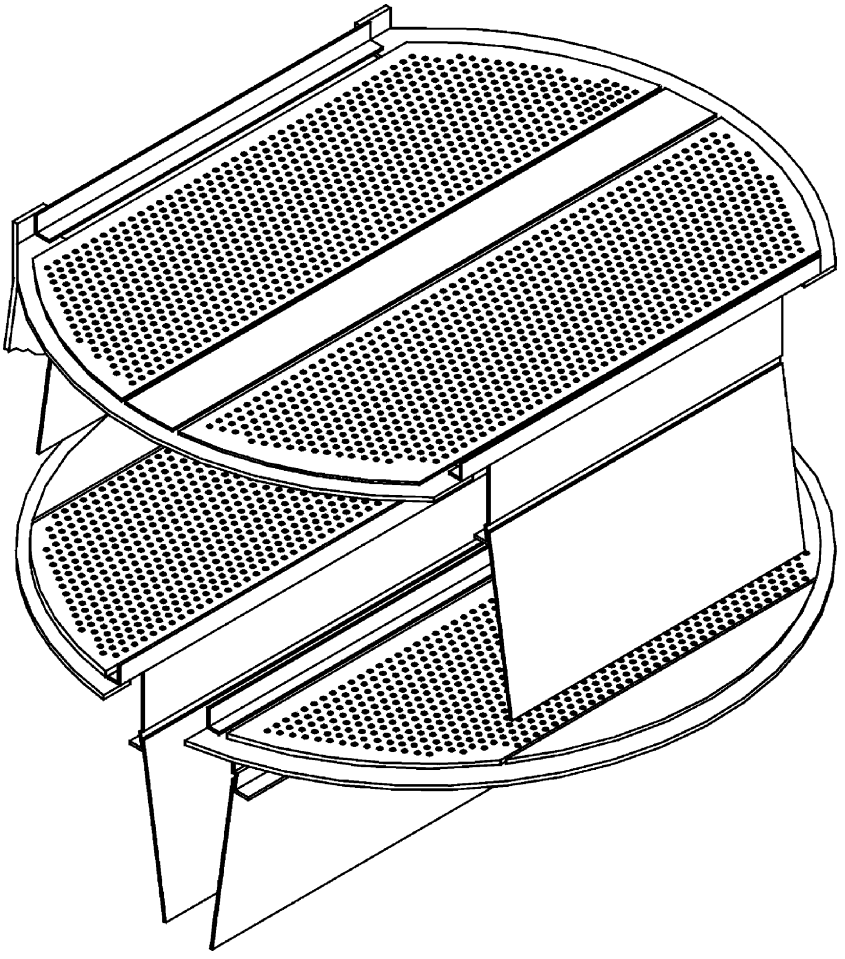

Fig. 9 Sloped downcomers.

(G_m and L_m are in consistent units.)

$$E_o = \frac{\ln(1 + E_M[\lambda - 1])}{\ln\lambda} \quad (51)$$

for $\lambda \neq 1$.

$$E_o = E_M \quad (52)$$

for $\lambda = 1$.

The O'Connell correlation relates tray efficiency to liquid viscosity and system relative volatility:

$$E_o = K_{21}(\mu_L\alpha)^{K_{22}} \quad (53)$$

Table 7 Minimum diameters and flow passes recommended

Number of flow passes	Minimum diameter (ft)	Minimum diameter (m)
2	5	1.52
3	8	2.44
4	10	3.05
5	13	3.96

Where μ_L is in centipoise, $K_{21} = 0.492$ and $K_{22} = -0.245$. The liquid viscosity and relative volatility are for the column feed at the average temperature and pressure of the column.

O'Connell derived his correlation from binary systems in distillation service with bubble-cap trays. Calculated values are slightly conservative for sieve and valve trays. Credit for the slight improvement in valve and sieve tray efficiency should be ignored and counted as a design margin. A separate correlation was developed for absorption services.

Efficiency in multiple component systems is far more complex. Every component may have a different efficiency at each stage. Components may interact and composition profiles may even reverse. The equilibrium slope for each component depends on many coupling and interaction effects. Therefore, overall efficiency cannot be easily derived from Murphree tray efficiencies. Most designs for both binary and multiple component systems use overall efficiency values based on operating data or test systems.

Table 8 lists tray efficiencies for common systems.[22] Performance is for "well-designed" trays in distillation operation. Table 9 summarizes tray design features,

Table 9 Tray efficiency behavior

Feature	Behavior
Liquid viscosity	Low viscosity increases efficiency
Pressure	Froth systems: higher pressure slightly increases efficiency
Relative volatility	Low relative volatility increases efficiency
Surface tension	Minimal effect
Entrainment	Higher entrainment reduces efficiency. Impact minimal for entrainment below 5%
Flow path length	Longer flow paths improve efficiency. Flow paths longer than six deck devices have minimal impact unless composition profiles are created across tray (typically low relative volatility systems)
Hole area	Low hole area improves efficiency
Hole (valve) size	High-viscosity systems: small devices improve efficiency Froth systems: small devices slightly improve efficiency Spray systems: small devices slightly improve efficiency Efficiency changes in most systems are small. Most test data are from absorption systems. Limited test data from distillation systems have shown reduced efficiency with smaller tray devices in some cases
Multiple-pass tray flow maldistribution	More maldistribution reduces efficiency. L/V ratio variations under 1.2 between sections have minimal effect
Reflux ratio	Minimal effect
Stagnant regions on tray	Minimal efficiency reduction except in extreme cases
Weir height	Higher weirs improve efficiency in froth systems—moderate impact
Weeping	Higher weeping reduces efficiency. Large effect
Vapor-to-liquid ratio	Minimal effect

Froth systems: liquid continuous phase on tray; spray systems: liquid discontinuous phase on tray.

system characteristics, and general trends in tray efficiency. Kister has an excellent review of these factors.[11] Data from efficiency measurements show many inconsistencies. Pilot and plant tests are critical for determining the performance of a specific tray in a given system.

CONCLUSIONS

Fractional distillation, absorption, and stripping are the most common separation unit operations. All these services can use trays to achieve their mass-transfer objectives. Effective hydraulic and mass-transfer design for trays involves selection of the correct tray type. Industrially, most trays are either valve trays or sieve trays. Other types, including bubble-cap trays, have specialized uses. When properly selected and designed, trays meet the combined process and mechanical requirements of the service. The process and mechanical requirements are not independent. The equipment must work, and it must work as part of a process to achieve plant objectives. Applications for trays cover the gamut of the petroleum refining, petrochemical, gas processing, and chemical industries. The general design criteria here cover standard design issues for new towers. Revamps often involve extremely complex balancing of mechanical possibilities vs. process risk to meet economic and operating targets.

NOMENCLATURE

A_A	Active area
A_{AM}	Active area, design minimum
A_{CS}	Total tower cross-sectional area
A_{DC}	Area of the downcomer, actual or design
A_{DC1}	Area of the downcomer, top of outboard downcomer
A_{DC2}	Area of the downcomer, bottom of outboard downcomer
A_{DC3}	Area of the downcomer, top of inboard downcomer
A_{DC4}	Area of the downcomer, bottom of inboard downcomer
A_{DCE}	Downcomer escape area
A_{DM}	Area of the downcomer, design minimum
A_H	Area of the holes
A_{TM}	Total tower cross-sectional area, design minimum
α	Relative volatility
c_{AF}	Tray capacity factor
c_{AFO}	No liquid load capacity factor on tray free area
D	Tower diameter
ΔP_{dry}	Dry tray pressure drop
ΔP_{HUD}	Pressure drop (head loss) under the downcomer
ΔP_{total}	Total tray pressure drop
E	Vapor kinetic energy to liquid density ratio
E_o	Efficiency, overall
E_M	Efficiency, Murphree
F_D	Flooding factor, downcomer
F_A	Flooding factor, active area
F_F	Flooding fraction
F_P	Flooding percentage
G_m	Gas flow rate (moles per time)
H_1	Downcomer width at top of outboard downcomer (downcomer rise)
H_2	Downcomer width at bottom of outboard downcomer
H_3	Downcomer width at top of inboard (center) downcomer
H_4	Downcomer width at bottom of inboard (center) downcomer
H_C	Height of liquid crest over the outlet weir
H_{DC}	Downcomer backup height, clear liquid
H_{DCC}	Downcomer clearance height
H_L	Height of liquid on the tray
H_W	Height of outlet weir
λ	Ratio of the slope of the equilibrium curve and the slope of the component balance line.
L	Total liquid flow (mass or volume units as applicable)
L_m	Liquid flow rate (moles per time)
L_{FP}	Flow path length
m	Slope of equilibrium line on McCabe–Thiele diagram
μ_L	Liquid absolute viscosity (centipoise)
N_a	No. of actual trays
N_t	No. of theoretical trays
N_u	No. of valve units
ρ_L	Density, liquid
ρ_M	Density, tray material
ρ_V	Density, vapor
ρ	Tower radius
S	Angle for circular segment described by a downcomer
S_F	System factor
t_m	Valve thickness
T_S	Tray spacing
V	Total vapor flow (mass or volume units as applicable)
V_{DD}	Velocity, downcomer design (preliminary)
V_H	Velocity, vapor through holes
V_{load}	Vapor load
V_{UD}	Velocity under the downcomer

W	Weir length
W_{FP}	Active area to flow path length ratio
y_i	Mole fraction of light component in vapor to stage (inlet)
y_o	Mole fraction of light component in vapor from stage (outlet)
y^*	Mole fraction of light component in vapor if in equilibrium with liquid from stage (outlet)

INTRODUCTION

Drag reduction (DR), which was discovered more than 50 yr ago, is a turbulent flow phenomenon in which frictional energy losses can be significantly reduced by the addition of a small amount of a DR additive (DRA) to a turbulent flow system.[1,2] Drag reduction in internal flows is calculated using the following equation:

$$\%\mathrm{DR} = \frac{f_s - f}{f_s} \times 100 \quad (1)$$

where f is the measured friction factor of the solution with additive and f_s is that of the solvent at the same mean velocity.

Drag reduction additives in turbulent flowing systems can decrease system energy consumption, reduce pipe and pump size, increase flow rate or system length, and decrease heat transfer or a combination thereof.[3] The greatest use of DRA has been in crude and finished product petroleum pipelines as demonstrated in the 800 mi Alyeska Pipeline. Crude throughput in the 48 in.-diameter pipeline was increased by 30% by injecting a solution of high-polymer additive, at concentration as low as 1 ppm, downstream of the pumps at bottleneck sections of the line.[4] Other potential industrial applications include district heating and cooling (DHC) systems, oil well operations, sewage and floodwater disposal, hydraulic transport of solids, fire fighting, ships and submarines, jet cutting, irrigation, as well as heat tracer lines for cold North Sea crudes.[5–8]

Drag reduction systems can be either heterogenous (two phases) or homogenous (solution additives).[6] Heterogenous DR systems include solid-phase fibers or gas-phase microbubbles or even injection of concentrated polymer or surfactant solutions while polymers, aluminum disoaps, and surfactants are the main types of homogenous DRA.[9] Compared with heterogenous DRA, homogenous additives have the advantages of high effectiveness, low capital costs, and ease of operation. Homogenous polymer and surfactant systems have been the most widely studied DRAs and this entry will emphasize experimental findings with these two types of DRAs.

POLYMER DRA

Little progress was made in DR research until the early 1960s, but in the next 20 yr considerable progress was made.[6] Much of the early work focused on studies of poly(ethylene oxide) (PEO) in aqueous systems.[10] Research results on important solution variables affecting polymer DR, polymer structure, molecular weight (MW), concentration, and solvency, are described below as well as flow variables results.

Effect of Polymer Structure

Polymer DR effectiveness is related to molecular structure and polymer flexibility. Polymer backbone structure and side groups determine the flexibility of the molecule.[11] Liaw, Zakin, and Patterson showed that nonpolar polymers that are more flexible gave more effective DR.[12] They compared concentration effects of different polymer–solvent systems in a given tube in terms of a volume fraction, $C_c[\eta]$, where C_c is the critical concentration for disappearance of the laminar–turbulent transition in that tube and $[\eta]$ is the intrinsic viscosity. Values of $C_c[\eta]$ are very sensitive to the flexibility of the polymer molecules, increasing (becoming less DR effective) with increasing molecular rigidity. The most effective DR polymers, such as PEO and polydimethylsiloxane, are linear and flexible.[12,13] Other effective polymers include polyacrylic acid and polyacrylamide (PAM).[14,15] Mixtures of copolymers of linear α-olefins and 1-butene of very high MW are widely used as effective DRAs in hydrocarbon transport pipelines.[16]

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007743

Molecular Weight Effects

At a given polymer concentration, increased MW gives more effective DR. Polymers with MW lower than 100,000 are likely to be ineffective.[13] Liaw, Zakin, and Patterson, introduced a reduced MW, $m' = MW/M_c$, which takes into account the entanglement capacity of a polymer chain to compare MW effects of different polymers.[12] M_c is the minimum chain size for molecular entanglements to occur in polymer melts.

Molecular weight effects are illustrated in Figs. 1 and 2, showing the increasing DR effectiveness of higher-MW polystyrene samples at all concentrations regardless of solvent type.[17]

Hunston and Reischman showed that the contribution of 25 ppm of a 2×10^6 polystyrene in benzene solution to DR was negligible when added to 2.5 ppm of a 7×10^6 polystyrene (Fig. 3), demonstrating that a small amount of high-MW polymer dominates DR behavior in a mixture.[18]

Concentration

Drag reduction increases with polymer concentration until it reaches a maximum. The optimum concentration, and minimum torque in a turbulent Couette experiment with PEO in water decreased with increasing MW.[19] Hunston and Zakin studied the effect of concentration and MW on DR for polystyrene in toluene, a good solvent, and in toluene–isooctane, a poor solvent.[17] They observed increasing DR effectiveness with increasing concentration until offset by viscosity enhancement (Figs. 1 and 2). Liaw, Zakin, and Patterson found that increased concentration and decreased tube diameter reduced the onset Reynolds number (N_{Re}) leading to the disappearance of the laminar–turbulent transition, i.e., no observed onset, only a gradual departure from the laminar line (see section entitled "Onset" and Fig. 5).[12]

Virk et al. defined an intrinsic concentration for comparing DR effectiveness of homologous polymers of different MW and also different polymers:[20]

$$[C] = \frac{DR_m}{\lim_{C \to 0}(DR/C)} \tag{2}$$

where C = concentration, $\lim_{C \to 0}(DR/C) = [DR]$ is the intrinsic DR, i.e., a measure of DR per unit concentration at high dilution, and DR_m is the "maximum DR" as $C \to \infty$ for a given tube size and flow rate.[21]

Little simplified Eq. (2):[22]

$$\frac{DR}{DR_m} = \frac{C}{[C] + C} \quad \text{or} \quad \frac{C}{DR} = \frac{[C]}{DR_m} + \frac{C}{DR_m} \tag{3}$$

This equation predicts a linear relationship between C/DR and C and fits dilute aqueous PEO and PAM solutions also. $DR_m/[C]$ can be used to compare the effectiveness of different polymers at the same N_{Re} or to show the MW effect of a homologous series.[21]

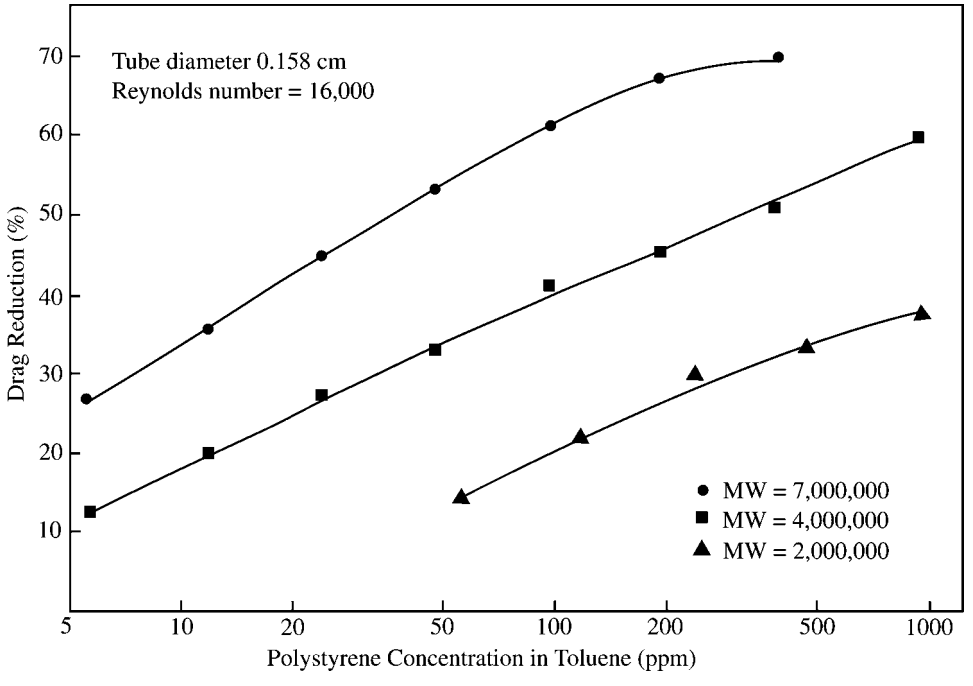

Fig. 1 Drag reduction effectiveness vs. polystyrene concentration in toluene, a good solvent. (From Ref.[17].)

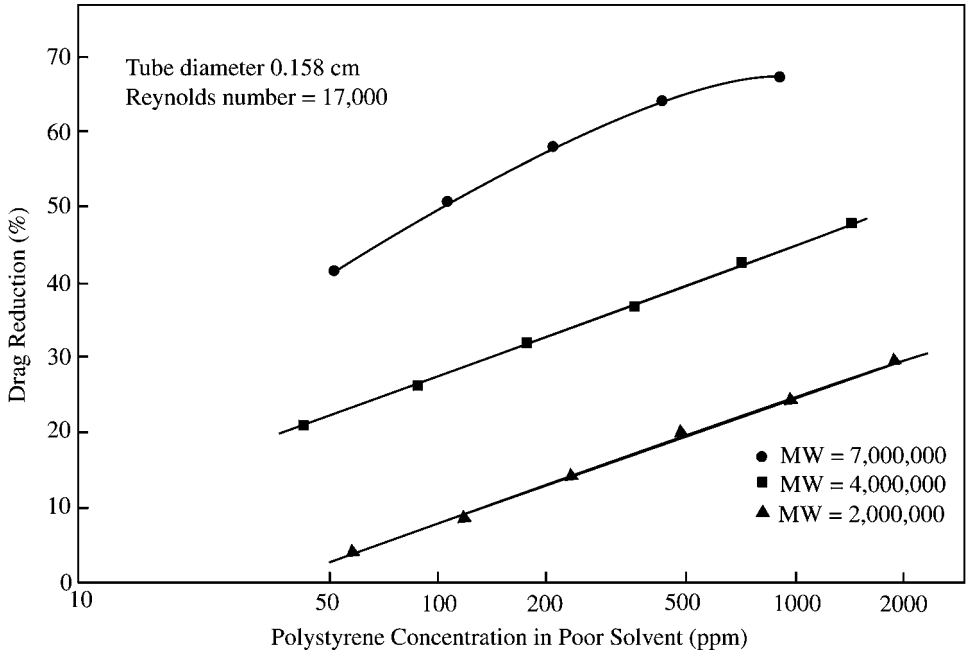

Fig. 2 Drag reduction effectiveness vs. polystyrene concentration in 58% toluene–42% isooctane, a poor solvent. (From Ref.[17].)

Solvency

For nonpolar linear polymers that form coils, Hershey and Zakin observed 40% less DR for polyisobutylene in benzene, a poor solvent, than in cyclohexane, a good solvent.[23] Hunston and Zakin showed that polystyrene in the good solvents, toluene or benzene, gave more DR than the same samples in a poor, mixed solvent of toluene and *iso*-octane as shown in Figs. 1 and 2.[24] These results and those of White and Gordon showed that expanded coil conformations, which enhance molecular flexibility, enhance DR effectiveness.[25]

Fig. 4 shows the pH effects on DR for a PAA-water system.[26] The untreated polymer solution (pH 5.0) has slight DR. Its DR ability increased slightly when pH was raised to 9.0, where the polymer molecules are fully ionized and extended (rod-shaped). Drag reduction also increased slightly as pH was lowered to 3 but increased abruptly at pH 2.1 and also at 1.0. They suggested that at these low pH values, the polymer chains undergo a second-order phase transition

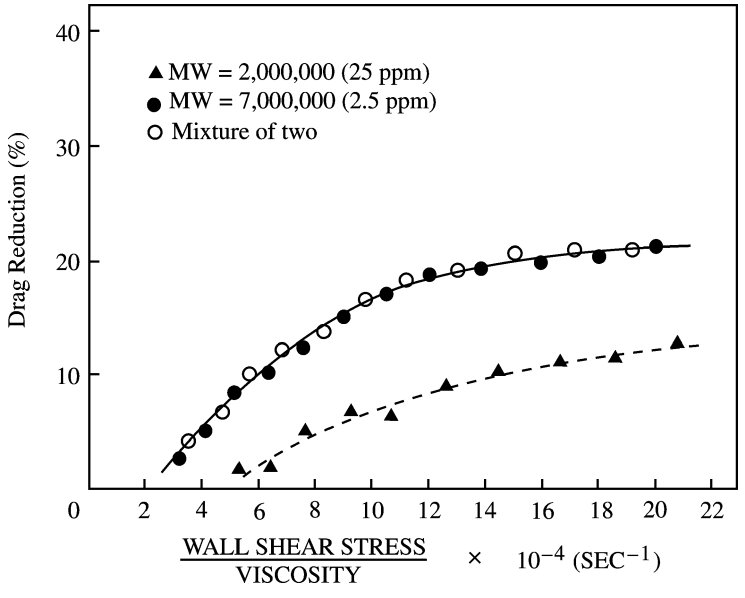

Fig. 3 Molecular weight effects on DR. (From Ref.[18].)

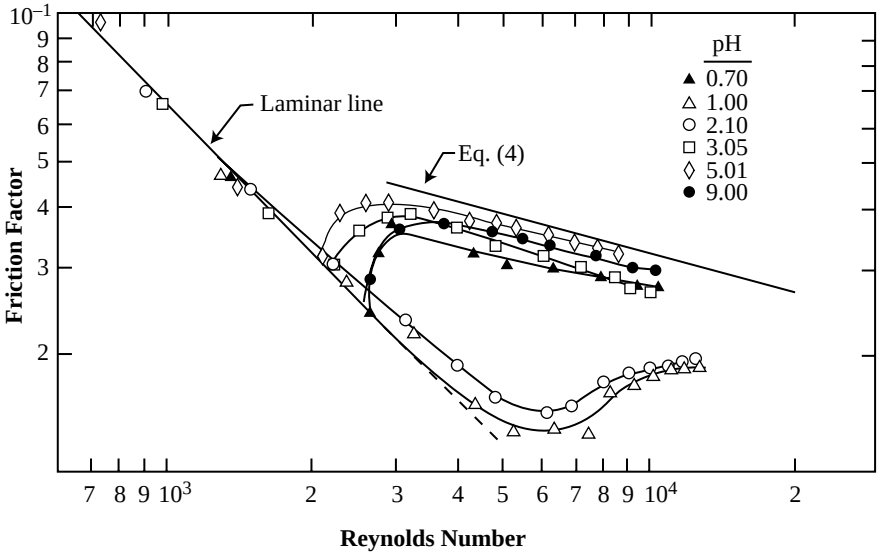

Fig. 4 pH effects on DR for a PAA–water system. (From Ref.[26].)

from extended rod to a more compact helical structure, which was very DR effective. Further increase in hydrogen ion concentration to pH of 0.7 led to reduction of DR, for which no explanation was provided.

For xanthan gum (XG) in water, Rochefort and Middleman observed that DR effectiveness is significantly reduced at high salt concentration.[27] Their rheological results indicated that as the ionic strength increased, XG molecules underwent a transition from highly extended, semiflexible rods with disordered backbone structure to collapsed, semirigid rods with ordered backbone structure.

Onset

For turbulent pipe flow of Newtonian, non-DR solutions, friction factors are predicted by the Prandtl-von Karman (PK) equation:

$$\frac{1}{\sqrt{f}} = 4\log_{10}\left(N_{\mathrm{Re}}\sqrt{f}\right) - 0.4 \tag{4}$$

which can be approximated by the Blasius equation:

$$f = 0.0791(N_{\mathrm{Re}})^{-1/4} \tag{5}$$

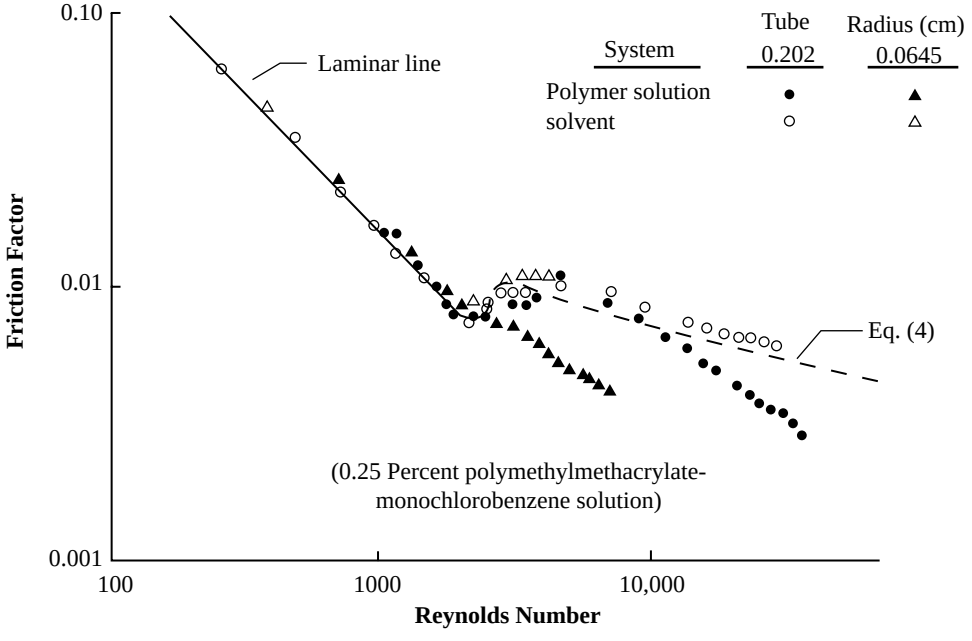

Fig. 5 An illustration of onset behavior. (From Ref.[1].)

Fig. 4 shows Toms' $f - N_{Re}$ data for both a Newtonian solvent and a DR polymer solution. Drag reduction onset occurs at $N_{Re} \approx 10{,}000$ in the 0.202 cm tube, while the critical conditions for DR are reached in the laminar region for the 0.0645 cm tube and there is no apparent onset. Rather, friction factors depart gradually from the laminar equation as N_{Re} increases (see also the section Concentration). Virk proposed that onset of DR in turbulent pipe flows, at which the friction factor departs abruptly from Eq. (4), occurs at a distinct wall-shear stress, τ_w, which does not depend on the pipe size and is only weakly dependent on concentration for a given polymer–solvent combination, but depends strongly on the radii of gyration, R_G, of the polymer molecules:

$$R_G{}^g \tau_w = \Omega \tag{6}$$

where Ω is an average onset constant characteristic of a given polymer species–solvent pair and g should vary between 2 and 3.[28] Virk's data for the PEO–water system showed that concentration hardly affects onset, but changes the slopes after onset.[28] However, concentration effects on onset were observed by Paterson and Abernathy for PEO–water and Hunston and Zakin for polystyrene in hydrocarbon solvent.[24,29] Paterson and Abernathy found that onset moved to higher N_{Re} as concentration decreased but that this dependence on concentration was considerably weaker than on the R_G. Hunston and Reischman showed that onset was determined by the highest-MW molecules in the polymer sample and occurred at lower N_{Re} with increase in MW.[18] Fabula, Lumley, and Taylor, and Hershey postulated that onset occurs when the product of wall-shear rate $\dot{\gamma} = \tau_w/\eta$, ($\eta$ = shear viscosity) and polymer molecule relaxation time, T_1, is of order 1.[30,31] This hypothesis was later supported by Berman and George from pipe flow experiments with dilute Polyox WSR N-80 (PEO) in glycerine–water solvents of different viscosities.[32] Hershey and Zakin proposed that the time scale theory might be applicable at values of $C[\eta] > 0.10$.[23] Hunston and Zakin observed that $\dot{\gamma} T_1$ was fairly constant ($\approx$10) for polystyrenes of different MW in a good solvent, but was larger in a poor solvent.[24] Later, Gyr and Bewersdorff hypothesized that DRAs are ineffective until the stress field is sufficiently strong to stretch and align the molecules.[33] Sreenivasan and White used an elastic theory to explain onset suggesting that onset is principally a near-wall effect (manifested through interference with turbulent bursting near the wall) and the polymers are only partially stretched at onset.[34]

Types A and B Drag Reduction

Virk and Wagger classified DR types based on the conformation of polymer molecules under flow.[35] Type A occurs in random-coiling systems and Type B with fully extended macromolecules. Type A DR is seen in Fig. 6, where a series of solutions of increasing concentration yield friction factor segments fanning outward from a common onset point on the PK line. Their slopes increase with increasing concentration

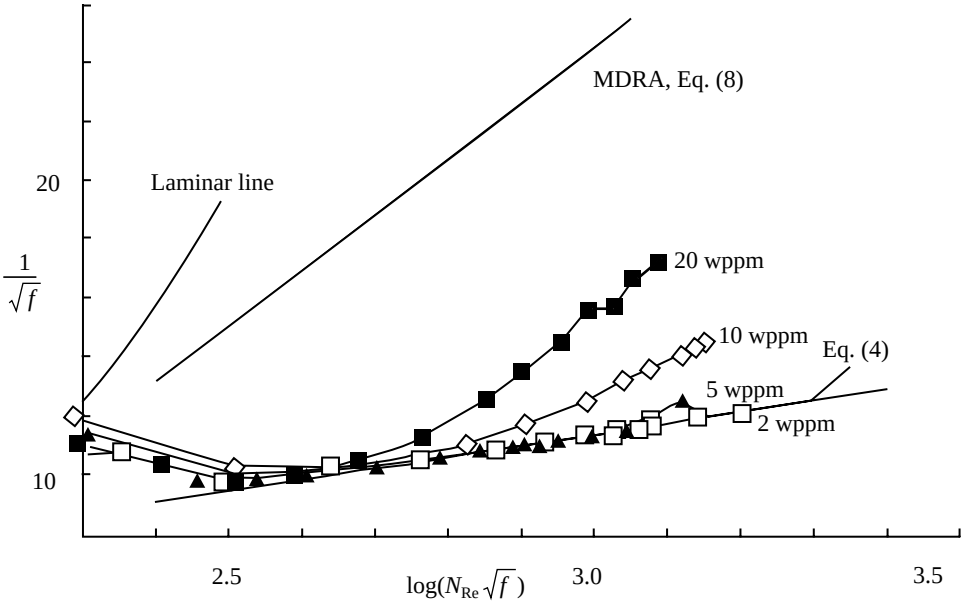

Fig. 6 Type A DR "fan" for coiled conformation. The polymer was partially hydrolyzed PAA of MW $\approx 15 \times 10^6$ at different concentrations. Pipe ID = 14.6 mm; Nacl = 0.1 mol/L. (From Ref.[35].)

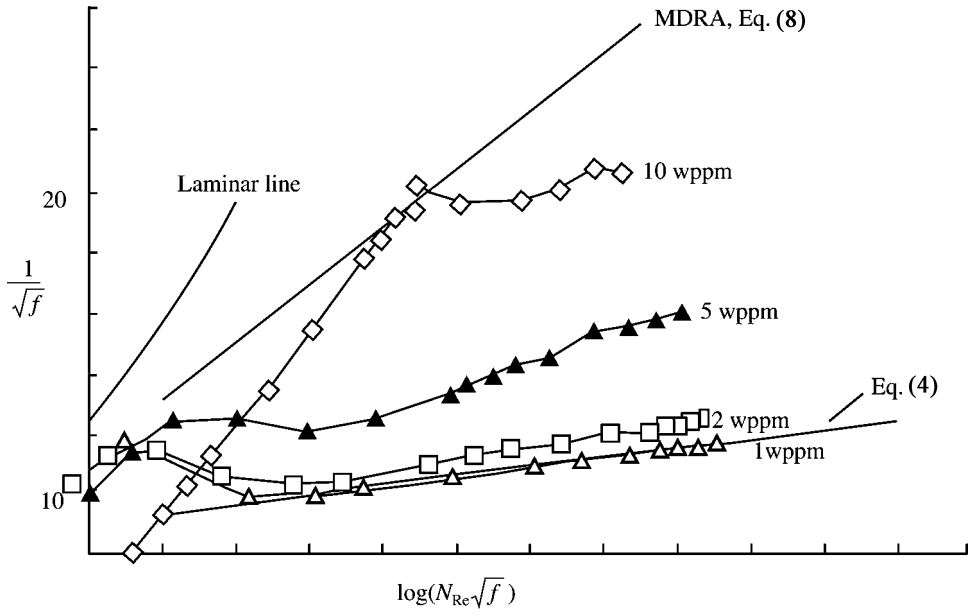

Fig. 7 Type B DR showing "ladder" for extended conformation. The polymer was partially hydrolyzed PAA of MW $\approx 15 \times 10^6$ at different concentrations. Pipe ID=14.6 mm; No salt added. (From Ref.[35].)

and DR increases with $N_{Re}\sqrt{f}$. They postulated that Type A DR is a result of the stretching or extension of random-coiled macromolecules by the turbulent flow field. In Type B DR (Fig. 7), the friction factor segments are parallel to, but displaced upward from the PK line as concentration varies from 2 to 10 ppm, with DR essentially independent of $N_{Re}\sqrt{f}$ but increasing with increasing concentration. Virk and Wagger observed a transition from Type A to Type B DR with decreasing salinity for a partially hydrolyzed PAM solution as salt concentration affected the molecular conformation.[36]

Shear Degradation

Polymer DRAs exposed to mechanical or extensional shear lose their DR effectiveness, as primary bonds are broken predominantly near the molecules' midpoints. Shear is particularly pronounced as solutions pass through a centrifugal pump, which presents a serious problem in long-distance pipeline transport, where booster pumps may be required every 50–100 mi. Pollert and Sellin reviewed in detail the mechanical degradation of DR polymers. The degradation rate increases with increasing MW and τ_w and decreases with concentration.[37] Patterson et al. studied 0.4% polyisobutylene (with a weight-average MW of 4.5×10^6) in cyclohexane, toluene, and *n*-heptane showing that the highest MW fractions of a polymer are most susceptible to shear degradation.[38] This was also observed by other researchers (for example, Refs.[39,40]).

Hunston and Zakin found that mechanical degradation rates are always larger in a poor solvent than in a good one.[24] Degradation is also related to molecular structure. Elata, Lehrer, and Kahanovitz noted that guar dissolved in water is more resistant to shear degradation than many other water-soluble polymer DRAs.[41] Patterson, Shen, and Chen reviewed reports on temperature effects on mechanical degradation, which showed, surprisingly, little effect or a negative effect.[42] That is, slower degradation was reported as the temperature rose, which was attributed to greater molecular flexibility. Thus, the factors governing shear degradation in DR include the stress level, concentration, molecular structure, molecular weight distribution, solvency, and temperature.

Initial degradation is relatively rapid and degradation can be represented by an exponential decay expression where time of exposure to shear is the independent variable. Minoura et al. showed that degradation could be characterized by a rate constant for molecular scission and a critical (minimum) MW below which no scission occurs at a given shear stress.[43] Similarly, Levinthal and Davison showed that for a given polymer chain length and strength of bond in laminar flow, there is a critical value of wall-shear stress below which shear degradation is negligible.[44] Based on this and the observation that a narrow high MW distribution polystyrene has greater resistance to degradation than a broader distribution polystyrene with a high MW tail, each initially of comparable DR ability, Hunston proposed a mechanism showing how the MW distribution affects shear

degradation.[45] He noted that chemical structure affects the critical lower MW for molecular scission and that MW distribution determines the fraction of DR effective molecules subject to scission.

SURFACTANT DRA

Introduction

Surfactant additives have been studied intensively in recent years because of the ''self-reparability'' or self-assembly of their microstructures after degradation by mechanical or extensional stresses. This ability has led to many studies of their applications in DHC recirculation systems. Classifications of surfactant DRAs and their self-assembly nature are described. Also discussed in this section are the main research results on microstructures, rheological properties, HTR of surfactant DR solutions, and approaches to enhance heat transfer coefficients. Significant field tests around the world are reviewed.

Classification of Surfactant DRAs

Surfactant DRAs can be roughly grouped into four types according to the charge properties of their hydrophilic head groups: cationic (positively charged) with anionic counterions, anionic (negatively charged), zwitterionic (with both positive and negative charges, zero net charge), and nonionic (uncharged) surfactants. Until now, cationic surfactants have received the most attention because of their lower costs compared with zwitterionic surfactants, broad DR temperature ranges (unlike nonionic surfactants with narrow temperature ranges), and insensitivity to the presence of calcium and magnesium ions in tap water, which cause DR anionic surfactants to precipitate. Typical cationic surfactants studied for DR are quaternary ammonium salts with one long alkyl chain (carbon number from 14 to 22) and methyl or hydroxyethyl groups in the other positions.[5] Recently, however, because of the unique DR properties mixed surfactant solutions exhibit, there has been increasing interest in mixed surfactant solutions, such as cationic and anionic, zwitterionic and anionic, and cationic surfactant solutions with different alkyl chain lengths.[46–53]

Self-Assembly of Surfactant DRAs

Primary bonds in high MW polymers subjected to high-shear or extensional flows, such as in pumps, contraction or expansion flows, break up and the degradation is permanent. The microstructures of surfactant solutions also break up under strong shear, but they self-assemble soon after the shear is released recovering their microstructures.[5]

Fig. 8 shows DR vs. N_{Re} of a typical DR cationic surfactant with counterion solution, $C_{17}H_{35}N(CH_3)_3Cl$/3,4-Cl-benzoate (5 mM/12.5 mM). Drag reduction reaches a maximum of 65%. In the effective temperature range (15–85°C), DR first increases with N_{Re} until a critical N_{Re} (critical wall shear stress) is reached above which it begins to lose its DR ability because of the

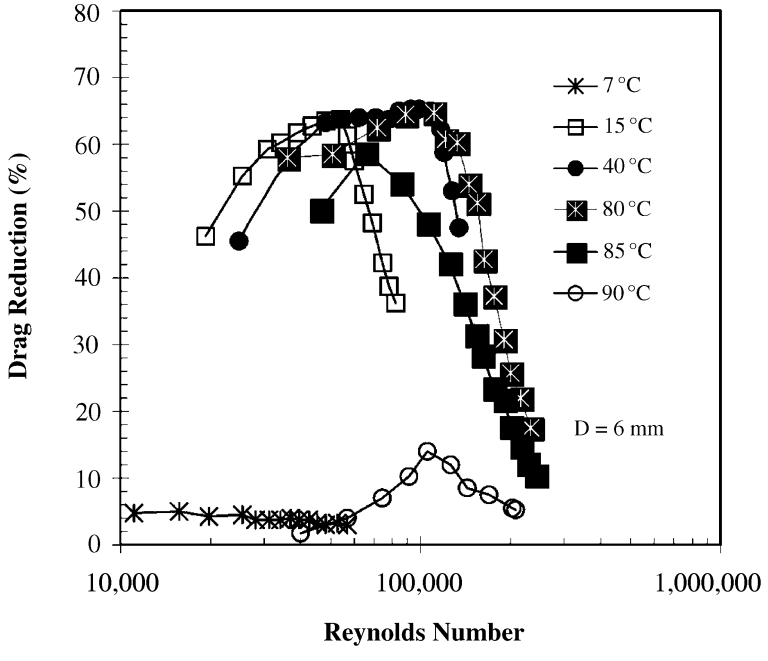

Fig. 8 Drag reduction vs. Reynolds number of a typical drag reducing cationic surfactant solution $C_{17}H_{35}N(CH_3)_3Cl$/3,4-Cl-benzoate (5 mM/12.5 mM).

high-shear stress breakup of the microstructure. If N_{Re} is decreased, the solution recovers its DR ability. That is, surfactant DR is mechanically recoverable. Surfactant DR is also temperature reversible. At 90°C, the surfactant microstructure no longer provides DR capability. However, if the solution temperature is reduced to 85°C, the solution will regain its DR ability. Each DR surfactant solution has an effective DR temperature range and, at each temperature and pipe diameter, an N_{Re} range.

Microstructures of DR Surfactant Solutions

Fig. 9 is a schematic phase diagram of a dilute aqueous cationic surfactant solution showing temperature and concentration effects on its microstructures. When the temperature is lower than the Krafft point [the temperature at which the solubility equals the critical micelle concentration (CMC)], the surfactant is partially in crystal or in gel form in the solution. At temperatures above the Krafft point and concentrations higher than the CMC, spherical micelles form in the surfactant solution. With further increase in concentration and/or on addition of counterions, the micelles form cylindrical rods or threads or worms with entangled thread-like and sometimes branched thread-like structures.

The concentration at which surfactants form rod-like micelles is called CMCII. Critical micelle concentration is almost independent of temperature while CMCII increases with temperature. Spherical micelles, rod-like or thread-like micelles, and vesicles are the three most common microstructures seen in dilute DR surfactant solutions.

An oppositely charged surfactant, organic counterions, and uncharged small compounds like alcohols are three common additives that induce the transformation of spherical micelles of cationic surfactants to thread-like micelles.[54] Addition of these additives gives a much smaller interfacial charge density on the micelle, shielding head group repulsions and allowing denser packing of surfactant molecules in the micelles.[55] Organic counterions, typically hydroxy- or halo-substituted benzoates at equimolar or higher concentrations, are the most effective and commonly used counterions for cationic DR surfactant solutions. They are small molecules, which can disperse both intermicellar repulsions and intramicellar repulsions and have organic portions that can penetrate into the lyophilic center of the micelle.[56] Fig. 10 shows a proposed elongated cylindrical micelle structure cartoon with a negatively charged organic counterion, 4-chlorobenzoate, inserted between positively charged ammonium cationic surfactant head groups.

Thread-like or worm-like micelles are believed to be necessary for surfactant solutions to be DR.[5,57] Many theoretical and experimental studies have investigated the kinetics, rheology, and microstructures of thread-like micelles. An important finding by Mendes et al. in their small-angle neutron scattering studies of microstructures and by Zheng et al. in their cryogenic transmission electron microscope studies of surfactant solutions is that vesicle microstructures can transform to thread-like micelles under shear.[58–60] This explains Zheng et al.'s surprising observation that a surfactant solution with vesicle structures in the quiescent state can also show very good DR ability.[60]

Such systems can form the thread-like micelles necessary for surfactant solutions to be DR under the shearing conditions in turbulent flows. The thread-like micelles align themselves along the flow direction causing DR of the solution.[61] Details of microstructures DR of aqueous cationic surfactant solutions vary with surfactant chemical structure and concentration, counterion chemical structure and

concentration, temperature and pipe diameter, shear, and pH.

Rheological Properties of Surfactant DR Solutions

It has often been stated that DR of surfactant solutions is related to their rheological properties. A rise in shear viscosity at a critical shear rate, caused by a shear-induced structure (SIS), viscoelasticity (nonzero first normal stress difference, quick recoil, and stress overshoot), and high extensional viscosity/shear viscosity ratios (~100) are rheological properties found in many DR surfactant solutions. After reviewing the rheological behavior of many DR surfactant solutions, Qi and Zakin concluded that SIS and viscoelasticity are not always observed in DR surfactant solutions while high extensional/shear viscosity ratios may be a requirement for surfactant solutions to be DR.[57]

Enhancing Heat Transfer Ability of Drag Reducing Surfactant Solutions in Heat Exchangers

In addition to reduced friction factors (reduced momentum transfer), the heat transfer abilities of DR solutions are also greatly reduced. This may be caused by the thickened viscous boundary layers of DR flow and/or by reduced velocity fluctuations perpendicular to the flow.[62] Heat transfer reduction is defined as:

$$\%\mathrm{HTR} = \frac{Nu_s - Nu}{Nu_s} \times 100 \qquad (7)$$

where Nu_s and Nu are the Nusselt numbers measured for the solvent and the DR solution with additives.

Heat transfer reduction can be beneficial or detrimental to the practical use of DR solutions in DHC systems. On the beneficial side, the cost of insulation is reduced in pipelines in DHC systems. However, methods to locally enhance the heat transfer ability of DR surfactant solutions in heat exchangers to facilitate heat exchange while still maintaining their overall DR efficiency need to be developed. Three main approaches have been proposed: 1) modifying the inner surfaces of a heat exchanger to give a swirling motion and add disturbances to the viscous boundary layers of DR turbulent flows; 2) installing a pump, mechanical destructive devices, or an ultrasonic energy generator at the heat exchanger entrance to break up surfactant micelle structures temporarily; and 3) increasing the flow velocity of the fluid so that the critical wall-shear stress limit at the entrance or inside the heat exchanger is exceeded. In the second and the third method, surfactant solutions with broken microstructures will exhibit Newtonian flow behavior with reduced DR and HTR when passing through the heat exchanger. Surfactant solution microstructures are recovered downstream of the exchanger and the solution recovers its DR and HTR character.[63] The recovery time depends on surfactant species, temperature, system geometry, and on the solvent.[64]

Modifying the inner surface character of heat exchangers, especially fluted tube heat exchangers, is a very promising technique for enhancing heat transfer in new DHC systems with modest pressure drop penalty and low capital investment.[65] However, for existing DHC systems, it may not be practical. Installing mechanical destructive devices, such as static mixers or meshes, are practical for existing systems as they are cheap, easy to install, and easy to clean.[63,66,67] None of these techniques are useful for enhancing heat transfer of DR polymer solutions, however, as they would cause permanent mechanical degradation.

The effectiveness of different techniques to enhance the heat transfer ability of DR surfactant solutions depends on the surfactant solution, its concentration and temperature, and details of the circulating system. Minimum added costs and maximum heat transfer enhancement are the goals.[63]

Field Tests on Surfactant DRAs

The temperature reversibility and mechanical recoverability of surfactant DRAs are particularly important for a very promising application of DRAs, DHC systems, where hot or cold fluids are circulated in a loop between a waste heat source or a chiller and heat exchange stations in buildings in a district. District heating provides more efficient use of energy sources and reduces environmental pollution by combustion products. It is widely used in northern and eastern Europe and Japan and use in the United States, Canada, and Korea is expanding.[5] District cooling is often used in the United States, Canada, and Japan.

A field test in Herning, Denmark (1988–1991) demonstrated that Habon, a cationic DR surfactant, provided 70% DR from 40°C to 130°C, and its concentration was stable over 10 mo.[68] However, the slow biodegradability of Habon raised environmental concerns and prevented its commercial use in Denmark.

A similar ammonium cationic surfactant, Dobon-G, was tested in a larger-scale district heating system in Völklingen, Germany, from 1988 to 1990.[69] With the addition of sodium salicylate, up to 80% DR was achieved from 40°C to 130°C. Only slight HTR was observed in a plate heat exchanger, and, contrary to laboratory studies, the operation of the tube bundle heat exchanger was not influenced by using DRA, possibly because it was overdesigned. Another field test in the Czech Republic using Habon G also gave promising results.[70]

A district cooling test on a cationic surfactant solution, 2300 ppm Ethoquad T13/50 with 2000 ppm sodium salicylate, was conducted in a building-size system at Santa Barbara, CA, in 1995.[71] The results showed that 30% pumping energy saving can be achieved by using DRA for complex hydronic systems in buildings, with relatively low HTR. In a later study with a nonionic surfactant, the HTR in both evaporator and cooling coils was reduced by temporarily mechanically degrading the microstructure.[3] Even with total elimination of HTR, 12% saving on pumping in this small system was obtained at full load. Greater savings would be expected in larger systems.

Despite the efficiency of DR cationic surfactant solutions and several successful large-scale field tests, commercial use of these solutions has not been widespread largely because of their slow biodegradation properties.[5,51] A new series of biodegradable mixed zwitterionic/anionic surfactant solutions, which can be disposed of by normal sewage treatment, has been developed by Akzo Nobel with excellent field test results in the primary system of the same district heating system in Herning, Denmark.[51,72]

CHARACTERISTICS OF TURBULENT DRAG REDUCING SYSTEMS

Introduction

Mean flow behaviors and turbulence characteristics of DR solutions differ from those of Newtonian solutions. Topics covered in this section include the maximum DR asymptote (MDRA), mean velocity profiles, diameter scale-up, turbulence intensities, stress balance, and streak spacing in polymer and surfactant DR solutions as well as the HTR–DR relationship for surfactant DR solutions. Numerical simulations for polymer DR are noted and speculations on DR mechanisms are offered.

Maximum DR Asymptote

Both polymer and surfactant DRAs have MDRA. Drag reduction flow data lie between the PK line and MDRA. The MDRA proposed by Virk shown in Eqs. (8) and (9) is widely acknowledged as valid for high-polymer DR.[28]

$$f^{-(1/2)} = 19.0 \log\left(N_{\mathrm{Re}} f^{1/2}\right) - 32.4 \tag{8}$$

or

$$f = 0.58 N_{\mathrm{Re}}^{-0.58} (N_{\mathrm{Re}} = 4000 - 40,000) \tag{9}$$

Zakin, Myska, and Chara showed that some surfactant DR systems have friction factors over 40% below Virk's MDRA for high polymers and more than 90% below Newtonian solutions (Fig. 11).[73] Their MDRA for surfactants is

$$f = 0.32 N_{\mathrm{Re}}^{-0.55} \tag{10}$$

Later, Myska and Chara observed even lower surfactant friction factors indicating that the MDRA for surfactant solutions is even lower than in Eq. (10).[74]

Mean Velocity Profiles and Limiting Asymptote

The turbulent flow velocity profile for Newtonian fluids is arbitrarily divided into three regions: the viscous sublayer, the buffer layer, and the turbulent core. To represent velocity profiles in pipe flow, friction velocity defined as

$$u^* = \sqrt{\frac{\tau_{\mathrm{w}}}{\rho}} \tag{11}$$

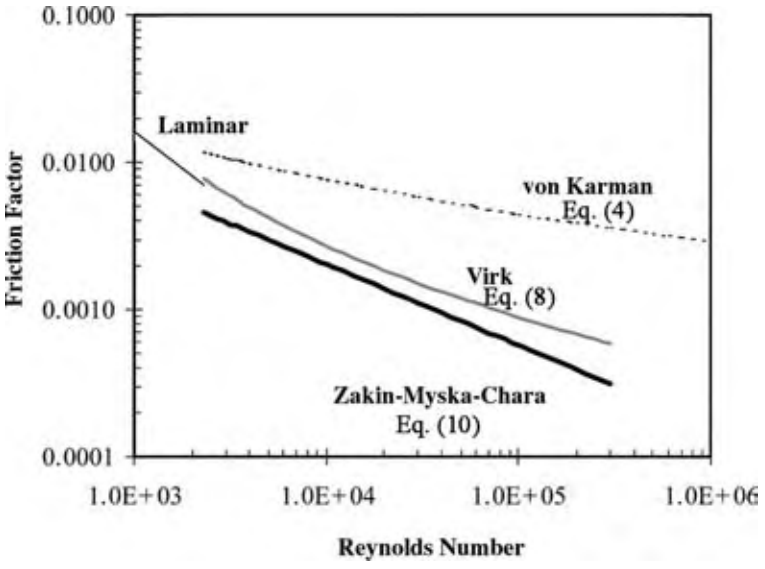

Fig. 11 Maximum DR asymptotes. *(View this art in color at www.dekker.com.)*

is used to form two nondimensional terms,

$$u^+ = \frac{u}{u^*} \tag{12}$$

$$y^+ = y\frac{u^*}{\nu} \tag{13}$$

where u is the local mean velocity, which varies with y, the distance from the wall, ν, is kinematic viscosity, and ρ is density. The velocity profile in the viscous sublayer of DR solutions is similar to that for Newtonian fluids. Fig. 12 shows turbulent core velocities for Newtonian fluids in pipe flow represented by:

$$u^+ = 2.5\ln(y^+) + 5.5 \tag{14}$$

while an additional term, ΔB, is needed for a parallel profile for fluids with moderate DR:

$$u^+ = 2.5\ln(y^+) + 5.5 + \Delta B \tag{15}$$

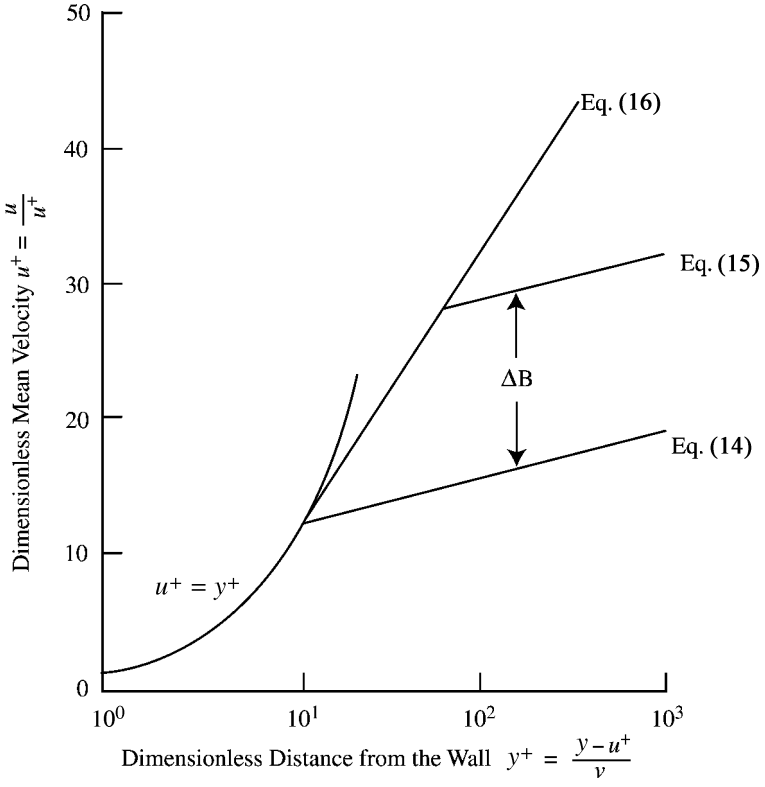

Fig. 12 Boundary layer and turbulent core velocity profile relationships for Newtonian and DR flows. (From Ref.[13].)

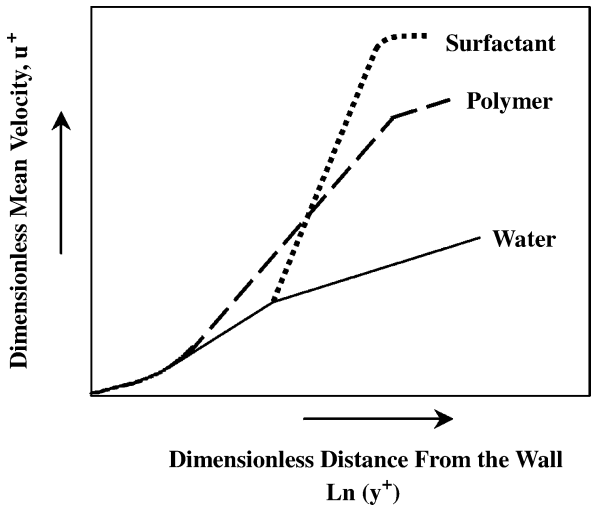

Fig. 13 Comparison of limiting turbulent mean velocity profiles.

However, for polymer and surfactant solutions close to their MDRA, limiting mean velocity profile asymptotes much steeper than Eqs. (12) and (13) are found in the turbulent core as shown in Eqs. (14) and (15) and Fig. 13.[28,73]

High-polymer asymptote:

$$u^+ = 11.7 \ln y^+ - 17.0 \tag{16}$$

Surfactant solution asymptote:

$$u^+ = 23.4 \ln y^+ - 65 \tag{17}$$

The limiting mean velocity profile for surfactant solutions is almost twice as steep as that for high polymers. These different limiting mean velocity profiles are related to the different MDRAs of their solutions.

Diameter Scale-Up

Diameter effects on DR are important for DR applications as practical economic pipe sizes are usually much larger than those in laboratory experiments. Virk showed that pipe size affects neither the value of τ_w for onset of DR nor the slope of the straight line describing the data on a PK plot.[28] As onset for small pipes occurs at lower N_{Re} than for larger pipes, Patterson, Zakin, and Rodriguez pointed out that the low velocities and τ_ws in larger commercial pipes may result in relatively low DR.[11]

Eq. (13) can be used for DR polymer solutions showing onset to scale from one pipe diameter to another. Techniques using the parameter ΔB assume similarity of velocity profiles for different pipe sizes or N_{Re} ranges. By measuring ΔB and u^* in one pipe size and assuming that they are independent of diameter, the friction factor of another pipe size can be obtained. However, this method gave only limited success in diameter scale-up with very small pipe sizes for polymer DR.[13]

Gasljevic and Matthys expressed DR as a function of both u^* and V.[75] They showed that polymer DR as a function of V is independent of diameter. However, diameter scale-up was only valid for Type A DR. Usui, Itoh, and Saeki suggested that the fluid relaxation time was essential to surfactant DR.[76] Their scaling law for DR as a function of either u^* or V (mean flow velocity) included the effect of shear thinning behavior of their surfactant solution.

Turbulence Intensities

A number of authors have observed lower root mean square time averaged turbulent intensities, v', normal to the flow direction for both high-polymer and surfactant DR systems compared with Newtonian solvents.[77–83] There is a subtle difference between high-polymer and surfactant solution data. The former peak is at y^+ values >100 while the latter is at $y^+ < 100$. Newtonian solvents peak at about $y^+ \approx 100$.[84] This, along with their different MDRAs and different limiting velocity profile slopes, suggests that their DR mechanisms may differ.

Warholic, Schmidt, and Hanratty showed that peak root mean square axial turbulent intensities, u', of a DR surfactant solution can be greater or lesser than solvent intensities depending on the N_{Re}—lower at low N_{Re} and higher at high N_{Re}.[82]

Stress Balance with Reduced Reynolds Stress

Several investigators have observed lower Reynolds stresses than expected for DR solutions caused by low v' and difference in phase between u' and v'. Recently, several researchers observed zero Reynolds stress profiles for high-DR surfactant solutions, clearly illustrating a major stress deficit in these systems.[74,79,82,83,85] Fig. 14 is a schematic illustrating the magnitude of the additional term, τ_{DR}, needed to satisfy the stress balance at any point for systems with zero Reynolds stresses.

$$\tau_{Total} = \tau_{viscous} + \tau_{Reynolds} + \tau_{DR} \tag{18}$$

$$\tau_{viscous} = \eta \, du/dy \tag{19}$$

$$\tau_{Reynolds} = -\rho \overline{u'v'} \tag{20}$$

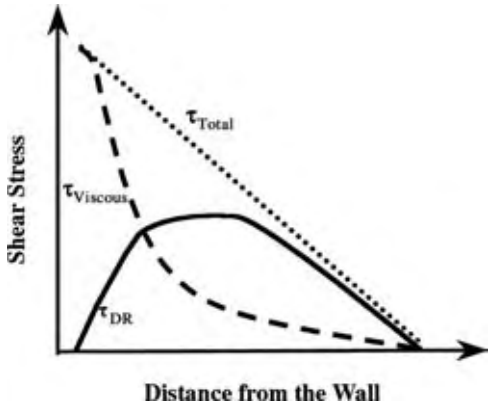

Fig. 14 Turbulent stress profiles for solution with zero Reynold stress. [See Eq. (18).]

Understanding the character of τ_{DR} and predicting it are major unresolved challenges.

Streak Spacing

Turbulent streaks in Newtonian flows have an average spacing of 100 in y^+ units. In polymer or surfactant DR flows, the spacing is increased and the streaks are more persistent and more stable.[86,87]

Relationship of HTR to DR

Aguilar studied the relationship of HTR in DR solutions to the reduction in drag.[88] He found that the ratio, HTR/DR, was greater than unity and relatively constant over a wide range of N_{Re} for both surfactants and high-polymer systems. A plot of the ratio for a number of surfactant solutions is shown in Fig. 15. He also showed that a slightly different ratio based on modified terms in the numerator and denominator of the HTR/DR ratio was even more constant. Thus, the more easily measured pressure drop data in straight tubes can be used to estimate the heat transfer coefficients.

Simulations of Polymer DR

A significant effort is under way to predict polymer DR in turbulent viscoelastic channel flow by direct numerical simulation using FENE, FENE-P, Gieskus, and other models (see, for example, Refs.[89–92]). While progress has been made by these and other authors, a review of these results is outside the scope of this entry.

Speculations on Surfactant and Polymer DR Mechanisms

Because of the interaction of the two complicated and not well-understood fields, turbulent flow and non-Newtonian fluids, understanding of DR mechanism(s) is still quite limited. Cates and coworkers (for example, Refs.[93,94]) and a number of other investigators have done theoretical studies of the dynamics of self-assemblies of worm-like micelles. Because these so-called "living polymers" are subject to reversible scission and recombination, their relaxation behavior differs from reptating polymer chains. An additional form of stress relaxation is provided by continuous breaking and repair of the micellar chains. Thus, stress relaxation in micellar networks occurs through a combination of reptation and breaking. For rapid scission kinetics, linear viscoelastic (Maxwell) behavior is predicted and is observed for some surfactant systems at low frequencies. In many cationic surfactant systems, however, the observed behavior in Cole–Cole plots does not fit the Maxwell model.[95,96]

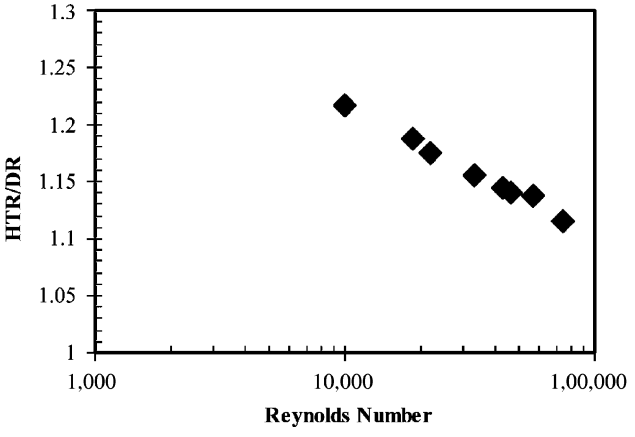

Fig. 15 Heat transfer reduction/DR ratio for a number of surfactant solutions. (From Ref.[88].)

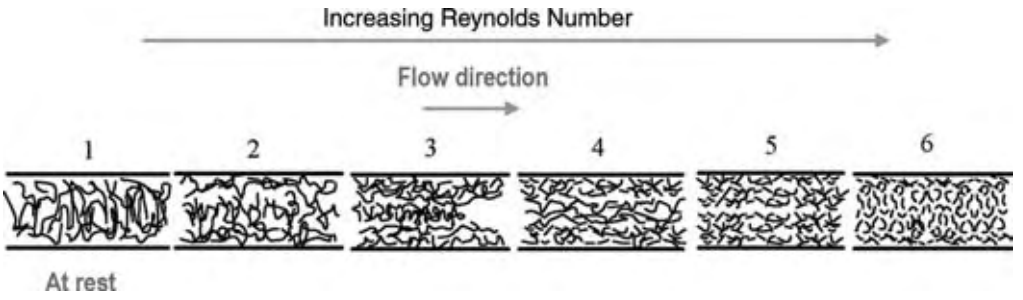

Fig. 16 Postulations on surfactant DR mechanism. 1) At rest, threadlike micelles distribute randomly in the solution. 2) As the Reynolds number increases, threadlike micelles near the wall get extended and start to align along the flow direction due to high wall shear stress. Micelle alignment decreases as the distance from the pipe wall increases and surfactant solution starts to show drag reduction as turbulent fluctuations in the radial direction which accompany the micelle alignment decrease. 3) With an increasing Reynolds number, more and more threadlike micelles get extended and align along the flow direction. Maximum drag reduction is observed when a maximum amount of long, extended threadlike micelles align along the flow direction. 4) At a higher Reynolds number, the wall shear stress becomes so large that the extended threadlike micelles near the wall are broken up. However, due to the non-uniform stress distribution in the pipe (maximum near the wall, zero at the center), the threadlike micelles away from the wall are not affected. Depending on how fast these micelles away from the wall can move to the wall, the maximum drag reduction of the surfactant solution can be maintained to even higher Reynolds number. 5) With further increase in the Reynolds number, threadlike micelles far from the wall are broken up resulting in loss of solution drag reduction ability. The corresponding shear stress at this critical Reynolds number is defined as the critical shear stress for surfactant drag reduction. 6) As the Reynolds number further increases, all of the micelles in the surfactant solution are broken down to a length which can not sustain drag reduction and the solution completely loses its drag reduction ability. (From Ref.[63].) *(View this art in color at www.dekker.com.)*

For DR surfactant solutions with thread-like micelles, Qi proposed a possible DR mechanism in pipe flow as shown in Fig. 16.[64] At rest, thread-like micelles are distributed randomly in the solution. As N_{Re} increases, the thread-like micelles near the wall are extended and start to align along the flow direction because of high wall-shear stress and the solution starts to show DR. Turbulent fluctuations decrease in the radial direction because of the micelle alignment and turbulent energy dissipation is reduced.

Shear stress and micelle alignment decrease as distance from the pipe wall increases, but with increasing N_{Re}, more and more thread-like micelles are extended and aligned along the flow direction. Maximum DR is observed when a maximum amount of long, extended thread-like micelles align along the flow direction. At higher N_{Re}, the wall-shear stress is so large that the extended thread-like micelles near the wall are broken up. However, because of the nonuniform stress distribution in the pipe (maximum near the wall, zero in the center), thread-like micelles away from the wall are still not affected. Depending on micelles' resistance to break up and how fast micelles away from the wall can move to the wall, the maximum DR of the surfactant solution may be maintained to large N_{Re}.

With further increase of N_{Re}, even thread-like micelles further from the wall are broken up and the small number of thread-like micelles in the center cannot reach the wall in sufficient number to maintain high DR. The wall-shear stress corresponding to this critical N_{Re} is defined as the critical shear stress for surfactant DR. With further increase in N_{Re}, more micelles in the surfactant solution are broken up, the remainder cannot sustain DR, and the solution loses its DR ability.

The amount, flexibility, and strength of the thread-like micelles determine the temperature range, critical wall-shear stress, and maximum DR ability of surfactant solutions.

The DR mechanism of high-polymer solutions may be similar to that of surfactant solutions with thread-like micelles being replaced by long polymer chains. However, the different MDRAs, limiting mean velocity profile slopes, and different locations of the transverse turbulent intensity peak positions in polymer and surfactant DR solutions suggest that their mechanisms may be different, probably because of the continual breakup and rapid self-reassembly of the micellar microstructures.

Other proposed DR mechanisms for both types of additives include high extensional viscosity providing additional resistance to vortex stretching and turbulent eddy growth and viscoelasticity, which dampens small turbulent eddies and stores turbulent fluctuation energy that would otherwise be dissipated.

CONCLUSIONS

Drag reduction in turbulent flows of dilute high-polymer of surfactant solutions is a striking

phenomenon. At concentrations of 1 ppm for high-MW polymer solutions and 200 ppm or less for surfactant solutions, significant DR can be attained, although there is little effect on the ordinary physical properties of the solvent. Heat transfer reduction of slightly greater magnitude accompanies DR. High-polymer DRAs have found a major application in reducing energy requirements in hydrocarbon pipeline transport while surfactant DRAs are highly promising for reducing energy requirements in DHC systems.

NOMENCLATURE

Roman Symbols

ΔB	Dimensionless shift in turbulent core velocity profile for DR solutions
% DR	Percent DR
% HTR	Percent HTR
$[C]$	Intrinsic concentration (ppm)
[DR]	Intrinsic DR (ppm^{-1})
C	Concentration (ppm)
C_c	Critical concentration for disappearance of the laminar-turbulent transition in a tube (g/dl)
DR_m	Maximum DR at infinite C
f	Friction factor in DR solutions
f_s	Friction factor in Newtonian solvents
g	Exponent of R_G in Eq. (6)
m'	MW/M_c
M_c	Minimum MW for entanglements to occur in polymer melts (g/mol)
MW	Molecular weight (g/mol)
N_{Re}	Reynolds number $= \rho Du/\eta$, where D is inner pipe diameter
Nu	Turbulent Nusselt number for DR solutions = hD/K, where h is the heat transfer coefficient and k is the thermal conductivity
Nu_s	Turbulent Nusselt number for Newtonian solvents
R_G	Radius of gyration of polymer molecules (M)
T_1	Polymer molecule relaxation time (sec)
u	Mean flow velocity (M/sec)
u^*	Friction velocity (M/sec)
u^+	Dimensionless velocity
u'	Root mean square fluctuating axial velocity (M/sec)
v'	Root mean square fluctuating velocity perpendicular to the flow direction (M/sec)
V	Mean flow velocity (M/sec)
y	Distance from the wall (M)
y^+	Dimensionless distance from the wall

Greek Symbols

$[\eta]$	Intrinsic viscosity (dl/g)
$\dot{\gamma}$	Wall-shear rate (Sec^{-1})
η	Shear viscosity (Pa/sec)
ν	Kinematic viscosity (M^2/sec)
ρ	Density (kg/m^3)
τ_{DR}	Additional stress for DR fluids (Pa)
$\tau_{Reynolds}$	Reynolds stress (Pa)
τ_{Total}	Total stress (Pa)
$\tau_{Viscous}$	Viscous shear stress (Pa)
τ_w	Wall-shear stress (Pa)
Ω	Average onset constant in Eq. (6)

Dust Explosion Hazard Assessment and Control

Vahid Ebadat
Chilworth Technology, Inc., Princeton, New Jersey, U.S.A.

INTRODUCTION

Statistics clearly show that fire/explosion hazards could exist in any plant/equipment that handles or processes a combustible dust. The consequences of a dust explosion can range from disruption of production to loss of plant and injury or fatality of personnel.

To eliminate/control potential dust cloud explosion hazards the following information is required:

- Understanding of the explosion characteristics of the dust(s).
- Identification of locations where combustible dust cloud atmospheres are or could be present during normal and abnormal operating conditions.
- Identification of potential ignition sources that could be present under normal and abnormal conditions.
- Proper plant design to eliminate and/or minimize the occurrence of dust explosions and protect people and plant against their consequences.

The intent of this document is to provide the readers with basic information on how to identify, assess, and eliminate/control potential dust explosion hazards in their facilities. More detailed information on the topics that are covered in this document may be obtained from Bibliography.

CONDITIONS REQUIRED FOR DUST EXPLOSIONS TO OCCUR

A number of conditions must exist simultaneously and in one location for a dust explosion to occur:

Dust must be combustible: (As far as dust clouds are concerned, the terms ''combustible,'' ''flammable,'' and ''explosible'' all have the same meaning and could be used interchangeably.)

The first stage of a dust explosion hazard assessment is to determine whether the dust will explode when dispersed as a cloud. The combustibility of a dust can be assessed by conducting an explosion classification test on a representative sample of the dust. In this laboratory test the observation of flame propagation determines whether or not a suspended dust is capable of initiating and sustaining an explosion. It should be noted that some powders that are noncombustible at ambient temperature conditions could become combustible at elevated temperatures. Therefore, if a noncombustible dust cloud is to be subjected to above ambient temperatures as a part of the process the explosion classification test should be conducted at the operating (elevated) temperature.

Dust must be airborne: If a layer of dust on a surface is ignited, the burning process will be relatively slow, releasing heat over a long period of time. However, if a sufficient concentration of finely divided dust particles are suspended in air and ignited, because of the availability of oxygen around each particle, the combustion process will be very rapid giving rise to a dust explosion.

Dust concentrations must be within the explosible range: If the concentration of a dust cloud is below the minimum explosible concentration (MEC) an explosion cannot propagate. The ease of ignition of a dust cloud and also the resulting explosion violence increase as the dust cloud concentration is increased above the MEC until an optimum concentration is reached causing the highest explosion violence. At higher dust cloud concentrations the explosion violence decreases. The MEC of dust clouds is typically in the range of 10–500 gm^{-3}.

The maximum explosible concentration—the concentration above which an explosion cannot propagate because of lack of sufficient oxidant—is not normally well defined for dust clouds.

The MEC of dust clouds can be determined by laboratory testing.

Dust must have particle size distribution capable of propagating flame: The sensitivity of a dust cloud to ignition and the resulting explosion violence (severity) increase with a decrease in particle size. This is because the combustion process involves chemical reaction at the solid–oxidant interface. Therefore, as the dust particles get finer the total surface area that is available for oxidation will increase. It should be noted that, in practice, very often dust clouds are made up of particles with sizes ranging from fine to coarse. As the fines become airborne more readily, they play a more prominent role in the initial ignition and explosion propagation.

The atmosphere in which the dust cloud is present must be capable of supporting combustion: A dust

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007763

cloud explosion will only occur if there is a sufficient amount of oxidant available. In practice, the oxygen in air is normally the most common oxidant. Other oxidants include chlorine, nitrous oxide, nitric oxide, and nitrogen tetraoxide.

Explosion prevention can be accomplished by the depletion of oxidant. The concentration of oxidant below which combustion cannot occur in a specific mixture is referred to as the limiting oxidant concentration (LOC).

Generally, combustible organic compounds are unlikely to propagate flame if the oxygen content of the atmosphere in which the dust cloud is present is below 8% v/v, using nitrogen or carbon dioxide as the inert gas. Other inert gases include argon, helium, steam, and flue gas (waste gas from on-site processes).

The LOC should be determined by laboratory testing.

An ignition source with sufficient energy to initiate flame propagation must be present: The ignition sources that have been found to be the cause of the majority of explosions in dust handling/processing plants include welding and cutting, heating and sparks generated by mechanical failure, sparks generated by mechanical impacts, flames and burning materials, self heating, electrostatic discharges, electrical sparks, etc.

The sensitivity of a dust cloud to ignition by different ignition sources could be determined through appropriate laboratory tests.

LABORATORY TESTING TO ASSESS EXPLOSION CHARACTERISTICS OF DUST CLOUDS

To assess the possibility of an explosion in a facility and to select the most appropriate basis of safety, explosion characteristics of the dust(s) that are being handled/processed in the facility should be determined.

The explosion characteristics of powders normally fall within one of two groups, ''likelihood of an explosion'' and ''consequences of an explosion.'' These two groups of tests are discussed below.

Laboratory Tests to Determine the Likelihood of an Explosion

The following tests provide information on the likelihood of a dust explosion:

Explosion classification test

The explosion classification test determines whether a dust cloud will explode when exposed to an ignition source, the test results in a material being classified as either combustible or noncombustible.

The explosion classification test is usually conducted in a modified Hartmann tube apparatus. The apparatus consists of a 1.2 L vertical tube mounted onto a dust dispersion system. Dust samples of various quantities are dispersed in the tube and attempts are made to ignite the resulting dust cloud by a 10 J electrical arc ignition source. If the material fails to ignite in the modified Hartmann tube apparatus, the testing is continued in the 20 L sphere apparatus. Dust samples of various quantities are dispersed inside the sphere and are exposed to a 10,000 J ignition source.

Minimum explosible concentration

The MEC test determines the lowest concentration of dust cloud in air that can give rise to flame propagation on ignition. The test involves dispersing a sample of the dust in a 20 L sphere apparatus and attempting to ignite the resulting dust cloud with an energetic ignition source. Trials are repeated for decreasing sample concentrations until the MEC is determined. The MEC of a given dust cloud is influenced by the size of the ignition source. An increase in the size of the ignition source will result in a lower MEC value.

The MEC test is performed in accordance with International Standards Organization (ISO) method 618411 or American Society for Testing and Materials (ASTM) E1515.

Minimum ignition temperature

The minimum ignition temperature (MIT) test determines the lowest temperature capable of igniting a dust dispersed in the form of a cloud. The MIT is an important factor in evaluating the ignition sensitivity of dusts to such ignition sources as heated environments, hot surfaces, electrical apparatus, and friction sparks.

The MIT test is performed in accordance with ASTM E-2021 and the European Standard 61241-2-1. Dust samples of various sizes are dispersed into the furnace and the minimum furnace temperature capable of igniting the dust cloud at its optimum concentration for ignition is determined.

The MIT value is influenced by particle size and moisture content of the dust. A decrease in particle size and moisture content of the dust particles results in a lower MIT value.

Minimum ignition energy

The minimum ignition energy (MIE) test determines the lowest electrostatic spark energy that is capable of igniting a dust cloud at its optimum concentration for ignition. The test is used primarily to assess the potential susceptibility of dust clouds to ignition by electrostatic discharges.

Minimum ignition energy test is performed in accordance with ASTM E2019, British Standard 5958, and International Standard: IEC 1241-2-3 using the modified Hartmann tube apparatus. Dust samples of various sizes are dispersed in a 1.2 L vertical tube and attempts are made to ignite the resultant dust cloud with discrete capacitive sparks of known energy.

The MIE value is influenced by particle size and moisture content of the dust and by process conditions, such as temperature and oxidant content. A decrease in particle size and moisture content of the dust particles results in a lower MIE value. An increase in the temperature of the atmosphere in which the dust cloud is suspended will result in a decrease in MIE.

Electrostatic volume resistivity

Volume resistivity is a measure of the electrical resistance for a unit volume of material and is the primary criterion for classifying powders as low, moderate, or high insulating. Insulating powders have a propensity to retain electrostatic charge and can produce hazardous electrostatic discharges when exposed to grounded plant, equipment, or personnel.

Volume resistivity can be measured in accordance with British Standard 5958. The method involves placing a powder sample into a standardized electrode cell. A voltage is applied to the cell and the current through the powder is measured. Volume resistivity is calculated using the known voltage, the measured current, and the geometrical relationship between the electrodes.

Because of the effect of atmospheric and absorbed moisture on volume resistivity, it is usually suggested that this test be performed at ambient and low relative humidity conditions.

Electrostatic chargeability

The concept of electrostatic chargeability refers to the propensity of powder particles to become charged when flowing through conveyances or when handled in containers. Electrostatic chargeability is measured by having samples flow through a pipe and measuring the resultant electrostatic charge. The test provides data that can be used to develop appropriate material handling guidelines.

Because of the effect of atmospheric and absorbed moisture on powder chargeability, this test is usually performed at ambient and low relative humidity conditions.

Limiting oxidant concentration

The LOC test determines the minimum concentration of oxygen (displaced by an inert gas such as nitrogen) capable of supporting combustion. An atmosphere having an oxygen concentration below the LOC is not capable of supporting combustion and thus cannot support a dust explosion. The LOC test is used to study explosion prevention or severity reduction involving the use of inert gases and to set oxygen concentration alarms or interlocks in inerted plants and vessels.

Limiting oxidant concentration testing can be performed using the 20 L sphere apparatus. Dust samples of various sizes are dispersed in the vessel and attempts are made to ignite the resulting dust cloud with an energetic ignition source. Trials are repeated for decreasing oxygen concentrations until the LOC is determined.

Limiting oxidant concentration of a given dust cloud is dependent on the type of the inert gas that is used to replace the oxidant of the atmosphere as well as some process conditions such as temperature. Therefore, LOC testing should simulate the process conditions and be performed by using an inert gas that is representative of the inert gas used in practice.

Laboratory Tests to Determine the Consequences of an Explosion

There are two laboratory tests (measurements) to determine the consequences of an explosion: maximum explosion pressure and maximum rate of pressure rise.

The maximum explosion pressure and maximum rate of pressure rise values are determined by using the 20 L sphere apparatus. The dust sample is dispersed within the sphere, ignited by chemical igniters, and the pressure of the resulting explosion is measured. The sample size is varied to determine the optimal dust cloud concentration. The maximum pressure and rate of pressure rise are measured and used to calculate the explosion severity (K_{st}) value of the dust cloud. These data can be used for the purpose of designing dust explosion protection measures.

Explosion severity testing is performed in accordance with the current ASTM Method E 1226, National Fire Protection Association (NFPA) Standard 68, German Society of Engineers (VDI) Method 3673, and ISO Method 6184/1.

BASIS OF SAFETY FROM DUST CLOUD EXPLOSIONS

Safety from potential dust cloud explosions could include taking measures to avoid an explosion (explosion prevention) or designing plant and equipment so that in the event of an explosion people and plant are protected (explosion protection). Selection of

explosion prevention and/or protection measures is usually based on:

- How much information is available on the sensitivity of the powder(s) to ignition and the resulting explosion severity.
- Nature of the processes and operations.
- Level of personnel's knowledge and appreciation regarding the consequences of a potential dust explosion and adherence to preventive measures.
- Environmental effects of a potential dust explosion.
- Business interruptions resulting from a potential dust explosion.

Explosion Prevention Measures

The risk of an explosion is removed when one of the following measures is taken.

An explosible dust cloud is never allowed to form

There are two main methods of ventilation for eliminating or controlling the spread of explosible atmospheres (fuel):

Dilution Ventilation. Dilution ventilation provides a flow of fresh air into and out of the building. This normally results in a reduction of the background concentration of the flammable atmosphere in the working area but there is no control of the flammable atmosphere at the source of release. This method is not practical for controlling the concentration of dust cloud atmospheres but is often used to control vapor concentrations.

Local Exhaust Ventilation. Local exhaust ventilation is designed to intercept the flammable atmosphere at the source of release and directs it into a system where air is safely separated from the fuel. Correctly designed local exhaust ventilation systems could be very effective in limiting the spread of dust cloud atmospheres beyond the source of release. Local exhaust ventilation is generally less expensive to run than dilution ventilation because less air is used.

A local exhaust ventilation system generally includes hood, ductwork, filter, and fan.

To ensure that the local exhaust system itself does not become an explosion hazard; the following suggestions should be considered:

- Exhaust air velocity in the ductwork should be high enough to prevent the powder from depositing in the ductwork.
- While extracting from several hoods or sources into a common duct, each branch duct should deliver the intended air volume at the required conveying velocity. It is preferable that the air balancing is achieved without using dampers. Air balancing without dampers safeguards the system against tampering with airflow rates, and also eliminates the possibility of dust accumulation behind the dampers.
- The degree of enclosure provided by the hood and the air capture velocity should be such that dust particles are prevented from entering the workplace.
- The air cleaning devices (air filters, dust collectors, cyclones, etc.) should be protected against the consequences of dust cloud explosions. This includes measures to prevent propagation of the explosion back through the exhaust ducting to other areas of plant and equipment.
- All the components of the local exhaust system should be made from conductive and/or static dissipative materials and electrically grounded. This includes the hoods, ductwork, filter housing, and metal support cages for filter socks (if any).

The atmosphere is sufficiently depleted of oxidant (normally the oxygen in air) so that it cannot support combustion

Safety may be based on reducing the oxidant concentration below a level that will no longer support combustion (LOC), by adding an inert gas. Nitrogen gas is perhaps the most commonly used inert gas. Other inert gases include carbon dioxide, argon, helium, steam, and flue gas (waste gas from on-site processes). Oxidant can also be removed by working under vacuum (safe vacuum pressure should be obtained by testing).

Limiting oxidant concentration for combustion is dependent on the type of dust and type of inert gas used. Once the LOC of the dust has been determined for the inert gas that will be used, the inert gas needs to be introduced into the vessel. Successful inert gas blanketing will only be possible if the entire volume of the vessel is inerted and the inert atmosphere is maintained throughout even when the vessel is opened during the addition of solids and/or liquids to the vessel.

The following techniques are commonly used to achieve an inert atmosphere in a vessel:

Pressure Purging. The vessel is pressurized with an inert gas and then relieved outside. This procedure is repeated until the desired oxygen concentration is reached. The number of pressure purges, n, required to achieve the desired LOC can be calculated by using the following equation:

$$n = \ln(21/\mathrm{LOC})/\ln P$$

where P is purge pressure (bar absolute) and n is the number of pressure purges.

In the above equation it is assumed that:

- Inert gas contains no oxygen.
- Initial oxygen concentration is 21%.

Vacuum Purging. The vessel is evacuated and then is increased to atmospheric pressure using the chosen inert gas. This procedure is repeated until the desired oxygen concentration is reached. The number of vacuum purges, n, required to achieve the desired LOC can be calculated by using the following equation:

$$n = \ln(\mathrm{LOC}/21)/\ln P$$

where P is vacuum pressure (bar absolute) and n is the number of vacuum purges.

In the above equation it is assumed that:

- Inert gas contains no oxygen.
- Initial oxygen concentration is 21%.

Flow-Through Purging. The vessel is purged with a continuous flow of inert gas. Flow-through purging will only be successful if there is a means of mixing the inert gas within the entire volume of the vessel. The required purge time, t, required to achieve the desired LOC is given by the following equation:

$$t = -V/\mathrm{Q}\log(\mathrm{LOC}/21)$$

where Q is purge gas flow rate (m^3/sec) and V is vessel volume.

All ignition sources capable of igniting the dust cloud are removed

The ignition sources that have been found to be the cause of the majority of explosions in dust handling/processing plants include welding and cutting, heating and spark generated by mechanical failure, mechanical impacts, flames and burning materials, self-heating, electrostatic discharges, and electrical sparks. This is not an exhaustive list.

Elimination of ignition sources involves the following steps.

Control of Heat Sources. Examples of heat sources are the following:

- External surfaces of hot process equipments such as heaters, dryers, steam pipes, and electrical equipment.
- Mechanical failure of equipment such as bearings, blowers, mechanical conveyers, mills, mixers, and unprotected light bulbs.
- Hot work.

A hot surface may directly ignite a dust cloud or first ignite a dust layer that may have settled on it and subsequently ignite a dust cloud.

Measures that may be considered for preventing a dust cloud ignition by heat sources include:

- Maintaining an effective housekeeping program to prevent/remove dust accumulations on potential hot surfaces.
- Maintaining the temperature of the processing equipment below the self-heating temperature of the powder.
- Providing regular inspection and maintenance of the processing plant to prevent overheating due to misalignment, loose objects, belt-slip/rubbing, etc.
- Preventing the overloading of processing equipment, such as grinders and conveyors. Consider installing overload protection devices on drive motors.
- Preventing ''foreign objects'' from entering the processing equipment by use of suitable separation devices, such as electromagnets or pneumatic separators.
- Isolating/shielding dust layers and clouds from hot surfaces.
- Using approved electrical equipment (correct temperature rating).

Control of Friction/Impact Sparks. The ability of friction/impact sparks to ignite flammable atmospheres is dependent, among other factors, on the composition of the impacting surfaces. In particular, incendive sparks could be expected in any one of the following conditions:

- Items constructed from light alloys strike a rusty steel surface.
- A rusty steel surface that has been coated with a layer of paint containing aluminum is struck by a hard object.
- Striking surfaces containing flint, rock, or grit with a hard object.

In any work where friction/impact sparks could be expected the measures that may be considered for preventing a dust cloud ignition include the following:

- Flammable (gas, vapor, and dust clouds) atmospheres should not be present.
- Hard surfaces, such as concrete, brick, or rock, should be kept wet with water. Alternatively, soft

rubber mats may be used to cover the surfaces and act as a cushion for the objects that might fall.

Welding, Cutting, and Similar Hot Work Operations. Flames and sparks that are present during welding/brazing/soldering and cutting and other similar operations could readily ignite dust layers and clouds.

To avoid fires and explosions, measures should be taken to prevent the formation of dust clouds and remove dust deposits from surfaces.

Electrical Equipment and Instruments. Electrical sparks produced during normal working of switches, contact breakers, motors, fuses, etc. can ignite dust layers and clouds.

The requirements for electrical equipment and wiring systems for use in locations where combustible dust clouds or layers may be present during normal and/or abnormal operation of the plant are provided by Article 500 of the National Electrical Code (NEC). The intent of Article 500 is to prevent electrical equipment from providing a means of ignition for an ignitable atmosphere.

Ensuring safety when electrical equipment and wiring systems are present normally involves:

1. Determining the explosion characteristics that are listed below for the dust, considered relative to those for Pittsburgh seam coal:
   a. Minimum explosible concentration, MEC.
   b. Minimum ignition temperature of the dust cloud, MIT.
   c. Minimum ignition energy of the dust cloud, MIE.
   d. Maximum explosion pressure, P_{max}.
   e. Maximum rate of pressure rise, dP/dt.
2. Calculating the ''ignition sensitivity'' and ''explosion severity'' as defined below:

$$\text{Ignition sensitivity} = (\text{MIT} \times \text{MIE} \times \text{MEC})_1 / (\text{MIT} \times \text{MIE} \times \text{MEC})_2$$

$$\text{Explosion severity} = (p_{max} \times dP/dt)_2 / (p_{max} \times dP/dt)_1$$

   Subscript 1 refers to the appropriate explosion characteristics for Pittsburgh seam coal (the standard dust used by the U.S. Bureau of Mines) and subscript 2 refers to the appropriate explosion characteristics for the specific dust present in the plant.
   Using the above equations, dusts having ignition sensitivity equal to or greater than 0.2 or explosion severity equal to or greater than 0.5 are considered combustible (for electrical area classification purposes only).
3. Conducting an electrical area classification: An electrical area classification involves identifying the extent (if any) of location(s) in a facility where combustible materials could be present during normal and/or abnormal conditions. According to Article 500 of the NEC, major categories of hazardous locations are:
   a. Class I, in which the combustible material is a gas or a vapor (NFPA 497).
   b. Class II, in which the combustible material is dust (NFPA 499).

Within Class II hazardous locations, Article 500 recognizes two degrees of hazard: Division 1 and Division 2.

Class II, Division 1 locations are considered to be any of the following:

- Combustible dust is in the air under normal operating conditions in quantities sufficient to produce explosible or ignitable mixtures.
- Mechanical failure or abnormal operation of machinery or equipment might cause such explosible or ignitable mixtures to be produced and might also provide a source of ignition through simultaneous failure of electrical equipment, operation of protection devices, or other causes.
- Group E dusts may be present in hazardous quantities. Group E dusts include combustible metal dusts, including aluminum, magnesium, and their commercial alloys, or other combustible dusts whose particle size, abrasiveness, and conductivity present similar hazards in the use of electrical equipment. The NEC does not recognize any Division 2 areas for such dusts.

Note: Dusts having a volume resistivity less than 1 Ωm are considered conductive and therefore Group E.

Class II, Division 2 are locations where combustible dust is not normally in the air in quantities sufficient to produce explosible or ignitable mixtures, and dust accumulations are normally insufficient to interfere with the normal operation of electrical equipment or other apparatus. However, combustible dust may be in suspension in the air as a result of infrequent malfunctioning of handling or processing equipment and where combustible dust accumulations on, in, or in the vicinity of the electrical equipment may be sufficient to interfere with the safe dissipation of the heat from electrical equipment or may be ignitable by abnormal operation or failure of electrical equipment.

Note: The quantity of combustible dust that may be present and the adequacy of dust removal systems are factors that merit consideration in determining the classification and may result in an unclassified area.

The following factors determine the extent of Class II locations:

- Combustible material involved [for example, the dust conductive (Group E)]
- Bulk density of the material
- Particle sizes of material
- Density of the particles
- Process or storage pressure
- Size of the leak opening
- Quantity of the release
- Dust collection system
- Housekeeping
- Presence of any flammable or combustible gas.

As discussed in this section, the intent of electrical area classification is to ensure that electrical equipment will not act as an ignition source. However, once the extent of a classified area is determined it is prudent to ensure that all potential ignition sources are eliminated or controlled.

Electrostatic Discharges. In this section it is assumed that the powder does not contain any flammable solvent and it is handled and processed in an atmosphere free from flammable gases and vapors.

Electrostatic charge generation: Although the magnitude and polarity of charge is usually difficult to predict, charge generation should almost always be expected whenever powder particles come into contact with another surface. It occurs, for example, during mixing, grinding, sieving, pouring, and pneumatic transfer. The chemical composition and the condition of the contacting surfaces can often influence the charging characteristics.

Electrostatic charge accumulation: Generally, powders are divided into three groups depending on their ability to retain static charge even if the powder is in contact with an electrically ground conductive object. This ability is known as volume resistivity:

1. Powders with volume resistivities up to about $10^6\,\Omega$m are considered conductive.
2. Powders with volume resistivities in the range 10^6–$10^9\,\Omega$m are of medium resistivity.
3. Powders with volume resistivities above $10^9\,\Omega$m are high-resistivity powders.

Charge will accumulate on a powder if the charge generation rate exceeds the rate at which the charge dissipates.

Electrostatic discharges: The accumulation and retention of charge on powder or equipment creates a dust explosion hazard only if the charge is suddenly released in the form of a discharge with sufficient energy to ignite the dust cloud. Potentially incendive discharges resulting from charged powder and equipment include spark discharges, brush discharges, propagating brush discharges, and cone (bulking) discharges.

General Precautions

Bonding and grounding

Spark discharges can be avoided by electrically grounding conductive items, such as metal plant, fiberboard drums, conductive liners, low-resistivity powders, and people.

Use of insulating materials

Where there could be high surface charging processes, nonconductive materials should not be used, unless the breakdown voltage across the material is less than 4 kV. Examples of nonconductive objects include plastic pipes, containers, bags, coatings, and liners.

Charge reduction by humidification

High relative humidity can reduce the resistivity of some powders and increase the rate of charge decay from bulk powder in grounded metal containers. However, in most cases this will only be effective if a relative humidity in excess of 65% is maintained.

Charge reductions by ionization

Localized ionization (corona discharges) from sharp, grounded, conducting probes or wires can on occasions be used to reduce the level of electrostatic charge from powder particles entering a vessel. Electrostatic ionization devices are not, however, without problems, and should only be used after consulting expert advice.

Explosion protection

In some powder handling processes it is not possible to avoid the simultaneous presence of an explosible dust cloud and a hazardous buildup of charge. In those situations, measures should be taken to protect against or prevent explosions. These include inerting, use of explosion-resistant equipment, explosion venting, or explosion suppression.

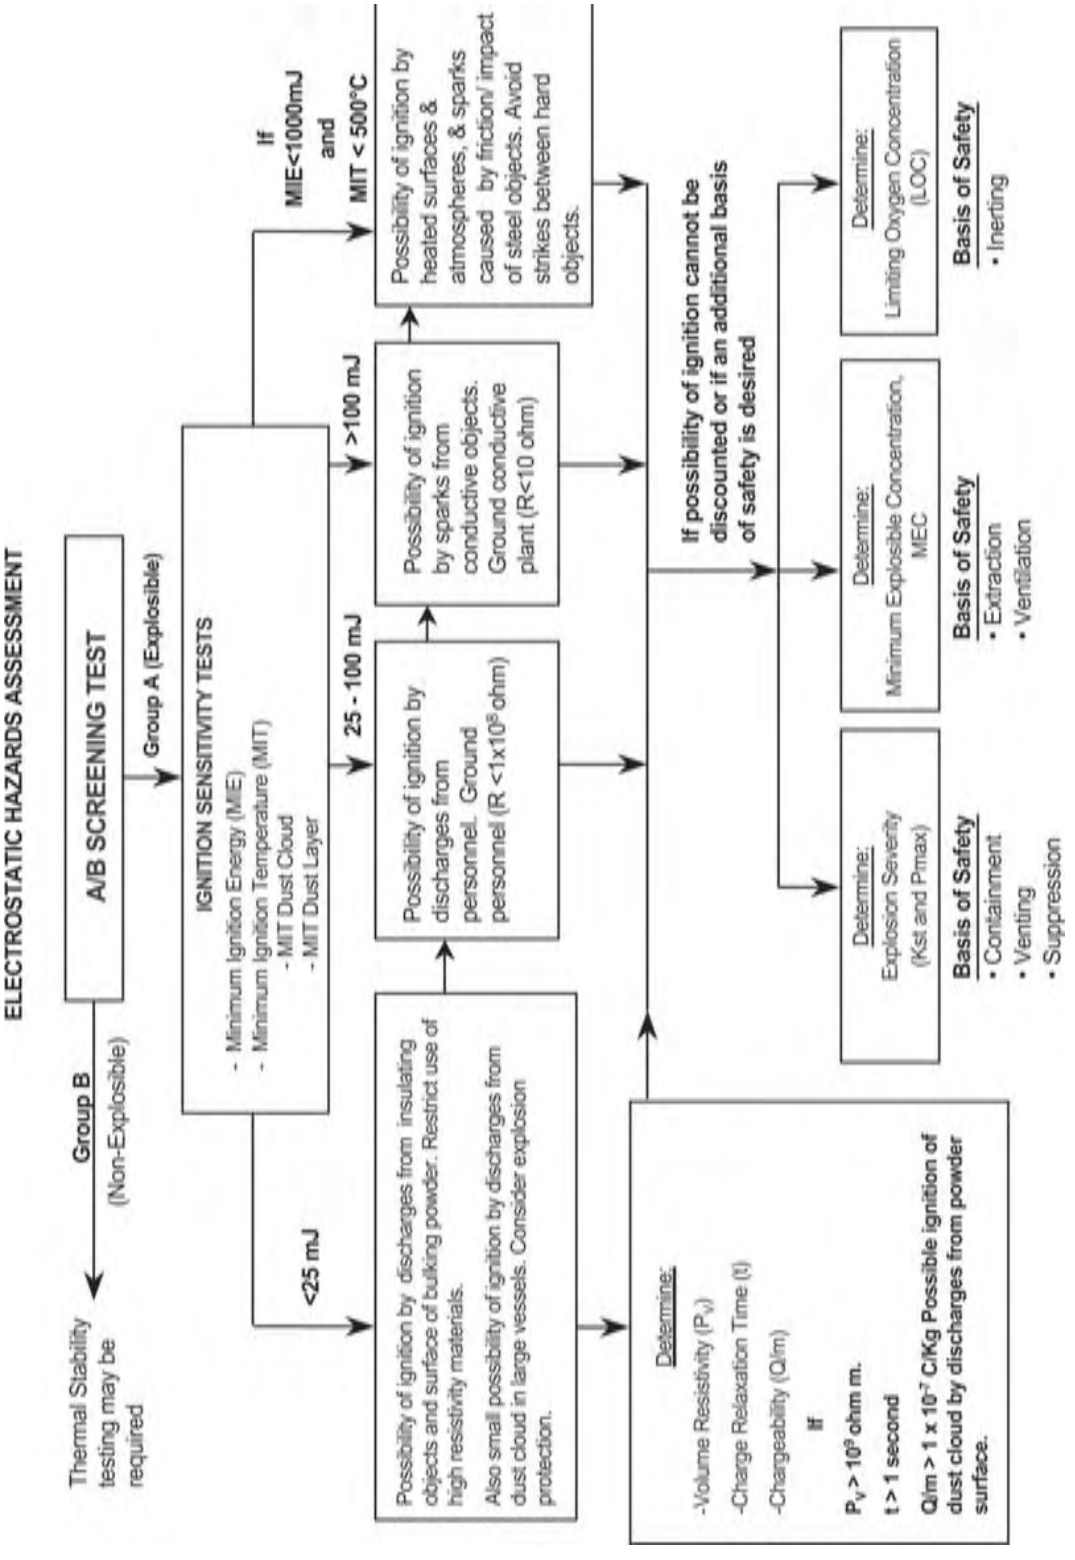

Fig. 1 Electrostatic hazards assessment.

The flow diagram in Fig. 1 provides a summary of the hazards and laboratory tests required to quantify electrostatic properties and measures that may be taken to ensure safety.

Finally, if the basis of safety from potential dust cloud explosions is the elimination of ignition sources, the answers to the following questions should be ''yes'':

- Can all ignition sources be identified?
- Is the sensitivity to ignition by these sources known for all process materials?
- Can all ignition sources be eliminated under normal and abnormal conditions?

If the answer to one or more of the above questions is ''no,'' then in addition to taking all reasonable steps to reduce the possibility of formation/spread of dust clouds and exclude potential ignition sources, other measures, such as exclusion of oxidant or explosion protection, should also be considered.

Explosion Protection Measures

If evolution or formation of an explosible atmosphere cannot be prevented and all sources of ignition cannot be reasonably eliminated or excluded, then the possibility of a dust cloud explosion persists. Under such conditions, explosion protection measures should be taken to protect people and minimize damage to the plant. It should be noted that explosion protection measures should be considered in addition to taking all reasonable steps to reduce the possibility of formation/spread of dust clouds and exclude potential ignition sources. Explosion protection measures include the following.

Explosion containment

Construct the plant to withstand the maximum explosion pressure resulting from the deflagration (propagation of a combustion zone at a velocity that is less than the speed of sound in the unreacted medium) of the dust present in the equipment.

The following guidelines should be applied when considering explosion containment as a basis of safety:

- Equipment should withstand the maximum explosion pressure that is expected for the dust present under the process (pressure, temperature, etc.) conditions.
- All interconnected pipes, flanges, covers, etc. should withstand the maximum explosion pressure of the dust being handled.
- If an explosion-resistant vessel fails, the pressure effects will be more severe than if an extremely weak vessel fails as a result of a dust explosion.
- Because of the relatively high cost of constructing plant to withstand the maximum explosion pressure (plus a safety factor), explosion containment is normally considered for smaller equipment.

Explosion suppression

Explosion suppression is detecting an explosion at an early stage and suppressing it with a suitable suppressant. Explosion suppression relies on early detection of an explosion and rapid injection of the suppressant. A typical explosion pressure at the moment of detection is 0.035–0.1 barg. Suppressant extinguishes the flame within 0.08 sec. An explosion suppression system normally includes explosion detector, control unit, suppressor, and a suitable suppressant.

To achieve explosion suppression, the following information is required:

- Type of powder
- Explosion severity (K_{st}) of the dust cloud
- Strength (P_{red}) of the vessel to be protected
- Dimensions and volume of the vessel to be protected
- Pressure and temperature of the vessel.

Explosion suppression has the following advantages and disadvantages compared to explosion relief venting:

- Extinguishing the flame.
- Reducing the risk of ejecting toxic and/or corrosive materials to the atmosphere.
- Process equipment does not need to be located in an area suitable for explosion relief venting.
- Suppression systems are generally more expensive to install and maintain than explosion relief venting.
- Some suppression systems are not suitable for powders with very high explosion severity (K_{st}) (generally above 300 bar/m/sec, although the limits are being extended all the time).

Explosion relief venting

Explosion relief venting is the process of relieving the explosion products (pressure and flame) from the plant to a safe location. The principle of explosion relief venting is that a dust explosion in a vessel causes vent(s) of sufficient area to open rapidly and relieve hot gases and dust to a safe location. In other words, the vessel ''fails'' in a predictable way such that people and plant are protected from the effects of the dust explosion.

Explosion relief venting has the advantage of being relatively inexpensive compared to other explosion protection options and is simple to install in many cases.

Some of the limitations of explosion relief venting include:

- Not suitable for toxic materials some of which could be released to the atmosphere in the event of explosion.
- Very strongly explosible dusts, such as explosives or industrial powders, with K_{st} values in excess of 600 bar m/sec would be expected to be very difficult to vent because of the lack of available space on the vessel to be protected.
- Venting of explosions to inside a building is not usually acceptable.

Explosion Relief Venting Requirements. Three elements are required for the design and specification of explosion relief vent(s) for a vessel:

- Information on the explosion severity of the airborne dust present is required. This is generally obtained by subjecting representative dust samples to a 20 L sphere explosion test. This measures the explosion severity as expressed by maximum explosion pressure and maximum rate of pressure rise (K_{st} index).
- Shape, volume, pressure rating (P_{red}), and location of the vessel in relation to outside walls, available vent area on the vessel, and vent activation pressures (P_{stat}).
- Vent sizing method based on the dust type and plant to be protected. In the United States, NFPA 68 provides the required information for vent sizing calculations.

Explosion Isolation Measures

Regardless of what type of explosion protection measure is considered, the dust cloud explosion should be prevented from propagating from the location where it originates to other locations in the plant. This is referred to as explosion isolation. Dust explosions can propagate through pipes, chutes, conveyors, etc. The first step in isolating an explosion is to avoid unnecessary connections. If this is not possible, barriers should be created in the path of the explosion.

There are two types of barriers that could be considered for isolating a dust explosion:

Mechanical barriers: Explosion propagation is prevented by some type of physical barrier. Mechanical barriers could include rotary valves that have a sufficient number of blades to form a barrier, screw feeders that are modified to continuously contain a plug of material, and fast acting shutoff valves.

Chemical barriers: Flame front or pressure wave is detected and a suitable suppressant is injected to extinguish the flame. Although chemical barriers extinguish the flame, they cannot prevent the explosion pressure from propagating. Downstream process equipment should therefore be able to withstand the resulting pressure.

CONCLUSIONS

The majority of powders that are used in the processing industries are combustible (also referred to as flammable and explosible). An explosion will occur if the concentration of the combustible dust that is suspended in air is sufficient for flame propagation when ignited by a sufficiently energetic ignition source.

A systematic approach to identifying potential dust cloud explosion hazards and taking measures to ensure safety against their consequences generally involves the following:

1. Determining the dust cloud's ignition sensitivity and explosion severity characteristics.
2. Identifying areas of the plant where combustible dust cloud atmospheres could exist under normal and/or abnormal conditions.
3. Identifying potential ignition sources.
4. Taking measures to eliminate/control
   a. Potential ignition sources
   b. Combustible dust cloud concentrations
   c. Oxidant concentrations.
5. Taking measures to protect against the consequences of potential dust cloud explosions. Explosion protection measures include:
   a. Explosion relief venting
   b. Explosion suppression
   c. Explosion containment
   d. Explosion isolation.

Dynamic Mechanical Thermal Analysis

Kevin P. Menard
PerkinElmer Thermal Laboratory, Materials Science Department, University of North Texas, Denton, Texas, U.S.A.

INTRODUCTION

Dynamic mechanical analysis (DMA), or in the older literature dynamic mechanical thermal analysis (DMTA), is the technique of applying a stress or strain to a sample and analyzing the response to obtain phase angle and deformation data. This data allows the calculation of the damping or tan delta (δ) as well as complex modulus and viscosity data. Two approaches are used: a) forced frequency, where the signal is applied at a set frequency and b) free resonance, where the material is perturbed and allowed to exhibit free resonance decay. Most DMAs are the former type while the torsional braid analyzer (TBA) is the latter. In both approaches, the technique is very sensitive to the motions of the polymer chains, and it is a powerful tool for measuring transitions in polymers. It is estimated to be 100 times more sensitive to the glass transition than differential scanning calorimetry (DSC), and it resolves other more localized transitions not detected in the DSC. In addition, the technique allows the rapid scanning of a material's modulus and viscosity as a function of temperature or of frequency. Frequency scanning can be used to study a materials apply to damp or sustain vibrations. Despite the power of these techniques, only a few books have concentrated on them.[1] Modern DMA analyzers are either forced oscillation or free resonance: the former is mby for the more common technique. In a forced oscillation instrument, a load is applied to a sample sinusoidally and the sample will deform sinusoidally.

INSTRUMENTATION

One of the biggest choices made in selecting a DMA is to decide whether to choose stress (force) or strain (displacement) control for applying the deforming load to the sample. Because most DMA experiments run at very low strains ($\sim$0.5% maximum) to stay well within a polymers linear region, both analyzers give the same results.

Dynamic mechanical analyzers are normally built to apply the stress or strain in three ways (Fig. 1). One can apply force in a twisting motion; so one is testing the sample in torsion. Axial analyzers are normally designed for solid and semisolid materials, and apply a linear force to the sample. Finally, one can allow the sample to swing freely and damp the oscillations in a TBA.

APPLICATIONS

Thermoplastic Solids and Cured Thermosets

As mentioned above, the thermal transitions in polymers can be described in terms of either free volume changes[2] or relaxation times. A simple approach to looking at free volume, which is popular in explaining DMA responses, is the crankshaft mechanism,[3] where the molecule is imagined as a series of jointed segments. From this model, it is possible to simply describe the various transitions seen in a polymer. Other models exist that allow for more precision in describing the behavior; the best seems to be the Doi–Edwards Model.[4] Aklonis and Knight[5] give a good summary of the available models, as does Rohn.[6]

The crankshaft model treats the molecule as a collection of mobile segments that have some degree of free movement. This is a very simplistic approach, yet very useful for explaining behavior (Fig. 2). As the free volume of the chain segment increases, its ability to move in various directions also increases. This increased mobility in either side chains or small groups of adjacent backbone atoms results in a greater compliance (lower modulus) of the molecule. These movements have been studied, and Heijboer[7] classified β and γ transitions by their type of motions. The specific temperature and frequency of this softening help drive the end use of the material.

Moving from very low temperature, where the molecule is tightly compressed, to higher temperatures the first changes are the solid-state transitions. This process is shown in Fig. 3. As the material warms and expands, the free volume increases so that localized bond movements (bending and stretching) and side chain movements can occur. This is the gamma transition, T_γ, which may also involve associations with water. As the temperature and the free volume continue to increase, the whole side chains and localized groups of 4–8 backbone atoms begin to have enough space to move, and the material starts to develop some toughness.[8] This transition, called the beta transition,

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007745

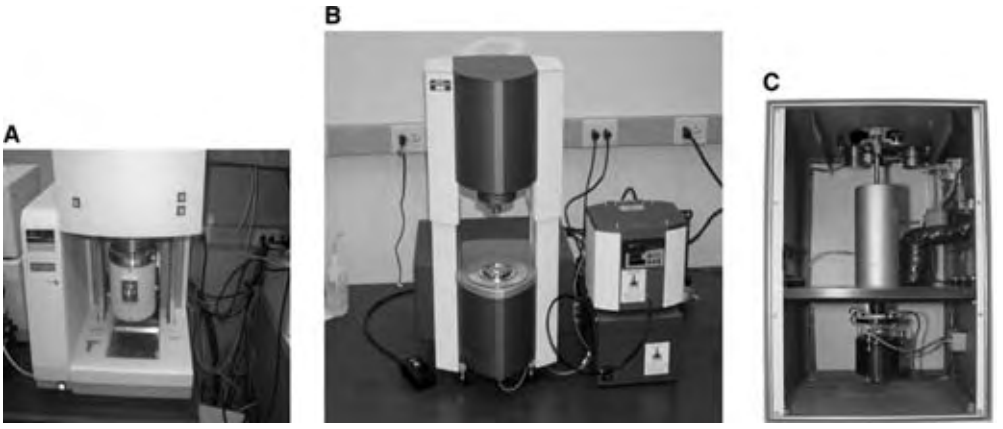

Fig. 1 Torsion vs. axial analyzers: The PerkinElmer Diamond DMA (A) is an axial analyzer while the ATS Rheo; (B) is a torsional instrument. Both are controlled stress but can act as strain controlled because of the feedback programmed in. Photos taken by the author of Equipment at the University of North Texas (C) shows the TBA. T_β, is not as clearly defined as described here. Often it is the T_g of a secondary component in a blend or a specific block in a block copolymer. However, a correlation with toughness is seen empirically.[9]

As heating continues, the T_g or glass transition appears when the chains in the amorphous regions begin to coordinate large-scale motions. One classical description of this region is that the amorphous regions have begun to melt. As the T_g only occurs in amorphous material, in a 100% crystalline material, there would not be a T_g. Continued heating drives the material through the $T_\alpha{}^*$ and T_{ll}. The former occurs in crystalline or semicrystalline polymer, and is a slippage of the crystallites past each other. The latter is a movement of coordinated segments in the amorphous phase that relates to reduced viscosity. These two transitions are not universally accepted. Finally, the melt is reached where large-scale chain slippage occurs and the material flows. This is the melting temperature, T_m. For a cured thermoset, nothing happens after the T_g until the sample begins to burn and degrade because the crosslinks prevent the chains from slipping past each other.

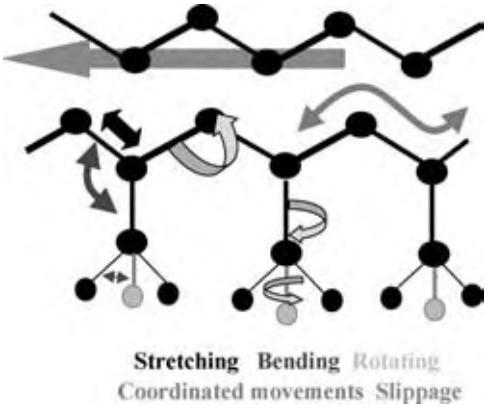

Fig. 2 The crankshaft mechanism is a simple way of considering the motions of a polymer chain permitted by increases in free volume. The molecule is visualized as a series of balls and rods, and these move as the free volume increases. *(View this art in color at www.dekker.com.)*

Sub-T_g transitions

The area of sub-T_g or higher order transitions has been heavily studied[10] as these transitions have been associated with mechanical properties. These transitions can sometimes be seen by DSC and TMA, but they are normally too weak or too broad for determination by these methods. DMA, DEA, and similar techniques are usually required.[11] Some authors have also called these types of transitions[12] as second order transitions to differentiate them from the primary transitions of T_m and T_g, which involve large sections of the main chains. Boyer reviewed the T_β in 1968[13] and pointed out that while a correlation often exists, the T_β is not always an indicator of toughness. Bershtien[14] has reported that this transition can be considered the ''activation barrier'' for solid-phase reactions, deformation, flow or creep, acoustic damping, physical aging changes, and gas diffusion into polymers as the activation energies for the transition and these processes are usually similar. The strength of these transitions is related to how strongly a polymer responses to those processes. These sub-T_g transitions are associated with the materials properties in the glassy state. In paints, for example, peel strength (adhesion) can be estimated from the strength and frequency dependence of the sub-ambient β transition.[15] Cheng[16] reports in rigid rod polyimides that the β

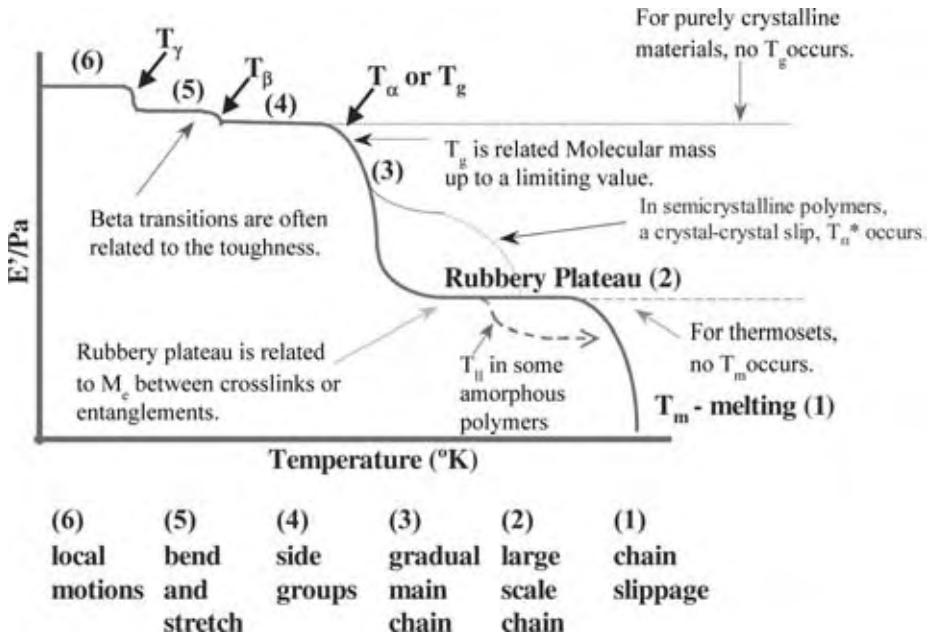

Fig. 3 Idealized temperature scan of a polymer: starting at low temperature, the modulus decreases as the molecules gain more free volume resulting in more molecular motion. This shows main curve as divided into six regions, which corresponds to: local motions (6), bond bending and stretching (5), movements in the side chain or adjacent atoms in the main chain (4), the region of the T_g (3), coordinated movements in the amorphous portion of the chain (2), and the melting region (1). Transitions are marked as described in the text. (From Ref.[1].) *(View this art in color at www.dekker.com.)*

transition is caused by the noncoordinated movement of the diamine groups although the link to physical properties was not investigated. Johari has reported in both mechanical[17] and dielectric studies[18] that both the β and γ transitions in bisphenol-A-based thermosets depend on the side chains and unreacted ends, and that both are affected by physical aging and postcure. Nelson[19] has reported that these transitions can be related to vibration damping. This is also true for acoustical damping.[20] In these cases, the strength of the β transition is taken as a measurement of how effectively a polymer will absorb vibrations.

Boyer[21] and Heijboer[7] showed that this information needs to be considered with care as not all β transitions correlate with toughness or other properties. This can be due to misidentification of the transition or that the transition does sufficiently disperse energy. A working rule of thumb[22] is that the β transition must be related to either localized movement in the main chain or very large side chain movement to sufficiently absorb enough energy. The relationship of large side chain movement and toughness has been extensively studied in polycarbonate by Yee[23] as well as in many other tough glassy polymers.[24]

Less use is made of the T_γ transitions and they are mainly studied to understand the movements occurring in polymers. Wendorff[25] reports that this transition in polyarylates is limited to inter- and intramolecular motions within the scale of a single repeat unit. Both Mc Crum[26] and Boyd[27] similarly limited the T_γ and T_δ to very small motions either within the molecule or with bound water. The use of what is called 2D-IR, which couples at FTIR and a DMA to study these motions, is a topic of current interest.[28]

The glass transition (T_g or T_α)

As the free volume continues to increase with increasing temperature, the glass transition, T_g, occurs where large segments of the chain start moving. This transition is also called the alpha transition, T_α. The T_g is very dependent on the degree of polymerization up to a value known as the critical T_g or the critical molecular weight. Above this value, the T_g typically becomes independent of molecular weight.[29] The T_g represents a major transition for many polymers, as physical properties change drastically as the material goes from a hard glassy to a rubbery state. It defines one end of the temperature range over which the polymer can be used, often called the operating range of the polymer. For where strength and stiffness are needed, it is normally the upper limit for use. In rubbers and some semicrystalline materials like polyethylene and polypropylene, it is the lower operating temperature. Changes in the temperature of the T_g are commonly used to monitor changes in the polymer, such as plasticizing by environmental solvents and increased crosslinking from thermal or UV aging.

The T_g of cured materials or thin coatings is often difficult to measure by other methods and more often than not the initial cost justification for a DMA is measuring a hard to find T_g. While the estimates of the relative sensitivity of DMA to DSC or DTA vary, it appears that DMA is 10–100 times more sensitivity to the changes occurring at the T_g. The T_g in highly crosslinked materials can easily be seen long after the T_g has become too flat and broad to be seen in the DSC. This is also a problem with certain materials like medical grade urethanes and very highly crystalline polyethylenes.

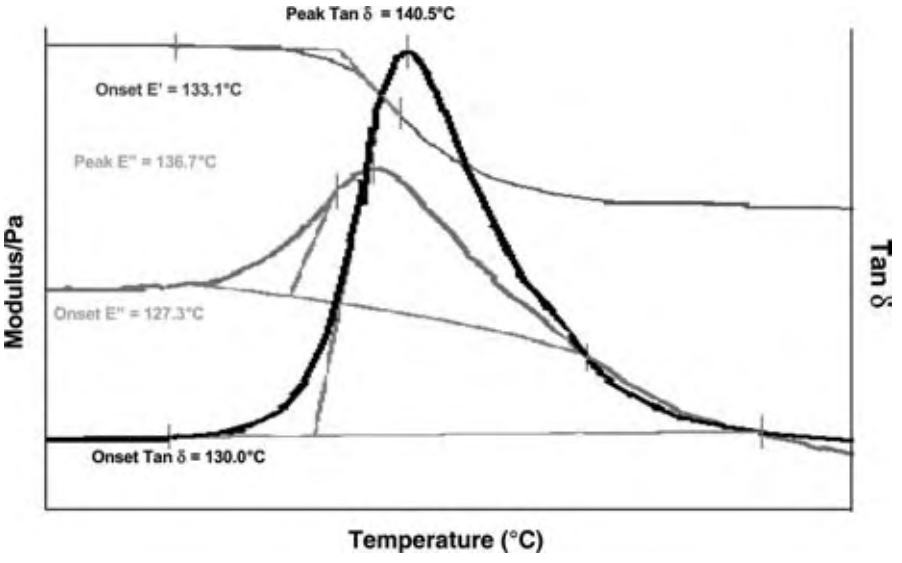

Fig. 4 Methods of determining the T_g are shown for the DMA. The temperature of the T_g varies by as much as 10°C in this example depending on the value chosen. Differences as great as 25°C have been reported. (From Ref.[1].) *(View this art in color at www.dekker.com.)*

The method of determining the T_g in the DMA can be a manner for disagreement as at least five ways are in current use (Fig. 4). Depending on the industry standards or background of the operator, the peak or onset of the tan δ curve, the onset of the E' drop, or the onset or peak of the E'' curve may be used. The values obtained from these methods can differ up to 25°C from each other on the same run. In addition, a 10–20°C difference from the DSC is also seen in many materials. In practice, it is important to specify exactly how the T_g should be determined. For DMA, this means defining the heating rate, applied stresses (or strains), the frequency used, and the method of determining the T_g. For example, the sample will be run at $10°C\,min^{-1}$ under 0.05% strain at 1 Hz in nitrogen purge ($20\,cc\,min^{-1}$), and the T_g determined from peak of the tan δ curve.

It is not unusual to see a peak or hump on the storage modulus directly preceding the drop that corresponds to the T_g. This is also seen in the DSC and DTA, and corresponds to a rearrangement in the material to relieve stresses frozen below the T_g by the processing method. These stresses are trapped in the material until enough mobility is obtained at the T_g to allow the chains to move to a lower energy state. Often a material will be annealed by heating it above the T_g and slowly cooling it to remove this effect. For similar reasons, some experimenters will run a material twice or use a heat-cool-heat cycle to eliminate processing effects.

The rubbery plateau, T_α^* and T_{ll}

The area above the T_g and below the melt is known as the rubbery plateau, and the length of it as well as its viscosity are dependent on the molecular weight between entanglements (M_e)[30] or crosslinks. The molecular weight between entanglements is normally calculated during a stress-relaxation experiment but similar behavior is observed in the DMA. The modulus in the plateau region is proportional to either the number of crosslinks or the chain length between entanglements. This is often expressed in shear as:

$$G' \cong (\sigma RT)/M_e \tag{1}$$

where G' is the shear storage modulus of the plateau region at a specific temperature, ρ is the polymer density, and M_e is the molecular weight between entanglements. In practice, the relative modulus of the plateau region shows the relative changes in M_e or the number of crosslinks compared to a standard material.

The rubbery plateau is also related to the degree of crystallinity in a material, although DSC is a better method for characterizing crystallinity than DMA.[31] Also as in the DSC, there is evidence of cold crystallization in the temperature range above the T_g (Fig. 5). This is one of the several transitions that can be seen in the rubbery plateau region. This crystallization occurs when the polymer chains have been quenched (quickly cooled) into a highly disordered state. On heating above the T_g, these chains gain enough mobility to rearrange into crystallites, which causes sometimes a dramatic increase in the modulus. Differential scanning calorimetry or its temperature-modulated variant, StepScan™ DSC, can be used to confirm this.[32] The alpha star transition, $T_\alpha{}^*$, the liquid–liquid transition, T_{ll}, the heat set temperature, and the cold crystallization peak are all transitions that can appear on the rubbery plateau. In some crystalline and semicrystalline polymer, a transition is seen called $T_\alpha{}^*$.[33] The α^* transition is associated with the slippage between crystallites, and helps extend the operating range of a material above the T_g.

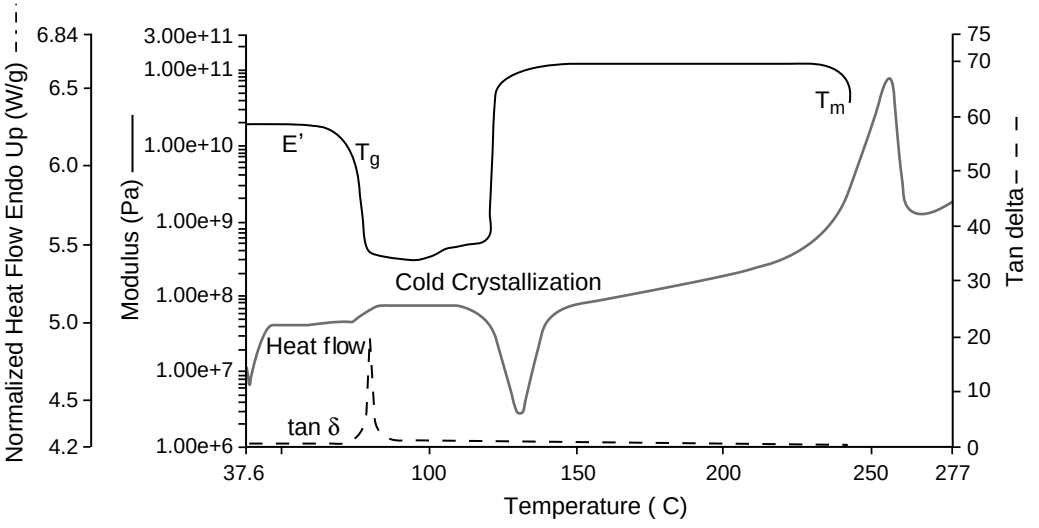

Fig. 5 Cold crystallization in PET caused a large increase in the storage modulus, E', above the T_g. A DSC scan of the same material is included. (From Ref.[1].) *(View this art in color at www.dekker.com.)*

This transition is very susceptible to processing induced changes and can be enlarged on decreased by the applied heat history, processing conditions, and physical aging.[34] Hence, the $T_\alpha{}^*$ has been used by fiber manufacturers to optimize the properties in their materials.

In amorphous polymers, the T_{ll} transition is seen instead, which is a liquid–liquid transition associated with increased chain mobility and segment–segment associations.[35] This order is lost when the T_{ll} is exceeded and regained on cooling from the melt. Boyer[36] reports that, like the T_g, the appearance of the T_{ll} is affected by the heat history. The T_{ll} is also dependent on the number average molecular weight, M_n, but not on the weight average molecular weight, M_w. Bershtien[37] suggests that this may be considered as quasi-melting on heating or the formation of stable associates of segments on cooling. While this transition is reversible, it is not always easy to see, and Boyer[38] spent many years trying to prove that it was real. It is still not totally accepted. Following this transition, a material enters the terminal or melting region.

The terminal region

On continued heating, the melting point, T_m, is reached. The melting point is where the free volume has increased, so the chains can slide past each other and the material flows. This is also called the terminal region. In the molten state, this ability to flow is dependent on the molecular weight of the polymer (Fig. 3). The melt of a polymer material will often show changes in temperature of melting, width of the melting peak, and enthalpy as the material changes[39] resulting from changes in the polymer molecular weight and crystallinity.

Degradation, polymer structure, and environmental effects all influence what changes occur. Polymers that degrade by crosslinking will look very different from those that exhibit chain scission. Very highly crosslinked polymers will not melt as they are unable to flow.

The study of polymer melts and especially their elasticity was one of the areas that drove the development of commercial DMAs. Although a decrease in the melt viscosity is seen with temperature increases, the DMA is most commonly used to measure the frequency dependence of the molten polymer as well as its elasticity. The latter property, especially when expressed as the normal forces, is very important in polymer processing.

Frequency dependencies in transition studies

The choice of a testing frequency or its effect on the resulting data must be addressed. A short discussion of how frequencies are chosen and how they affect the measurement of transitions is in order. Considering that higher frequencies induce more elastic-like behavior, there is some concern that a material will act stiffer than it really is, if the test frequency is chosen to be too high. Frequencies for testing are normally chosen by one of the three methods. The most scientific method would be to use the frequency of the stress or strain that the material is exposed to in the real world. However, this is often outside of the range of the available instrumentation. In some cases, the test method or the industry standard sets a certain frequency and this frequency is used. Ideally, a standard method like this is chosen so that the data collected on various commercial instruments can be shown to be compatible. Some of the ASTM methods for TMA

[a]This standard qualifies a DMA as acceptable for all ASTM DMA standards.

and DMA are listed in Table 1. Many industries have their own standards, so it is important to know whether the data is expected to match a Mil-spec, an ASTM standard, or a specific industrial test. Finally, one can arbitrarily pick a frequency. This is done more often than not, so that 1 Hz and 10 rad/sec are often used. As long as the data are run under the proper conditions, they can be compared to highlight material differences. This requires that frequency, stresses, and the thermal program be the same for all samples in the data set.

Lowering the frequency shifts the temperature of a transition to a lower temperature (Fig. 6). At one time, it was suggested that multiple frequencies could be used, and the T_g should then be determined by extrapolation to 0 Hz. This was never really accepted as it represented a fairly large increase in testing time for a small improvement in accuracy. For most polymer systems, for very precise measurements, one uses a DSC. Different types of transitions also have different frequency dependencies. If one looks at the slope of the temperature dependence of transitions against frequency, one sees that in many cases that the primary transitions like T_m and T_g have a different dependence on frequency than the lower temperature transitions. In fact, the activation energies are different for α, β, and γ transitions because of the different motions required and the transitions can be sorted by this approach.[1]

Polymer Melts and Solutions

A fluid or polymer melt responds to strain rate rather than to the amount of stress applied. The viscosity is one of the main reasons why people run frequency scans. As the stress–strain curves and the creep recovery runs show, viscoelastic materials exhibit some degree of flow or unrecoverable deformation. The effect is strongest in melts and liquids where frequency vs. viscosity plots are the major application of DMA. Fig. 7 shows a frequency scan on a viscoelastic material. In this example, the sample is a rubber above the T_g in three-point bending, but the trends and principles apply to both solids and melts. The storage modulus and complex viscosity are plotted on log scales against the log of frequency. In analyzing the frequency scans, trends in the data are more significant than specific peaks or transitions.

The zero shear plateau

On the viscosity curve, η^*, a fairly flat region appears at low frequency, called the zero shear plateau.[40] This is where the polymer exhibits Newtonian behavior and its viscosity is dependent on molecular weight, not the strain rate. The viscosity of this plateau has been shown to experimentally related to the molecular weight for Newtonian fluid:

$$\eta \propto cM_\nu^1 \tag{2}$$

for cases where the molecular weight, M_v, is less than the entanglement molecular weight, M_e and for cases where M_v is greater than M_e:

$$\eta \propto cM_\nu^{3.4} \tag{3}$$

where η_o is the viscosity of the initial Newtonian plateau, c is a material constant, and M_v is the viscosity

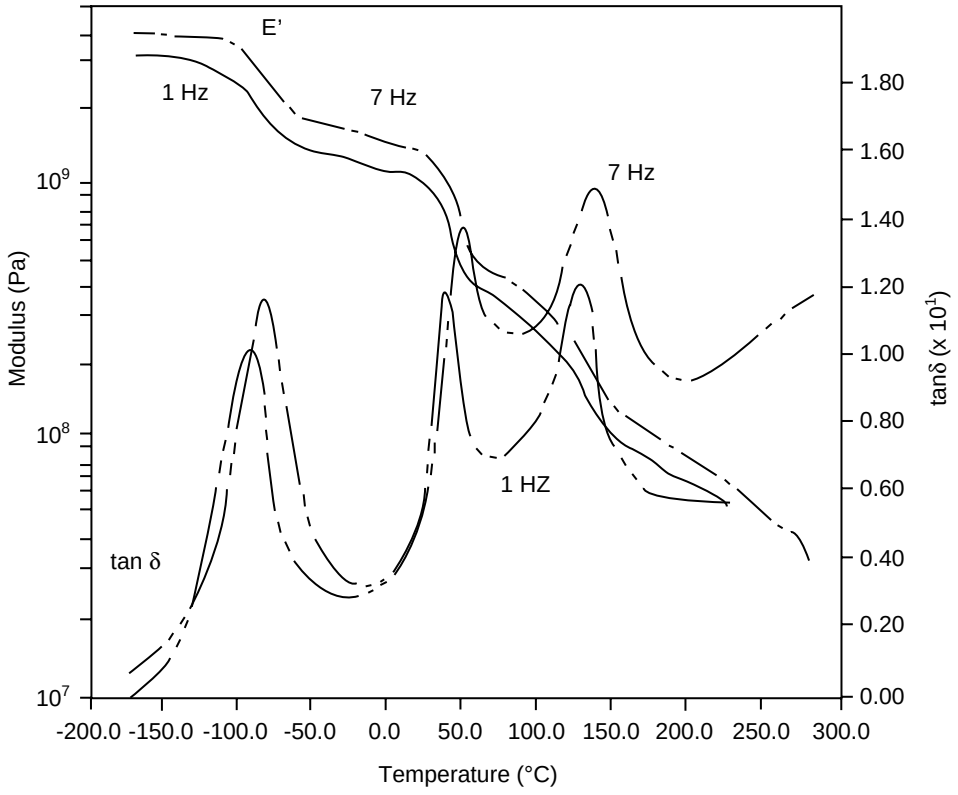

Fig. 6 Effect of frequency on transitions: (A) the dependence of the T_g in PMMA on frequency.

average molecular weight. This relationship can be written in general terms, replacing the exponential term with the Mark-Houwink constant, *a*. Eq. (3) can be used as a method of approximating the molecular weight of a polymer. The value obtained is closest to the viscosity average molecular weight obtained by osmometry.[41] In comparison with the weight average data obtained by Gel Permeation Chromatography, the viscosity average molecular weight would be between the number average and weight average molecular weights, but closer to the latter.[42] This was originally developed for steady shear viscosity but applies to complex viscosity as well.

The relationship between steady shear and complex viscosity is fairly well established. Cox and Merz[43] found that an empirical relationship exists between complex viscosity and steady shear viscosity when the shear rates are the same. The Cox–Merz rule is stated as follows:

$$|\eta(\omega)| = \eta(\dot{\gamma})|_{\dot{\gamma}=\omega} \tag{4}$$

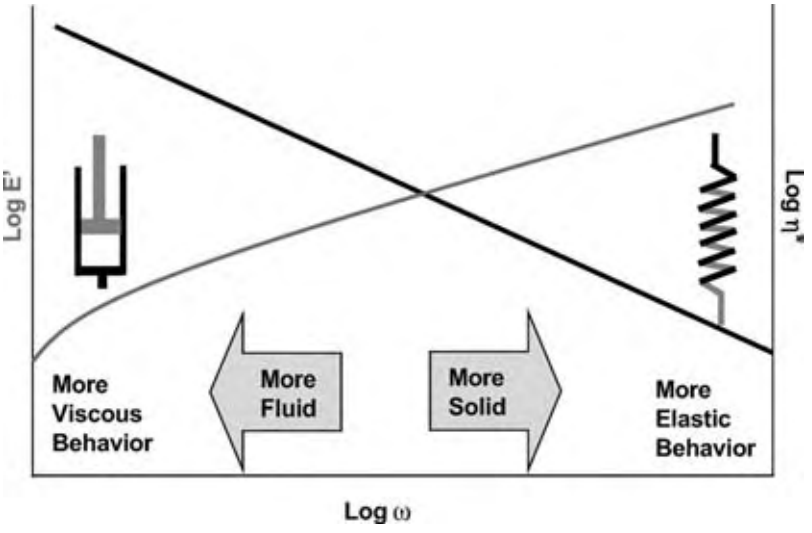

Fig. 7 An example of a frequency scan showing the change in a materials behavior as frequency varies. Low frequencies allow the material time to relax and respond, hence, flow dominates. High frequencies do not and elastic behavior dominates. (From Ref.[1].) *(View this art in color at www.dekker.com.)*

where η is the constant shear viscosity, η^* is the complex viscosity, ω the frequency of the dynamic test, and $d\gamma/dt$ the shear rate of the constant shear test. This rule of thumb seems to hold for most materials to within approximately $\pm 10\%$. Another approach is the Gleissele[44] Mirror Relationship that states the following:

$$\eta\dot{\gamma} = \eta^+(t)|_{t=1/\dot{\gamma}} \quad (5)$$

when $\eta^+(t)$ is the limiting value of the viscosity as the shear rate, , approaches zero.

The low frequency range is where viscous or liquid–like behavior predominates. If a material is stressed over long enough times, some flow occurs. As time is the inverse of frequency, this means materials are expected to flow more at low frequency. As the frequency increases, the material will act in a more and more elastic fashion. Silly Putty™, the children's toy, shows this clearly. At low frequency, Silly Putty™ flows like a liquid while at high frequency, it bounces like a rubber ball. This behavior is also similar to what happens with temperature changes.

A polymer becomes softer and more fluid as it is heated, and it goes through transitions that increase the available space for molecular motions. Over long enough time periods, or small enough frequencies, similar changes occur. As this implies, one can move a polymer across a transition by changing the frequency. This relationship is also expressed as the idea of time–temperature equivalence.[45] Often stated as low temperature is equivalent to short times or high frequency, it is a fundamental rule of thumb in understanding polymer behavior.

The power law region

As the frequency is increased in a frequency scan, the Newtonian region is exceeded and a new relationship develops between the rate of strain, or the frequency, and the viscosity of the material. This region is often called the power law region and can be modeled by:

$$\eta^* \cong \eta(\dot{\gamma}) = c\dot{\gamma}^{n-1} \quad (6)$$

where η^* is the complex viscosity, $\dot{\gamma}$ is the shear rate, and the exponent term n is determined by the fit of the data. This can also be written as:

$$\sigma \cong n(\dot{\gamma}) = c\dot{\gamma}^n \quad (7)$$

where σ is the stress and η is the viscosity. The exponential relationship is why the viscosity vs. frequency plot is traditionally plotted on a log scale. With modern curve fitting programs, the use of log–log plots has declined and is a bit anachronistic. The power law region of polymers shows shear thickening or thinning behavior. This is also the region in which the E'–η^* or the E'–E'' crossover point is found. As frequency increases and shear thinning occurs, the viscosity (η^*) decreases. At the same time, increasing the frequency increases the elasticity (E'). This is shown in Fig. 7. The E'–η^* crossover point is used an indicator of the molecular weight and molecular weight distribution.[46] Changes in its position are used as a quick method of detecting changes in the molecular weight and distribution of a material. After the power law region, another plateau is seen, the infinite shear plateau.

Infinite shear plateau

This second Newtonian region corresponds to where the shear rate is so high that the polymer no longer shows a response to increases in the shear rate. At the very high shear rates associated with this region, the polymer chains are no longer entangled. This region is seldom seen in DMA experiments and usually avoided in use because of the damage done to the chains. It can be reached in commercial extruders and causes degradation of the polymer, which causes the poorer properties associated with regrind.

As the curve in Fig. 7 shows, the modulus also varies as a function of the frequency. A material exhibits more elastic-like behavior as the testing frequency increases, and the storage modulus tends to slope upward towards higher frequency. The storage modulus' change with frequency depends on the transitions involved. Above the T_g, the storage modulus tends to be fairly flat with a slight increase with increasing frequency as it is on the rubbery plateau. The change in the region of a transition is greater. If one can generate a modulus scan over a wide enough frequency range, the plot of storage modulus vs. frequency appears like the reverse of a temperature scan. The same time–temperature equivalence discussed above also applies to modulus, as well as compliance, tan delta, and other properties.

The frequency scan is used for several purposes that is discussed here. One very important use, that is very straightforward, is to survey the material's response over various shear rates. Different properties are required at these regimes, and to optimize one property may require chemical changes that harm the other. Similarly, changes in polymer structure can show these kinds of differences in the frequency scan. Branching affects the response to different frequencies.[6]

For example, in a tape adhesive, sufficient flow under pressure at low frequency is desired to fill the pores of the material to obtain a good mechanical bond. When the laminate is later subjected to peel,

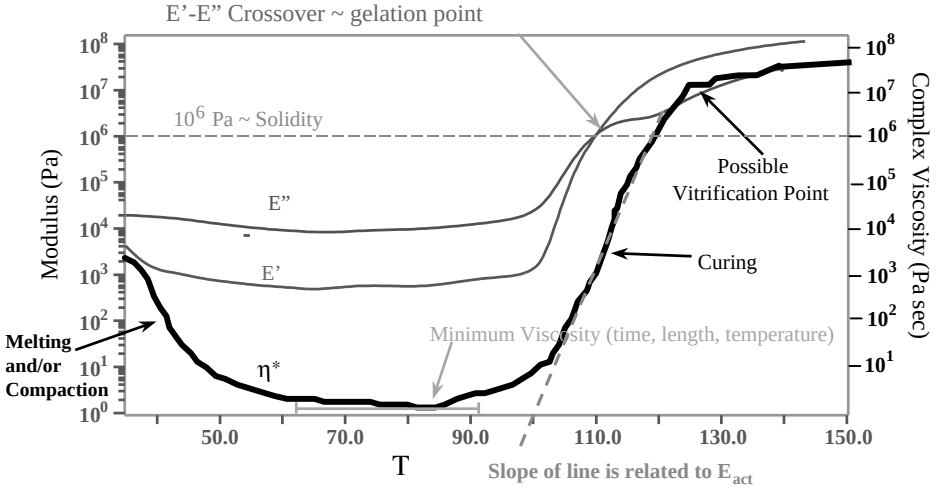

Fig. 8 The DMA cure profile of a two-part epoxy showing the typical analysis for minimum viscosity, gel time, vitrification time, and estimation of the action energy. (From Ref. [1].) *(View this art in color at www.dekker.com.)*

the material needs to be very elastic so it will not pull out of the pores.[47],[a] The frequency scan allows measurement of these properties in one scan, so ensuring that tuning one property does not degrade another. Viscosity vs. frequency plots are used extensively to study how changes in polymer structure or formulations affect the behavior of the melt. Often changes in materials, especially in uncured thermosetting resins and molten materials, affect a limited frequency range and testing at a specific frequency can miss the problem.

Thermosets

The DMA's ability to give viscosity and modulus values for each point in a temperature scan allow estimation of kinetic behavior as a function of viscosity. This has the advantage of describing how viscous the material is at any given time, so as to determine the best time to apply pressure, what design of tooling to use, and when the material can be removed from the mold. Recent reviews have summarized this approach for epoxy systems.[48]

Curing

The simplest way to analyze a resin system is to run a plain temperature ramp from ambient to some elevated temperature.[49] This ''cure profile'' allows collection of several vital pieces of information as shown in Fig. 8. Samples may be run ''neat'' or impregnated into fabrics in techniques that are referred to as ''torsional braid.'' Another problem area is paints and coatings,[50] where the material is used in a thin layer. This can be addressed experimentally by either a braid as above or by coating the material on a thin sheet of metal. The metal is often run first, and its scan subtracted from the coated sheet's scan to leave only the scan of the coating. This is also done with thin films and adhesive coatings.

From the cure profile seen in Fig. 8, it is possible to determine the minimum viscosity (η^*_{min}), the time to η^*_{min} and the length of time it stays there, the onset of cure, the point of gelation where the material changes from a viscous liquid to a viscoelastic solid, and the beginning of vitrification. The minimum viscosity is seen in the complex viscosity curve and is where the resin viscosity is the lowest. A given resin's minimum viscosity is determined by the resin's chemistry, the previous heat history of the resin, the rate at which the temperature is increased, and the amount for stress or strain applied. Increasing the rate of the temperature ramp is known to decrease the η^*_{min}, the time to η^*_{min}, and the gel time. The resin gets softer faster, but also cures faster. The degree of flow limits the type of mold design and when as well as how much pressure can be applied to the sample. The time spent at the minimum viscosity plateau is the result of a competitive relationship between the material's softening or melting as it heats, and its rate of curing. At some point, the material begins curing faster than it softens, and that is where the viscosity starts to increase.

As the viscosity begins to climb, an inversion is seen of the E″ and E′ values as the material becomes more solidlike. This crossover point also corresponds to where the tan δ equals 1 (since $E' = E''$ at the crossover). This is taken to be the gel point,[51] where the crosslinks have progressed to forming an ''infinitely'' long network across the specimen. At this point, the

[a]This is a very simplified version of adhesion. The reader is referred to Ref.[47] for a detailed discussion.

sample will no longer dissolve in solvent. While the gel point correlates fairly often with this crossover, it does not always. For example, for low initiator levels in chain addition thermosets, the gel point precedes the modulus crossover.[52] Temperature dependence for the presence of the crossover has also been reported.[49] In some cases, where powder compact and melts before curing, there may be several crossovers.[53] Then, the one following the $\eta^*_{\min}$ is usually the one of interest. Some researchers[54] believe that the true gel point is best detected by measuring the frequency dependence of the crossover point. This is done by either by multiple runs at different frequencies or by multiplexing frequencies during the cure. At the gel point, the frequency dependence disappears.[55] This value is usually only a few degrees different from the one obtained in a normal scan, and in most cases not worth the additional time. During this rapid climb of viscosity in the cure, the slope for η^* increase can be used to calculate an estimated E_a (activation energy).[56] This will be discussed below, but the fact that the slope of the curve here is a function of E_a is important. Above the gel temperature, some workers estimate the molecular weight, M_c, between crosslinks as:

$$G' = RT\rho/M_c \tag{8}$$

where R is the gas constant, T is the temperature in Kelvin, and ρ is the density. At some point, the curve begins to level off, and this is often taken as the vitrification point, T_{vf}.

The vitrification point is where the cure rate slows, because the material has become so viscous that the bulk reaction has stopped. At this point, the rate of cure slows significantly. The apparent T_{vf} however, is not always real: any analyzer in the world has an upper force limit. When that force limit is reached, the ''topping out'' of the analyzer can pass as the T_{vf}. Use of a combined technique like DMA–DEA[57],[b] to see the higher viscosities, or the removal of a sample from parallel plate and sectioning it into a flexure beam, is often necessary to see the true vitrification point. Vitirfication may also be seen in the DSC, if a modulated temperature technique like StepScan is used.[57],[b] A reaction can also completely cure without vitrifying and will level off the same way. One should be aware that reaching vitrification or complete cure too quickly could be as bad as too slowly. Often a overly aggressive cure cycle will cause a weaker material as it does not allow for as much network development, but gives a series of hard (highly crosslinked) areas among softer (lightly crosslinked) areas. On the way to vitrification, an important value is 10^6 Pa sec. This is the viscosity of bitumen,[58] and is often used as a rule of thumb for where a material is stiff enough to support its own weight. This is a rather arbitrary point, but is chosen to allow the removal of materials from a mold and the cure is then continued as a post-cure step. The cure profile is both a good predictor of performance as well as a sensitive probe of processing conditions. As discussed above under TMA applications, a volume change occurs during the cure.[59] This shrinkage of the resin is important and can be studied by monitoring the probe position of some DMA's as well as by TMA and dilatometry.

[b]DEA is dielectric analysis, where an oscillating electrical signal is applied to a sample. From this signal, the ion mobility can be calculated, which is then converted to a viscosity. See Mc Crum[3,26] for details. DEA will measure to significantly higher viscosities than DMA.

CONCLUSIONS

Dynamic mechanical analysis is an incredibly powerful technique for characterizing materials and predicting their in-service behavior. The technique is becoming better known and more commonly used for testing other than that just measuring very weak glass transitions, although it excels in that. As DMA becomes more common, it is being used to map modulus, viscosity, and damping as a function of temperature, time under adverse conditions (such as UV light, aggressive gases, or in solvent), or shear rate (frequency). This data can be obtained more quickly and cost effectively by DMA than by alternative methods. Current trends indicate increased interest in online methods that give similar results as well as extending the range of forces and frequencies to study nonlinear behavior.

NOMENCLATURE

δ	Phase angle
$\tan\delta$	Tangent of the phase angle, also called the damping
σ	Stress
γ	Shear strain
ε	Tensile strains
$\dot{\gamma}$	Shear strain rate
$\dot{\varepsilon}$	Strain rate
η	Viscosity
η^*	Complex viscosity
η'	Storage viscosity
η''	Loss viscosity
E^*	Complex modulus
E'	Storage modulus
E''	Loss modulus
J	Compliance
k	Deformation
T	Period

ρ	Density
G	Shear modulus
M_e	Entanglement molecular weight
M_c	Molecular weight between crosslinks
M_w	Molecular weight
f	Frequency
ω	Frequency in Hz
K	Rate constant
E_a	Activation energy
DMA	Dynamical mechanical analysis or analyzer
DMTA	Dynamic mechanical thermal analysis or analyzer
DEA	Dielectric analysis or analyzer
DSC	Differential scanning calorimeter
TBA	Torsional braid analyzer
TGA	Thermogravimetric analyzer
ν^f	Free volume
$T_{\alpha,\beta,\gamma}$	Transition (subscript type)
Λ	Logarithmic decrement
Γ	Torque

Education on Plant Design

Truman S. Storvick
Chemical Engineering Department, University of Missouri–Columbia, Columbia, Missouri, U.S.A.

INTRODUCTION

The goal of any practicing chemical engineer is to visualize processes and assemblies of equipment that will produce products beneficial to mankind. These products result when the chemical compositions of the starting materials are transformed by chemical reactions to form the prized new compounds. The processes include the preparation of the materials that go to the reaction system and the isolation of the products that flow from it. It is this intentional change in the chemical composition of matter that distinguishes chemical engineering technology from the other engineering disciplines. What follows is a short presentation of the elements of plant design. Some of the tools available to the process engineer are identified. A discussion of topics that might work as an assignment for university students follows. The evolution of plant and process design over the professional lifetime of the practicing engineer will continue and require continuing education programs to renew skills. It is interesting to speculate what lies ahead.

DESCRIPTION OF PLANT DESIGN

The words ''plant design'' immediately bring to mind industrial applications. This makes it almost certain that it is an economic analysis that will provide the answer to the question ''Will this venture make a profit?'' It also implies that all of the science and technology used to select and assemble equipment to make the plant function must combine with the economic analysis to form a successful plant design. The economic analysis will include the cost of compliance with federal and state legislation and local ordinances, the policies written to ensure safety and compliance with local environmental regulations. Plant design brings into being the physical facility that must be located in contact with the civil and economic communities.

Process design is a team activity. Each person on the team brings everything they know to the design table. Persons who have special training and experience along with basic knowledge of science and technology related to the project are selected for assignment to the design team. Large firms may have those people on the payroll. Smaller firms and often large firms working on a design that requires specialized knowledge or skill will retain consultants to do part or all of the design. Process design success depends on the design team.

Plant design is both the object and the act of visualizing a chemical process or plant. Visualization is the mental activity that allows rapid scanning of many options from which an optimum will be selected. Plant design statements usually underspecify the design task. It is the plant designers who must ask the questions that must be answered to reach an optimum plant design. Douglas describes the process of conceptual design, a hierarchy of design decisions that quickly identifies the sequence of process steps that can lead to an optimum plant configuration.[1] These ''rules of thumb or heuristics'' are based on design experience. The lessons from the history of common process steps are used on a very large, complex design problem to decompose it into a series of small problems that are much easier to visualize and solve. The conceptual design method sorts through many processing sequence alternatives to select the one, two, or very few that show the most promise. Detailed design must be carefully done so it is important to quickly focus on the good alternative. The secret to successful process design is to spend time on the ''best'' option.

Plant design is an active part of the total lifetime of all chemical processes. The birth to death sequence of a chemical plant is characterized by the level of detail of the plant description required at each design step. Early death of a proposed process can occur at any step before it has been built and produces a product. Only a small fraction of the initial proposals survive beyond the second step. Design continues as the process is modified to keep the product profitable in the face of all competition. The stages of a process proposal can be described as follows:

1. Company management considers a move to manufacture a new product, take advantage of a new raw material, respond to a customer request for a product, reduce toxic emissions from the plant, buy or sell corporate technology from or to another firm.
2. Initial analysis leads to a recommendation that a design team be assembled to explore process options. This is where data are collected and the preliminary process steps are evaluated.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120008036

There is a preliminary cost estimate that becomes the basis for the decision to move to the next step.

3. The detailed specifications for the process streams and the equipment are set. All of the drawings and documents required by construction contractors and equipment vendors are prepared. Another cost estimate determines whether to proceed with a request to the business and legal departments to call for bids for plant construction. Construction cost estimates present another decision to proceed with the project.
4. A new group of engineers who work for the construction contractor join to build the plant. The firm maintains supervisory control over construction and negotiates any construction change orders required to complete the project. There will be people writing operating manuals and setting the operator training schedules. This is the time when the equipment and construction fees are paid. The capital investment in the production facility is now committed.
5. The start-up and acceptance of the plant by construction contractors involves a new set of process engineers. Equipment must perform to specifications. There will be an agreement concerning product production rate and quality that must be met to complete the construction phase.
6. Plant operation and maintenance proceed throughout the life of the plant. There will be design of new equipment or procedures to improve the product quality, increase production, reduce energy requirements, etc. Process design never ends as long as the plant operates.
7. There comes a time when the plant is shut down and the equipment salvaged or scrapped. The engineering steps for equipment decommissioning can be as challenging as new construction. Important process design information is obtained by examining the equipment as it is moved out of service.

Many plant design assignments involve process changes that are made to improve an existing facility. A customer wants to change the purity or alter the composition of a product. Treatment of a by-product stream can eliminate a pollution problem and yield a saleable product. New separation technology improves the quality of a product and reduces energy costs. The sales force and the engineers who operate the production facilities play key roles in identifying these tasks assigned to the process engineer. Design changes in an operating plant advance through essentially the same steps as the design of a new plant.

New chemical products are usually produced on an existing plant site. The utilities, management support, maintenance staff, and operating personnel are there and can gradually be assigned to the new product facility as it gains commercial acceptance. Specialty chemicals and pharmaceutical plants are examples of manufacturing facilities that change rather quickly as demand for new products often, rises and falls over a few months rather than years.

There are examples of ''grassroots'' plants usually designed to produce an established product closer to a raw material source or to a product market Examples are fertilizer plants, fuel alcohol, and food processing plants. New petroleum and natural gas processing plants recently built in the Near East are set close to the huge crude oil reserves located there to provide fuel for local markets and to ship value-added products.

The time for completion of each design step is an important variable in the plant design sequence. Design problems by nature are underspecified, but the schedule to complete each step is fixed. More questions are answered at each step in the design sequence, but at every step there will be many unanswered questions. When the plant is well into production, there will be unanswered design questions. Each step in the lifetime of a design provides new insight and empirical data that can be used in the next design step or carried over as process information for the design of new production facilities.

COMPUTERS IN PROCESS DESIGN

Digital computers have been available to the educational community since the 1950s. Design of multicomponent distillation columns was one of the first industrial applications that were programmed. The tedious trial and error calculations for each equilibrium stage performed on desk calculators were replaced by this fast computing machine. Remarkably, a general solution to complex separations is not available and work to improve multicomponent distillation algorithms continues.

The computational speed and memory size of the digital computers increased in the 1960s. The computing power was sufficient to begin programming the mathematical representations of chemical processes. It was also possible to use the computers to record many (100 or 200) process variables (temperature and pressure) in real time while the plant was running. Samples were drawn from the process streams for chemical analysis and these were later matched to the timeline of the temperature and pressure measurements. These data gave a picture of the plant response to changes in the operating conditions. Data logging provided a way to select the settings for each unit in

the plant so that the overall plant performance was improved, justifying the cost of the computers to make the measurements.

Computers continued to get smaller, faster, and cheaper. The accuracy and speed of chemical analysis continued to improve. With real-time chemical analysis of process streams and a mathematical model for each unit in the process, the computer was programmed to set controllers on process streams using the new process control algorithms. With some additional programming and with the process control set points adjusted by the computer control system, the quality of the product improved. The physical property data for the chemicals in the process streams required for these model calculations were built into the process control program.

The past 20 yr has seen remarkable changes in the computational tools available to the process design engineer. The search for and access to data in the public domain and in company files has been reduced to minutes using communication software, global networks, and modern computers. Process simulator software provides graphical representation of the individual units in any process flow sheet. The simulators perform the tedious tasks of completing mass and energy balances on individual process steps and on the overall process sequence. It takes simple entry of process stream information to run the program. The simulators do an excellent job with equilibrium or steady-state calculations that use the exact differential forms of thermodynamics. The programs include an extensive file of thermodynamic data to make the computation algorithms work. New processes using new materials often require new data. These new data can be entered or one can elect a properties estimation procedure provided by the simulator to fill gaps in the properties data set.

It is more difficult to write the computer simulator programs that involve rates: the chemical reaction rate, thermal energy flow, diffusion, and the work required to move material through the equipment. There are no general mathematical solutions to the second-order partial differential equations that represent these physical rate processes. There are solutions for some of the important process steps and additional empirical functions are often used to complete the algorithms.[2] These empirical functions work when there are experimental data to fix the empirical constants. The programmers use information from available plant data as the basis for the algorithms. Simulating processes to produce chemical compounds similar to those used to develop the programs yields the best results. For example, processes involving compounds derived from petroleum are usually accurately represented. The results are less reliable when the process involves new materials. On adding water and inorganic compounds to the process streams, the accuracy of the calculations will be degraded unless provision is made to provide data for these complex mixtures.

The experience and judgment of the process engineer is an important part of the process design. The process simulator will give the correct numerical answer to the problem it has been programmed to solve. It takes experience with the simulator to know how it solves a problem and someone with plant design experience who can ''feel'' when the solution is right. It is easy to reject ridiculous numbers from the process simulator. It is much more difficult to detect a ''reasonable but wrong'' number. There is no substitute for a person with experience to check and verify the numbers the simulator generates.

The process simulators include options to estimate the size of the equipment for each process step. Historic equipment cost data have been correlated so that the equipment can be sized and cost estimated.

Selecting and sizing equipment to perform a single process step is an easy step in process design when the temperature, pressure, and composition of the streams are known. It is much more difficult to find the operating conditions of all the streams to and from each piece of equipment when they are connected to form a continuous flow process. The overall plant optimization calculations get progressively more difficult as the number of process steps increase and constraints on process streams are added to meet all the design objectives for the plant.

Firms often lease process simulators and customize them to model processes running in their plant. Proprietary data and process information are added to the programs and they become the plant process control system. Add another function to the program and it follows the cost and composition of feed materials and computes the process set points that will yield the distribution of products that maximize the economic return for the full array of products.

Writing a program to simulate the dynamic (time dependent) behavior of a process during normal startup and shutdown is more challenging than the steady-state calculations. It is yet another problem to design a program to monitor and control the stream conditions and the critical sequence of steps that must occur during an emergency plant shutdown. Each of these problems represents a special challenge for process design and computer programming.

Process simulators are very helpful but the difficult problem in design is always process selection, finding the best sequence of steps for that process. When a proposed process involves several steps (usually pieces of equipment), several starting materials to obtain several products, how do you decide what is the best way to arrange the necessary process steps? At what point in the process do you feed material and withdraw

product? One can visualize many configurations of the process equipment that will produce the desired products. Application of the conceptual design principles and process experience has been the primary source for selecting the process steps for a plant.

There are two parts to the design of an optimum process sequence that must be addressed to apply the full power of computers for process design. There must be a mathematical model of the proposed process and there must be a solution to that mathematical model. Most of the process simulators are programmed to solve the mathematical model. The more difficult problem is to program the computer to select the ''best'' sequence of process steps from raw materials to products, i.e., process synthesis.

A procedure for programming the synthesis of any process system was proposed in 1992.[3,4] This proposal is based on a reduction of general mathematical programming methods by using the unique features of the process structure to solve the process system selection problem. Specifications of a processing system can include the different operating units (feeders, mixers, reactor, separators, washer, etc.) and the raw materials, products, by-products, and waste materials that will be included in the process. A mathematical axiom system, graph theory, and combinatorial techniques are used to find all feasible process structures embedded in a maximal structure for a proposed process that can then be modified in response to technical, environmental, economic, and societal constraints. The representations of the process steps are mathematically exact. The mathematical structure of the solution is polynomial rather than combinatorial and it converges quickly to identify the possible solutions for complicated processing structures, and the program runs on modern personal computers.

This process synthesis procedure is versatile as demonstrated by the extent of the reported applications. There are computer simulated plant designs to control environmental waste.[5] Selecting the arrangement of operating units for azeotropic distillation has been reported.[6] Determining a best catalytic reaction mechanism and identifying preferred pathways for a biochemical reaction have been described.[7,8] An optimization of a retrofit design for steam supply to an existing manufacturing complex has been reported.[9] Optimum separation networks-reported in the literature were improved using this procedure.[10] Examples are cited where the program identified unnecessary steps in a process. Equally valuable, the program showed it was impossible to obtain the products when the proposal was incomplete. There will be continued development of this program and probably other algorithms will be developed that will search out optimum process sequences.

EDUCATION FOR PLANT DESIGN

Chemical process design is well established in the chemical process industries. The individual skills and problem solving methods have served a wide range of other industries. Education is important for sharpening the skills of the practicing engineer and essential to introduce young people to the methods of process design.

There are two areas where education on plant design for individuals takes place. Students working toward an academic degree in chemical engineering will surely see assignments that include process design principles. The second area is the practicing process engineer who must learn new design technology and how to use new design tools. The practicing design engineer and his or her supervisor will decide the content of this educational assignment. A process simulator vendor may provide tutorials or a software expert may be called in to teach the specialized technology. New technology may enter from in-house research, through a consultant, or from a course offered by a software specialist. The employee and the management will set the educational objectives, assign the resources, and provide the time that will be devoted to this learning experience.

Education on plant design for students studying in an academic institution presents a different and may be a more complex problem. The Accreditation Board for Engineering and Technology requires that a design problem be assigned in the courses in each of the 4 or 5 yr of all undergraduate engineering programs. There will be a comprehensive design course in the final year of the bachelor's degree program. Most of the exercises assigned in chemical engineering courses show how a mathematical function can be used to describe the chemical or physical changes that take place in some apparatus or equipment. Given the function and input data, everyone will get the same numerical answer. These exercises are completely specified and there is only one correct answer.

Design problems will always be underspecified. Given a design objective, the task is to select among operations (heating, mixing, filtering, etc.) and, select the equipment to produce the chemical and physical changes that will meet the objective. Each process description will produce a different numerical answer. It is a ''judgment call'' to rank the results to find the best design solution. Writing tighter objectives will usually drive the numerical answers closer together. In an industrial setting, the experience the process engineer brings to the design, the available facilities, and the financial commitment to the project will guide the design through the steps from concept to an operating facility. The academic setting brings each design

assignment to a new class with an experience level much like a ''clean slate.''

It is often difficult to find an instructor for an undergraduate design course. Usually, the instructor will be a late career teacher or someone with industrial experience who joined the faculty to fill the process design position. Effective design instructors need a general knowledge of chemical engineering technology and should be familiar with new developments. The computer and a wide range of software have become essential tools in process design so the instructor must be able to direct students as they use these resources.

There are textbooks and references available to ''coach'' the instructor and help the students in the academic setting. The following is a partial list of books written as teaching aids for students. There is a process flow diagram for many commercial chemicals and one-step biological transformations that can be useful in a design course.[10–12] Chemical reactions and reactor systems are important in process design.[13,14] Several recent textbooks on process design have been written.[15–21] Most of these books include CD-ROM tutorials with worked exercises using the process simulator software.

The academic setting limits the selection of plant design problems and the expectations for completion of a work assignment. Some considerations that apply to an academic setting are:

- Time is limited. The plant design course is one of three or four courses students take during the semester. There is a limit of about 150–200 hr each student has available during the semester.
- Students lack design experience. Each student has a plan for life after the B.S. degree. Many will choose employment as a chemical engineer. Some will attend a professional school (medicine, law, graduate school, and business are common). It is unusual to find two students in a class with common interests and similar career objectives.
- Students are usually assigned to work in small groups of three or four. This mimics the group effort of industrial design teams. Only those students with one or two semesters on an industrial internship or a summer job in industry bring industrial experience to the group. It is best to assume that there is no design experience in the class.
- Select a design problem that the students understand is ''real.'' Students do better work on a problem they recognize from their reading or hear about on broadcast media.
- Check that there are data and descriptions of the technology available to the students. They do not have time for a data ''treasure hunt.'' If information is really not there, the instructor must intervene and supply a ''data fix'' soon after assigning the problem.
- Monitor the progress of each group. Design is the process of formulating questions and finding the answers. Inexperience often leads students to do what they know how to do rather than what needs to be done to complete the design assignment.
- The results of the design project should be presented in a written report. Interim written and oral reports help students stay on track. Reporting is preparation for future employment opportunities.
- All design assignments are due at a specified date and time. Design problems are always underspecified and open ended so the design report never ends with QED. The conclusions will include recommendations for continuing the design. This report would be the basis for committing resources to the next design step in an industrial setting. Grades are assigned in the academic setting and the design sequence ends with the semester.

An academic design assignment must be a clear statement of the design objective. Examples include a change in the processing sequence of an existing plant, evaluating the advantage of a new catalyst in an existing plant to produce an improved product, assessing the economics of using microorganisms to decontaminate a waste water stream, producing hydrogen for transportation fuel. The list of possible assignments is long. The list of good class assignments is much shorter.

The library and the Internet are the prime sources for process information. Students should visualize the necessary process steps for their assignment, find what others have done that can be applied to their design. A feed cost and product revenue calculation is the first economic analysis. The early stage of the design process is where heuristics are helpful. A simple mass and energy balance is useful at this stage. Current textbooks suggest orderly ways of selecting process alternatives, sequencing process steps, and sizing equipment.[1,15,16,21] The best two or three process alternatives will usually produce one that will yield the final design report.

An academic process design course should include use of a process simulator. There are several simulators available with some offered at a high discount to academic institutions. The ''learning curve'' for these programs is rather steep, so it helps to start using the program in the sophomore and junior courses.

Students find it tempting to get on to simulator calculations before they have settled on a strategy or a process sequence for their design problem. It saves time to plan carefully what needs to be computed and what will be learned from those numbers. The numbers from the simulator have little value unless they provide

insight that supports the conclusions that become the final design report.

The advantage of process simulator calculations comes when the sequence of process steps has been set. The process simulator draws the process flow sheet specified and uses it to fix the computer algorithm for the process. There are optimization strategies to select the ''best'' conditions of the feed streams to the equipment and operating conditions for the whole process.

The American Institute of Chemical Engineers sponsors an annual process design contest for students. A problem statement is distributed and students are given 30 days to complete the design analysis and write their report to be eligible for judging in the competition. There is an individual and a small-group category in the contest. One or two of the best reports are selected from the class and submitted to the competition committee. Spending 30 days immersed in one design problem is a teaching strategy that can be a good learning experience. This is an opportunity for independent work, much like an industrial setting. Assign the problem early in the semester and use the remaining time to do the next iteration on the problem or select a new problem that covers another processing technology.

TRENDS IN CHEMICAL PROCESSING

The historic record of developments in chemical process technology indicates trends that point to the future. There are established industries that support our national infrastructure and there are new ideas for products that will be developed and become part of everyday commerce. Energy for transportation and electric power production represents large industrial investments in physical facilities. The energy industries generate huge revenues that make them powerful players in economics and politics on a global scale. Fossil fuels (petroleum, coal, and natural gas) are the source of most of the energy we use.

Petroleum refining is an example of a mature processing industry. It produces nearly all of the transportation fuels (cars, trucks, aircraft, and trains). A recent historic timeline of 100 yr of advances in chemical engineering technology was published and shows the dates of significant developments in refining.[22,23] As a mature industry, minor process changes reduced refining costs and the response to shifts in product demand yielded large financial savings. Major changes occurred when federal environmental policy mandated reduced air and water pollution. Tetraethyl lead used to increase the gasoline octane number was eliminated and this meant that the petroleum refiners had to learn to ''refine in'' higher octane numbers. This new fuel still had too low an octane number so the compression ratio of the automobile engines was reduced to efficiently use this fuel and meet the new exhaust emission standards. As the petroleum refining industry matured through the 20th, century it provided much of our modern chemical plant design technology.

The impact of greenhouse gases on local and regional climate is currently being debated. The average carbon dioxide concentration in the atmosphere has increased significantly over the past century with combustion of fossil fuels adding to the natural sources of this greenhouse gas. It does appear that international policy will be written for a reduction in the rate of release of carbon dioxide and other greenhouse gases. The response to such policies will require innovative fuel technology. Increasing the energy efficiency of automobiles and industrial processes that use fossil fuel is one way to reduce per capita carbon dioxide emissions and continue the trend of the past 30 yr.

One proposal to reduce pollution in cities is to use hydrogen as a transportation fuel. Hydrogen fuel cells produce electricity to power automobiles or to power televisions and they discharge water. However, most of the world's hydrogen is in hydrocarbons (methane, ethane, propane, ... petroleum) or in water. Extracting hydrogen from hydrocarbons releases carbon dioxide. Hydrogen can be obtained from water using electricity, but using coal to generate electricity releases carbon dioxide. So, use a solar cell to produce electricity or can a solar cell be made to produce hydrogen? Wind can produce electricity and yield hydrogen. Is electricity from thermal energy produced by nuclear fission (a nuclear power station) a possible source of hydrogen without producing carbon dioxide? All of these options are available today or can be made ready with additional scientific advances and new technology to produce fuel hydrogen. Switching from petroleum derived fuels to hydrogen requires large financial investments for production and distribution. Assuming there is the ''will'' to move to hydrogen fuel, it will probably take half of the 21st century to modify the petroleum fuel infrastructure and replace all of the vehicles that use petroleum based fuel.

Miniaturization and nanotechnology are becoming part of our technology tool kit. The discovery of the transistor revolutionized electronics and required new processing methods to produce the transistor chips. The circuits on a chip are now so small that quantum effects are important. ''Chemical analysis on a chip,'' which promises a medical doctor a complete blood analysis while interviewing a patient is being developed. Faster and cleaner chemical conversions may be possible with catalysts that use nanostructures. Process technology in miniature will follow these developments. Is there an answer to making new fuels concealed in ''small'' processing?

Technology development historically follows new science. Major research funding currently goes to the

biological and medical sciences. Basic studies seek to unravel the secrets that produce and maintain life. Plants are living chemical reactor systems that ''self-assemble'' from a seed, generate the enzymes required to function, and use solar energy to produce a remarkable array of chemical compounds. Animals have an even more dazzling array of attributes produced by a wider range of chemical reactions that run on energy extracted from those plant produced chemicals. All of this chemistry runs at nearly constant temperature (not far from room temperature) with mass and energy transport between cells and gels that make up the flesh and fluids of living systems. Yeast producing alcohol from sugars has been ''commercialized'' for centuries. Is there a new science and technology based on what we can learn from living organisms to collect energy from the sun? After all, the fossil fuels we use today are the naturally sequestered remains of living organisms.

FUTURE FOR PROCESS DESIGN

Education on plant design certainly has a future. Plant design in industry will always respond to the demands of maintaining production of commodity chemicals. Specialty chemicals are profitable if there is constant improvement in product quality and research continues to renew the list of products that come from scientific research and the new technology produces it to fill the new market demands.

The large investment in chemical production facilities usually keeps them in production for a long time. Most of the plants that are running today will be running 25 yr from now. There will be improvements in efficiency and response to the demands to reduce emissions. Process design will play a key role in maintaining these production facilities.

The economic competition that comes from the global economy will produce changes in the process industries and plant design.[24] Improved energy efficiency will be important in chemical processing. Fuel price fluctuations pass directly to the product costs are so designed for efficient energy use.

There will be a greater emphasis on safety. It is important for workers in the plant and essential to be a good industrial citizen in the community.

There will be new regulations limiting emissions from the production facility and from customer use of the chemical products. The optimum new process sequence will be designed so there is essentially zero discharge.

There will be a closer coupling between the new science and the new technology. Process modeling will begin as soon as there are results from the laboratory suggesting that there is a new product with commercial potential. New computer software will support this activity.

Process control of the manufacturing plants will continue to improve. There will be less material in process, the equipment will be smaller and of higher capacity so ''sharp'' control should be in place. Better control will give improved conversions and enhance product quality, especially for high-value-added products.

Current education on plant design emphasizes commodity chemicals in large manufacturing complexes. There is an increasing manufacturing response to customer demand for expensive, specialty products. This will lead to a shift from current process design toward product design.[24] These new production facilities will use general-purpose equipment that can be configured to make one specialty chemical and quickly switched to another product in response to seasonal or customer demand.

Education on process design does carry a bonus. Understanding how to work an open-ended process design problem is good citizenship training. Young people in process design courses will mature into leadership roles in industry and in their communities. Successful leaders spend every day working on open-ended problems. Process design is a discipline that provides the framework to select solutions to these problems.

CONCLUSIONS

The history of plant design spans more than 100 yr. In that time, the fingerprints of plant design specialists cover commercial developments that include extracting metals from ores, fixing nitrogen, bringing liquid fuels out of petroleum and coal, producing polymers for fibers, films, and solid plastics, processing foods, preparing pharmaceuticals, a long list of domestic and military products. Education on plant design focuses on the systematic procedure for visualizing the solution to a design proposal. The education of a process design specialist begins as an undergraduate student and continues over the professional lifetime. Digital computer software plays a key role in data collection, process control, and new plant design analysis. Plant design will move in the direction of product design with lower-volume, higher-value-added products using environment friendly processing. Biochemistry and biotransformations will be increasingly important in the chemical process industries.

INTRODUCTION

Most important concepts and techniques of electrodeposition are introduced and described here, with examples of technological applications are given, with emphasis on the fabrication of nanostructures. A brief history of the process development is also given.

DEFINITIONS AND HISTORY

Electrodeposition is an electrochemical process that allows the preparation of solid deposits on the surface of conductive materials. It is a commercially highly relevant process, providing the basis for many industrial applications, such as electro-winning, refining, and metal plating. Metal plating is the process that has perhaps the closest contact with most people's everyday life, because we are surrounded by things that have a protective or decorative coating, such as watches, buttons, belt buckles, doorknobs, handlebars, etc. Additionally and more recently, as will be seen below, not only do the circuit boards and the packaging modules of computers, but also the recording and reading heads of their hard disk drives and the microprocessor chip itself may have plated material on them.

Electrodeposits are formed by the action of an electric current passing in an electrochemical cell, a device that consists of two conductive or semi-conducting electrodes immersed in an electrolyte. The electrodes are called the working electrode (cathode), consisting of the object where electrodeposition is planned, and the counter-electrode (anode), necessary to complete the electrical circuit. Electrolytes for electrodeposition are usually aqueous solutions containing positive and negative ions, prepared by dissolving metal salts. The electric current that flows between the two conductive electrodes in the presence of an external voltage is because of the motion of charged species, via migration and diffusion, towards the surfaces of the polarized electrodes. At the surface of the electrodes, the conduction mechanism must change from ionic to electronic, an interface process mediated by the occurrence of electrochemical reactions that promote the reduction or the oxidation (redox reactions) of the ionic species.

An electrochemical cell with a battery is illustrated in Fig. 1, where the motion of the ions toward the electrodes is also sketched. In this case, the metallic salt $NiSO_4$ (nickel sulfate) dissolved in water is a practical example of an electrolyte for Ni-plating metallic objects. In this example, the object to be plated is a key, placed as the working electrode. By applying an external voltage with the negative terminal of the battery connected to the working electrode, the Ni^{2+} move to this electrode, where deposition takes place, and the SO_4^{2-} toward the positively charged counter-electrode.

An essential characteristic of electrochemical reactions is that the exchange of charge does not occur between chemical species, as it does in a typical chemical reaction, but between chemical species and the electrode. The electrochemical reaction that is most important for the electrodeposition process is the one that occurs at the working electrode; i.e., for the example, in Fig. 1, it is the reduction reaction $Ni^{2+} + 2e^- \rightarrow Ni^0$, where the Ni ions are reduced by receiving two electrons (e^-) from the electrode. At the counter-electrode, the oxidation of the sulfate radical is too energetic to occur, and the most probable oxidation reaction for inert electrodes in an aqueous electrolyte is the electrolysis of the water, forming H^+ and O_2 through the reaction $H_2O \rightarrow 2H^+ + {}^1/_2O_2 + 2e^-$. This reaction occurs by donating two electrons to the anode, completing the electrical circuit and keeping the electric charge balanced. Frequently used inert electrodes include platinum and glassy carbon. If the counter-electrode is a metallic bar or foil (a non-inert electrode), the electrodissolution of the metal could provide electrons for the electrode and ions for the solution.

Historically, the discovery of electrodeposition is attributed to Luigi V. Brugnatelli, an Italian professor, who in 1805 was able to electrodeposit gold on the surface of a metallic object, from a solution containing dissolved gold, using a voltaic pile (battery). About 40 years later, John Wright, from Birmingham, England,

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120037171

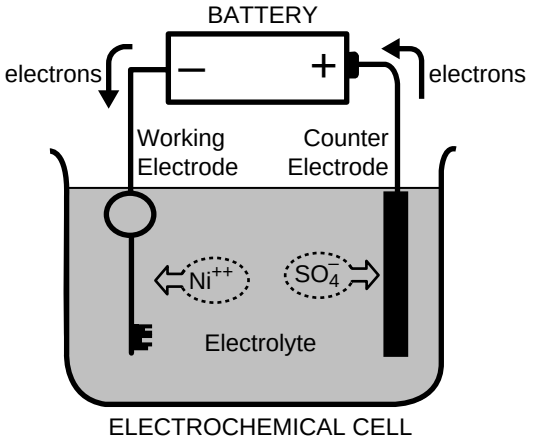

Fig. 1 Positively charged nickel ions in the electrolyte are attracted by the negatively charged key (working electrode). At the surface of the key they are reduced by gaining two electrons, and metal is deposited.

discovered that potassium cyanide was a suitable electrolyte for gold and silver electroplating. This discovery made electrodeposition an important commercial process for covering the surface of various kinds of metallic object with thin coatings of metals for corrosion protection and decorative purposes. Subsequently, baths for the deposition of other metals and alloys such as nickel, zinc, tin, and brass (an alloy consisting essentially of copper and zinc in variable proportions) were developed. For the next 100 years, the main idea was to use electrodeposition for covering the surface of inexpensive materials with a thin layer of a noble metal. By the 1940s, however, electrodeposition was rediscovered by the electronics industry. The electrodeposition of gold for electronic components was a totally different kind of application of electrodeposition techniques.

Over the years, electrodeposition became a highly developed process. Direct current (DC) power supplies were developed; anodic and cathodic reactions were described; new safer baths based on acid electrolytes, avoiding the earlier poisonous cyanide-based ones were discovered; models for the deposition process incorporating mass transport to the electrodes, charge transfer kinetics, and nucleation and growth at the working electrode were developed; and regulatory rules for waste water emission and waste disposal were created. Simultaneously, a gradual improvement in electrodeposition for large scale manufacturing processes took place.

ELECTRODEPOSITION APPARATUS AND CONCEPTS

Electrodeposition on the industrial scale requires an electrochemical cell and a DC current power supply. This approach is relatively simple and inexpensive, and is known as galvanostatic plating system, because the current between the electrodes is controlled (maintained constant). Another important deposition mode is the pontentiostatic one. This mode is a consequence of the development of electrochemical science, where electrochemical reactions at the surfaces of electrodes are carefully investigated. The electrochemist developed reference electrodes, in order to measure the potential drop near the surface of electrodes. Assuming that the electrolyte contains sufficient ions (has sufficiently high conductivity) to avoid any ohmic voltage drop, because of the resistance of the electrolyte between the electrodes, all the voltage applied by the battery (in Fig. 1) will appear near the surface of the electrodes, where a charged region is formed (usually named the double layer). It is very important to measure the voltage drop across these charged regions, because it controls the driving force for phase transformation from ion to reduced state. A simple metal foil could be used as a reference electrode; however, because of the need to have a standard electrode to measure potential drops at the surface of different types of working electrode in contact with different electrolytes, a hydrogen electrode was elected, and now all electrode potentials are quoted relative to this arbitrarily chosen reference electrode. What is always measured is the potential difference between two electrodes. By defining the potential of the hydrogen electrode as zero, it is possible to generate a table of all the possible redox reaction potentials relative to this electrode, and these potentials are called standard potentials. The standard hydrogen electrode (SHE), which is usually constructed by bubbling hydrogen gas over an immersed platinum foil, has its operation based on the redox reaction $H_2 \leftrightarrow 2H^+ + 2e^-$. Other reference electrodes that are robust, stable, and easily constructed than the SHE are frequently used in the laboratory, give potential measurements that can be converted to standard potentials by adding or subtracting a constant value. The most common are the calomel electrode (Hg/Hg_2Cl_2) and silver/silver chloride electrode (Ag/AgCl).

The potential of an electrochemical cell, also known as the cell potential or electromotive force (emf) is the sum of the potential drops at the cathode and anode, where the reduction and oxidation reactions occur. With the introduction of a reference electrode the potentials of these two electrodes can be measured independently, allowing the independent investigation of the reactions that are taking place at each electrode (working or counter). These redox reactions are called half-cell reactions or simply half-reactions. The half-reaction potential E^0 can be measured with a SHE electrode at standard conditions, i.e., at electrolyte concentrations of 1 M, gas pressures of 1 atm., and

Table 1 Standard electrode potentials in aqueous solution at 25°C

Cathode half-reaction	E^0(V)
Na^+ (aq) + e^- → Na (s)	−2.71
$2H_2O$ (l) + $2e^-$ → H_2 (g) + $2OH^-$ (aq)	−0.83
Fe^{2+} (aq) + $2e^-$ → Fe (s)	−0.41
Ni^{2+} (aq) + $2e^-$ → Ni (s)	−0.23
$2H^+$ (aq) + $2e^-$ → H_2 (g)	0.00
$2Cu^{2+}$ (aq) + $2e^-$ + $2OH^-$ → Cu_2O (s) + H_2O (l)	0.17
Cu^{2+} (aq) + $2e^-$ → Cu (s)	0.34
O_2(g) + $4H^+$ (aq) + $4e^-$ → $2H_2O$ (l)	1.23
$S_2O_8^{2-}$ (aq) + $2e^-$ → $2SO_4^{2-}$ (aq)	2.01

Note: aq., g and I denote aqueous, gas and liquid respectively.

temperature of 25°C, and tabulated. Table 1 shows a set of standard potentials for cathode half-reactions.

The introduction of the reference electrode led to a different experimental setup for electrochemical and electrodeposition experiments. Fig. 2A shows an electrochemical cell with three electrodes (working-, reference-, and counter-electrodes) and a potentiostat. The potentiostat is an electronic apparatus that maintains the potential difference between the working- and reference electrodes by controlling the potential difference between the working- and counter-electrodes. Fig. 2B shows a block diagram of the electronic circuitry of a potentiostat with an operational amplifier that keeps the voltage between reference electrode (RE) and working electrode (W) equal to the applied voltage E at the positive terminal, by regulating the cell potential between W and counter-electrode (CE). By convention W is connected to ground.

The three-electrode cell and the potentiostat enable the potentiostatic mode of deposition mentioned above. The potentiostatic mode means that the potential of the working electrode is kept constant during the experiment or deposition process, as depicted in Fig. 3A. An additional mode called pulsed deposition is also illustrated in Fig. 3B. In this mode, for pulsed potential, the potentiostat switches the working electrode potential between two values in order to have the potential varying as a square wave. For pulsed current deposition, a current source with a square wave output is sufficient.

The three-electrode cell and potentiostat is also a powerful experimental tool for electrochemical investigations, permitting the implementation of different techniques, such as voltammetry. This technique consists of applying a potential ramp to the working electrode, which is achieved by applying a potential ramp to the positive terminal of the operational amplifier (of Fig. 2B), and measuring the resultant cell current. When the applied potential starts at a defined level and comes back to the same value after a period of time, the technique is called cyclic voltammetry. When the applied potential starts at a level 1 and goes to a level 2, the resulting plot of the current versus the potential, is called a polarization curve or

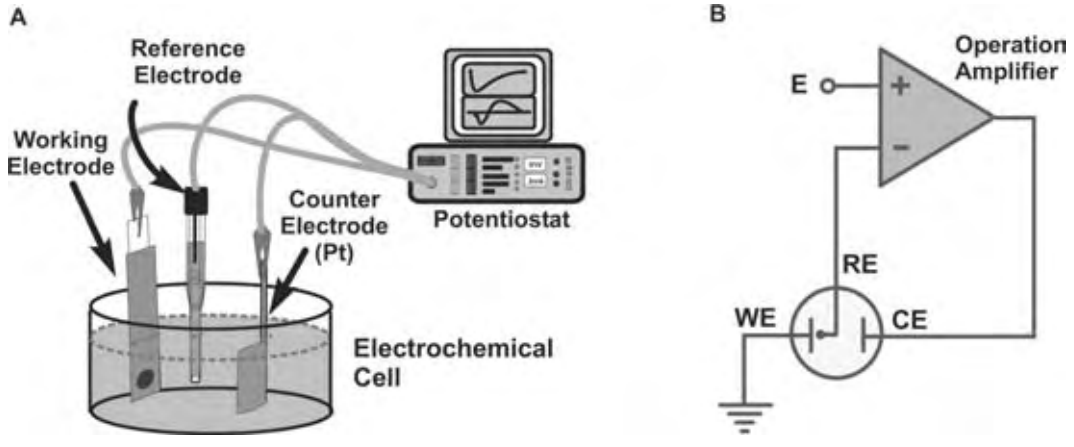

Fig. 2 (A) Electrochemical cell with three electrodes connected to a potentiostat. (B) Electronic sketch illustrating the mode of operation of a typical potentiostat.

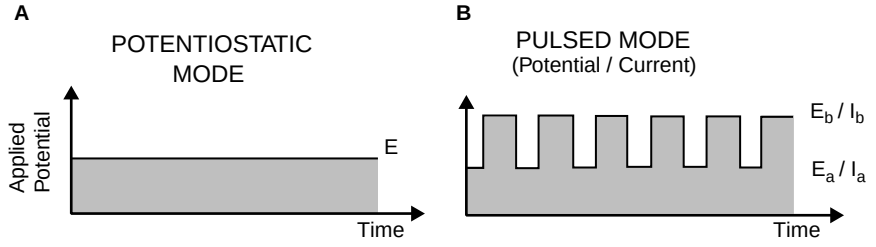

Fig. 3 Illustration of the potential as a function of time for potentiostatic and pulsed deposition modes.

simply voltammogram. Fig. 4A illustrates a potential ramp applied to the working electrode, and Fig. 4B the corresponding plot for the variation of the cathodic current as a function of the cathodic potential. This figure shows a typical polarization curve for the reduction of a metal at a conductive electrode. The onset of current, indicated by an arrow, corresponds to the minimum cathodic potential at which the reaction occurs (a fundamental value for electrodeposition purposes), the peak corresponds to the maximum current at a given rate of change of potential (also known as the reduction peak), while the third characteristic feature of the plot is the saturation of the current at more negative potentials. The intensity of the reduction peak depends on the potential scan-rate, this peak being not observed, in many cases, because of other reactions that occur simultaneously.

Potentiostatic Deposition

This section will describe the pontentiostatic mode using an electrolyte containing cobalt sulfate. By applying a potential ramp it is possible to obtain the polarization curve shown in Fig. 5A. In this figure the onset of Co reduction is about -0.8 V. By selecting a deposition potential negative than this value, it is possible to obtain a deposit. Fig. 5B illustrates a Co deposit that is very homogeneous, apart from a microscopic defect because of a hydrogen bubble, obtained at a deposition potential of -1.1 V. Fig. 5C shows a plot of the deposition current. This plot, known as a current transient, gives information about the deposition process and allows the calculation of the electrodeposited charge from the area below the curve.

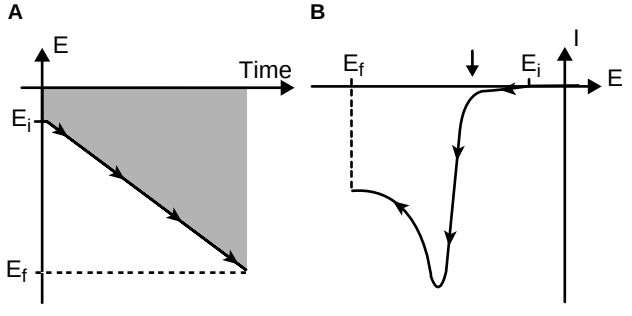

Fig. 4 Illustration of the applied potential ramp (A) to obtain a typical polarization curve (voltammogram) of metal deposition on a metal working electrode.

ELECTRODEPOSITION MECHANISMS

Electrodeposited Charge

Because the electrodeposition process involves the transfer of electrons to an electrode, by measuring the current in the electrochemical cell, it is in principle possible to calculate the amount of material deposited. If no other reaction occurs in parallel, then we can assume that the reaction at the working electrode in aqueous electrolyte is just the simple reduction of a metal (M)

$$M^{n+} + ne^- \rightarrow M^0, \quad (1)$$

where a metal ion M^{n+} is reduced to a metal atom M^0 after gaining n electrons. By assuming that all the metal ions reduced at the surface of the working electrode stick to this surface, the total amount of electrodeposited material can easily be calculated from the charge Q (in coulombs), which represents the product of the total amount of electrodeposited atoms N times the charge of n electrons, as given by the expression

$$Q = Nne, \quad (2)$$

where e is the charge of one electron, equal to -1.6×10^{-19} C. The charge Q is calculated from the current transient. If the deposition current is constant, Q can be calculated by simply multiplying the current I by the deposition time t,

$$Q = It. \quad (3)$$

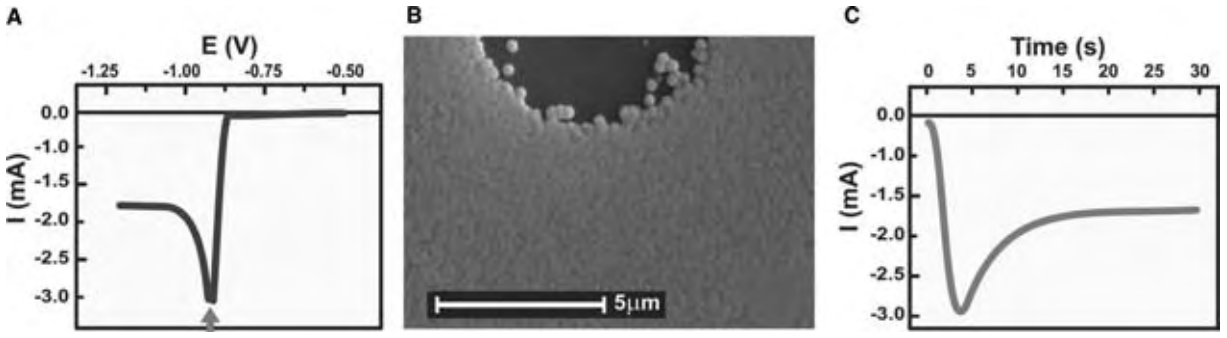

Fig. 5 (A) Polarization curve of an electrolyte containing cobalt sulfate, (B) scanning electron microscope (SEM) image of a Co deposit obtained at −1.1 V, and (C) the corresponding deposition current as a function of time (current transient). The reference electrode was saturated calomel and the working electrode semiconducting silicon. (From Ref.[1].)

However, if the current is varying during the deposition, as shown in Fig. 5C, Q can be calculated by integrating the current $I = I(t)$ as a function of time,

$$Q = \int I(t)\mathrm{d}t. \tag{4}$$

In order to calculate the thickness h (m) of the deposit on a known area A (m^2) of the surface of the electrode where deposition occurred, the quantity N can be expressed as

$$N = \frac{mN_a}{M}, \tag{5}$$

where m is the electrodeposited mass (g), N_a is Avogadro's number (the number of atoms in a mole, equal to 6.02×10^{23}) and M is the atomic weight. Using the density d (g/m^3), given by $d = m/V$, where the volume V (m^3) is given by the product of the area, and the thickness, $V = Ah$, Eq. (5) can be rewritten as

$$N = \frac{dAhN_a}{M}, \tag{6}$$

and Eq. (2) rewritten as

$$Q = \frac{ndAhN_a e}{M} = \frac{ndAhF}{M} \tag{7}$$

where F is Faraday's constant, defined as $F = N_a e$, equal to 96,485.34 C. By rearranging Eq. (7) and knowing the quantities M, Q, n, d, A and F, the thickness can be easily calculated from:

$$h = \frac{MQ}{ndAF}. \tag{8}$$

This calculation gives a deposit thickness in meters that has to be converted into more adequate units as microns ($1\,\mu m = 10^{-6}\,m$) or nanometers ($1\,nm = 10^{-9}\,m$). For a precise calculation of the thickness of deposits, it is necessary to take into account possible electrode reactions that occur simultaneously with the main reaction. One very common example is the hydrogen evolution reaction, $2H^+ + 2e^- \rightarrow H_2$. This reaction is so rapid, in conditions such as relatively high cathodic potentials in acidic electrolytes, that it dominates the exchange of electrons at the surface of the electrode. The contribution of hydrogen evolution to the cathodic current must be determined in order to obtain the efficiency of the plating process. This may be done indirectly by measuring the thickness of the deposit and calculating the amount of charge corresponding to ''missing'' metal. The presence of hydrogen during the deposition has several effects on the metallurgical properties of the deposits. One of these effects is the formation of gas bubbles that mask the surface of the electrode locally, introducing microscopic defects in the electrodeposited layers (see example of this effect in Fig. 5B).

Mass Transport

Electrodeposition has the ability to produce a relatively uniform distribution of metal upon a cathode of irregular shape. Though the uniformity depends on the distribution of electric fields inside the electrolyte toward the surface of the electrode, other important factors have to be considered. The addition of agents (additives) to the electrolyte, for example, can affect the microscopic mechanism of electrodeposition, reducing the roughness of the deposit and producing a visual effect known as brightening.

In order to obtain layers with a desired property, such as uniform thickness and low roughness, or an

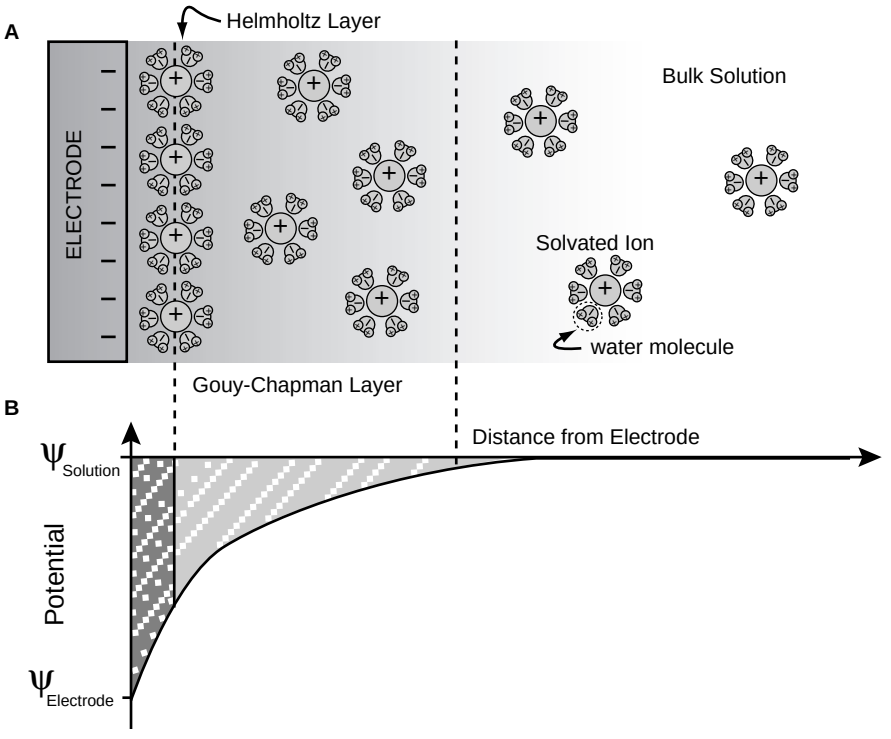

Fig. 6 Illustration of the electric double layer (A) and potential drop (B) near the surface of the electrode.

electrolyte with high filling capacity, i.e., with the ability to produce deposits inside holes or lith ographic features, one has to consider carefully the transport of different species inside the electrolyte and the reaction rates of these species on the surface of the electrode.

Basically, three mechanisms are responsible for mass transport inside an electrochemical cell: diffusion, migration, and convection. Diffusion is mass transport because of concentration gradients, i.e., variations in the concentration of a species with position. Diffusion occurs mainly near the electrode surface because of gradients created by the consumption of species that undergo redox reactions and are incorporated into the deposit. This incorporation process depletes the deposition species near the electrode, generating the concentration gradient.

The simple introduction of an electrode into an electrolyte will lead to an exchange of charge between electrolyte and electrode. An electric double layer, illustrated in Fig. 6, will be formed. Fig. 6A shows the double layer in greater detail. When the exchange process reaches equilibrium the double layer thickness depends on the physical and chemical properties of the electrode/electrolyte interface. In general, the description of the double layer considers the existence of two regions named the Helmholtz layer, a monolayer of ions on the surface of the electrode, and the Gouy-Chapman layer, a region that penetrates the bulk of the electrolyte with decreasing charge and concentration gradients. In the figure, the ions are shown with a sheath of water molecules. This solvation sheath is because of the electrostatic attraction of polar water molecules and the ionic species. Fig. 6B illustrates the potential drop near the surface of the electrode because of the presence of the double layer. In the bulk of the electrolyte the potential drop is

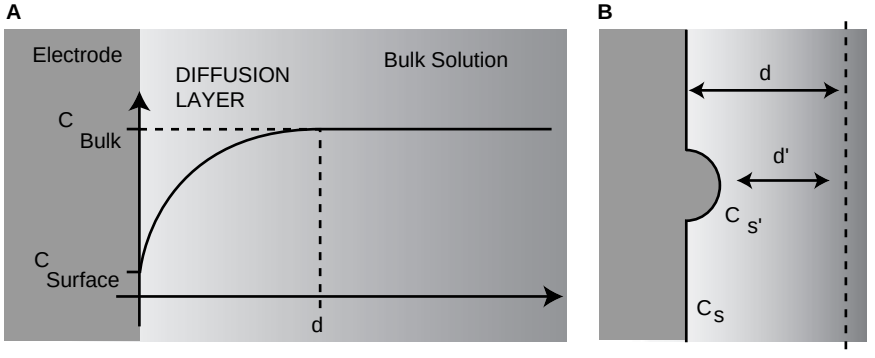

Fig. 7 (A) Idealized profile of the concentration gradient near the surface of the electrode and (B) an illustration of a deposition instability in the presence of an asperity.

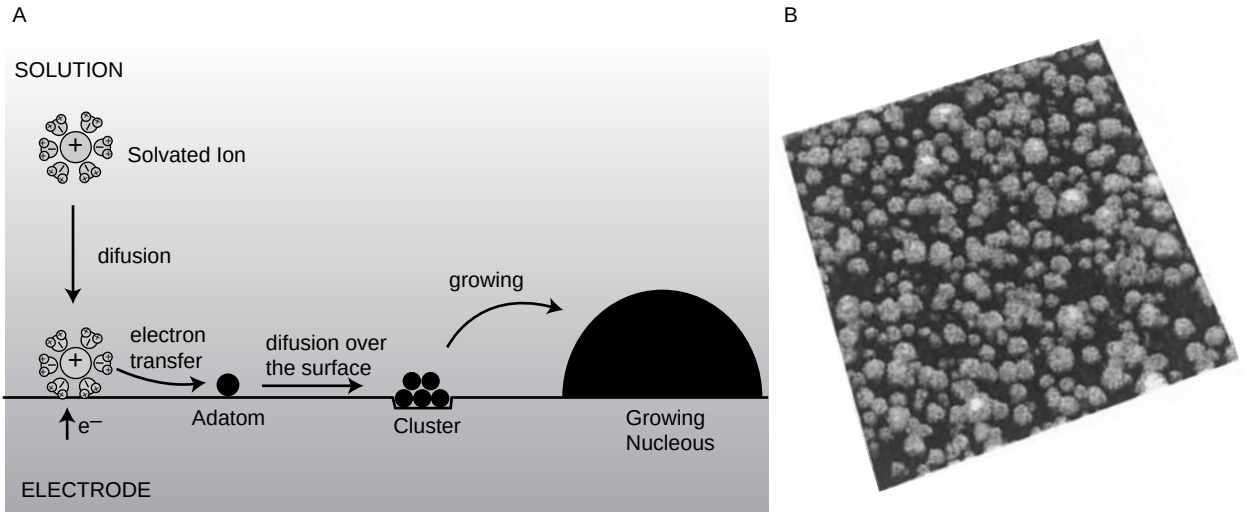

Fig. 8 (A) Mechanism of formation of electrodeposits on the surface of an electrolyte and (B) an atomic force microscope (AFM) image reveals the granular nature of a Co deposit. (From Ref.[1].)

normally very low, because this region is not depleted of ionic species.

Beyond the double layer, there is a depleted region named the diffusion layer with a thickness of microns, much wider than the double layer, formed during deposition by the consumption of a particular species. Fig. 7A is a plot of the concentration of an ionic species as a function of the distance from the surface of the electrode, showing the diffusion layer. The consumption of ions because of metal deposition generates a concentration gradient that, in steady-state conditions, is essentially determined by the redox reaction rate. If the consumption of ions arriving at the surface by diffusion is very high, the concentration of ions at the surface C_S is effectively zero, and the deposition process is controlled by diffusion. If the consumption is low, then the ion concentration at the surface is different from zero and the deposition is controlled by kinetics, i.e., by the velocity of the reaction.

Electrodeposition in the diffusion-limited regime is very sensitive to asperities on the surface of the electrode, as shown in Fig. 7B. These morphological structures reduce the size of the diffusion layer, thereby increasing the concentration gradient and hence the current. The local increase in current increases the deposition rate, favoring further growth of the asperities, and consequently an increase in roughness of the whole electrodeposited layer. This effect is known as deposition instability.

Inside the bulk of the electrolyte, mass transport is mainly because of migration, a mechanism of ionic motion caused by the presence of an applied electric field. In the electrochemical cell the potential drop creates an electric field that is much more intense in the regions near the surface of the electrodes, but is sufficiently intense in the bulk of the electrolyte to promote the migration of the ions to the border of the diffusion layers.

The third important mechanism of mass transport is convection. In this case, the fluid flows in an uncontrolled manner because of natural density gradients (gradients caused by concentration and temperature

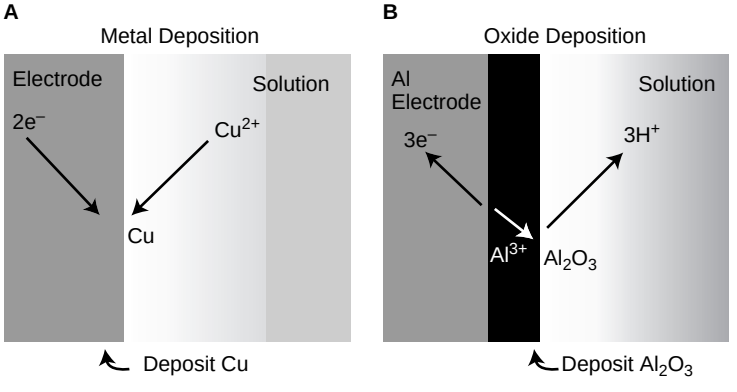

Fig. 9 Electrode reaction for (A) the cathodic electrodeposition of Cu and (B) the anodic electrodeposition of Al oxide.

fluctuations). Convection can also be produced in a controlled manner by different methods, such as mechanically stirring the electrolyte.

Growth Mechanisms

To complete the explanation about the mechanisms of electrodeposition, it is very important to give an idea about the formation of the deposits. A model for the electrodeposition process considers a solvated ion going through the diffusion layer as a first step, loosening of the solvation sheath by transferring electrons with electrode and being adsorbed (adatom) as the second step, and surface diffusion and incorporation in an energetically favorable site as the third step. The deposition sites can be punctual or extended surface defects, such as vacancies or kinks, known in general as nucleation sites. The nucleation sites allow the formation of nuclei (islands) that evolve to grains, forming compact deposits that grow on top of the surface of the electrode. Fig. 8A depicts the mechanism of layer growth and Fig. 8B shows an atomic force microscopy (AFM) image of an electrodeposited layer from an electrolyte containing cobalt sulfate. The image clearly reveals the formation of Co grains on top of electrode surface.

Electrode Reactions

The current that flows at the working electrode may be divided into two kinds: faradaic and non-faradaic. The faradaic processes are the ones where charges are transferred across the liquid–solid interface. These processes are called faradaic because they follow Faraday's law, which says the amount of substance that undergoes oxidation or reduction at each electrode is directly proportional to the amount of electricity that passes through the cell. Two faradaic processes that are directly related to electrodeposition are shown in Fig. 9, where Fig. 9A represents simply the deposition of Cu by reduction of Cu^{2+} and Fig. 9B the growth of Al anodic oxide by oxidation of metallic aluminum, this being an example of anodic electrodeposition. Non-faradaic processes are

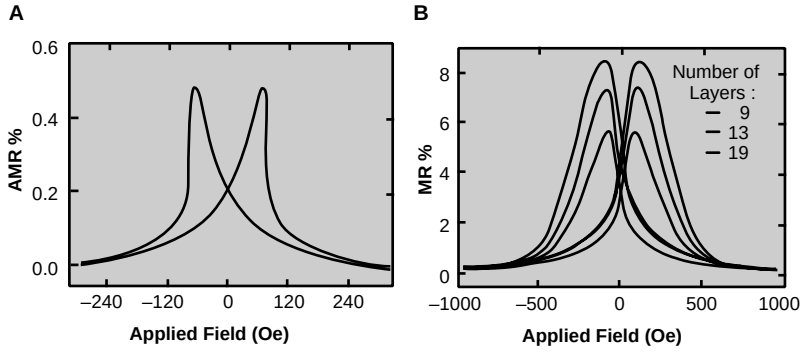

Fig. 12 (A) AMR of single layer of Co[1] and (B) GMR results depending on the number of layers. (From Ref.[5].) The substrate is semiconducting Si.

structural changes of the electrode–solution interface, such as absorption and desorption of species that change the potential of the electrode and solution composition without charge transfer.

ELECTRODEPOSITION IN MICROELECTRONICS

Recently, there has been a boom in the use of electrodeposition for microelectronics. The microelectronics industry came to the conclusion that the electrodeposition of Cu is the ideal manufacturing process for wiring for semiconductor logic and memory devices. Wiring is the network of wires that interconnects the devices (transistors) on integrated-circuit chips. Copper is a highly conductive metal and is relatively easy to electrodeposit. Since 1997, Cu has been successfully used for the production of interconnects.[2] Nowadays, such interconnects are electrodeposited in trenches with widths of 0.13 μm or less. The ability to fill trenches and vials with a plated material is called superfilling and is illustrated in Fig. 10A. The cross-section of the device illustrated in Fig. 10B depicts the multilevel wiring structure of an integrated circuit and Fig. 10C shows a real arrangement of electrodeposited interconnects in a device fabricated by IBM.

ELECTRODEPOSITION IN NANOSCIENCE AND NANOTECHNOLOGY

Simultaneously, with the rapid growth of electrodeposition in microelectronics, a new trend based on the electrodeposition of materials, structures, particles, devices, etc., generally called nano-objects, with dimensions below 100 nm commenced. Nano-objects are fundamental for nanoscience investigations and nanotechnology development. A nano-object is of particular interest if it has physical properties that differ from objects that have macroscopic sizes. Quantization of energy, for example, is observed in systems with greatly reduced size, such as atoms, molecules, and nanostructures.

Electrodeposition is an elegant and efficient technique for the production of nano-objects. Using the pulse deposition mode, it is possible to control the amount of atoms to be deposited with great precision. That is, pulsing with pulse durations of a few milliseconds to a few seconds, allows the deposition of clusters of atoms or layers with thickness of a few to hundreds of nanometers.

A typical example of an electrodeposited nanostructure is a multilayered structure. By having two salts in the electrolyte and applying two potentials in alternation, it is possible to deposit multilayer structures,

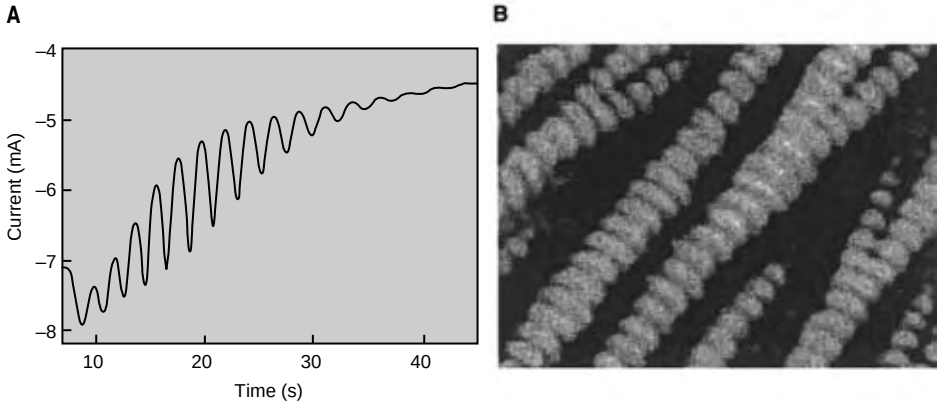

Fig. 13 (A) Spontaneous current oscillations during deposition at constant applied potential using an electrolyte containing Cu sulfate and lactic acid (Courtesy of R.G. Delatorre, Universidade Federal de Santa Catarina) and (B) SEM image of Cu/Cu_2O multilayered wires. (From Ref.[8].)

which are artificially fabricated materials that have application in the electronics industry. Fig. 11A shows the polarization curve for an electrolyte containing two salts, $CuSO_4$ and $CoSO_4$, where the reduction peaks of each metal are clearly seen. Pulsing the cathodic potential rapidly between a value at which only Cu is reduced, and one at which a Co-rich alloy is reduced, generates a deposit that is a Cu/Co multilayer with individual layers of nanometric thickness. The layer thickness may be controlled by integrating the current in real time and calculating the electrodeposited charge or, more simply, by controlling the deposition time. Fig. 11B shows typical current transients with characteristic peaks for each layer electrodeposited. The Co deposition current is much higher than the Cu one because to assure the deposition of a Co-rich alloy the concentration of Co sulfate in the electrolyte has to be much higher than the Cu sulfate concentration.

A multilayer structure with one of the repeating layers being a magnetic material is called magnetic multilayer. If the individual layers are only a few nanometers thick, which is easily achievable by electrodeposition, the electric resistance will vary with the magnetic field, an effect discovered very recently and known as giant-magnetoresistance (GMR).[3,4] The first observation of a magnetoresistive effect was by Lord Kelvin in 1857 by measuring the electrical resistance of magnetic alloys. Nowadays, the effect that he observed is called anisotropic magnetoresistance (AMR), and its magnitude does not exceed 6%. The GMR effect is about one order of magnitude greater than AMR and depends on many factors, such as the thickness and number of individual layers, the magnetic material used and the preparation method, and is observed also in non-layered granular structures. Magnetoresistive materials have been intensively used in the high-technology industry as magnetic sensors and reading heads for computer hard disk drives. Fig. 12A shows the magnetoresistance of a single layer of electrodeposited Co, similar to the one

depicted in Fig. 5, which shows an AMR effect of 0.5%. Fig. 12B illustrates the case of a magnetic multilayer, also electrodeposited, with the effect depending on the number of layers, reaching in this case a maximum of 8.5% for 15 Co/Cu layers.

An interesting achievement of electrodeposition in the preparation of nanostructures is the self-assembly of multilayers.[6] An electrolyte containing copper sulfate ($CuSO_4$) and lactic acid ($C_3H_6O_3$) is a standard example because under certain experimental conditions the cell current oscillates spontaneously leading to the growth of a nanometric Cu/Cu_2O multilayer. In Fig. 13A the spontaneous oscillations of the deposition current are illustrated, though a natural damping of the magnitude is observed. However, in stirred solutions the oscillatory behavior can be maintained for several days.[7] Fig. 13B shows a SEM image of filaments of spontaneously grown Cu/Cu_2O multilayers.[8]

The explanation for the spontaneous formation of multilayers lies in variations in the pH.[6,7,9] In the growth process, the electrodeposition of Cu_2O is favored, as it has an equilibrium potential more positive than that of Cu deposition (Table 1). However, the reaction $2Cu^{2+} + 2e^- + 2OH^- \leftrightarrow Cu_2O + H_2O$ depletes the OH^- species near the electrode, locally decreasing the pH and favoring the deposition of Cu. The above process is repeated, because the OH^- concentration is re-established during Cu^{2+} reduction.

Additionally, by having an experimental setup with a high-speed data acquisition system, it is possible to control deposition pulses with durations below milliseconds. This ultrafast pulsing method was called precision electrodeposition and allowed the deposition of sub-monolayer quantities of material.[10] Precision electrodeposition was demonstrated for the CuNi system, as shown in Fig. 14, where a sequence of ultrafast current pulses for the electrodeposition of a nanostructured CuNi alloy with a controlled composition of 48% Cu and 52% Ni is displayed. The duration of the pulses (tens of milliseconds), allows the deposition per cycle of 0.25 monolayer of Cu and 0.25 monolayer of Ni.

Nanowires

A special characteristic of electrodeposition is the fact the deposition occurs only where there is an electrical connection to the external circuit. This is a great advantage because it allows the deposition to be area selective. By covering the electrode surface with a patterned insulating layer, electrodeposition will occur only on the exposed areas. This makes electrodeposition an ideal method for growing materials on previously determined patterns and also for filling high-aspect ratio templates.

This advantage can be used for growing nanowires (wires with nanometric diameter). Nanoporous membranes that can be fabricated by the anodic oxidation of aluminum are appropriate templates. This process leads to the formation of an alumina layer with parallel nanopores, as shown in Fig. 15A, which can then be filled by electrodeposition. Fig. 15B shows a schematic view of a multilayer nanowire and Fig.15C a transmission electron microscopy image of a Cu/CuCoNi layered nanowire grown in the nanopores.

A different way to electrodeposit nanowires is by using the surface of a single crystal as a template. Fig. 16A shows an AFM image of a silicon surface, revealing large terraces with parallel steps. By electrodepositing Au at relatively low deposition rates, the steps act as deposition sites favoring the formation of wires of nanometric size along their edges, as shown in Fig. 16B.

CONCLUSIONS

Electrodeposition is a process widely used in industry. In this entry, emphasis was given to fundamental

aspects and to future potential applications of this technique.

Electronic Chemical Sensors

Chung-Chiun Liu
Electronics Design Center and Department of Chemical Engineering, Case Western Reserve University, Cleveland, Ohio, U.S.A.

INTRODUCTION

Sensor is a device that recognizes an event or a change, and then converts this recognition through a transduction mechanism, resulting in an indication of the event or the change. Chemical sensors recognize the molecular species of an analyte, and transmit a signal as an indicator that can be related to the molecular species qualitatively and/or quantitatively. This transmitted signal or indication can be a color change, an electrical signal, such as current or potential, or optical output. Chemical sensors have found extensive applications in process control, environmental monitoring, personal safety and security, as well as biomedical applications, and many others. Research and development of a chemical sensor involves various disciplines and special skills, and is truly a multi-disciplinary scientific endeavor. Chemists, engineers of different background, and material scientists are often working together in chemical sensor development. In recent years, the advancement of silicon based microfabrication processing provides a new means for the development of chemical and biological sensors. The importance, and scientific and commercial potentials, of the microfabricated chemical and biochemical sensors will continue to be appreciated in the years to come. One should also realize that most of the biological or biomedical sensors operate on principles of chemical sensors with a bio-molecule recognition step. Therefore, the impact of chemical sensor development to biological and biomedical sensors is direct and relevant.

In this entry, we focus on the discussion of the platform technology for electrochemical sensors, metal oxide semiconductive (MOS) sensors, and piezoelectric based quartz crystal microbalance (QCM) sensors. There are other types of chemical sensors, such as optical sensors, Schottky diode based sensors, calorimetric sensors, field-effect transistor (FET) based sensors, surface acoustic wave sensors, etc. Information of these specific sensors can be found elsewhere[1,2] and in current journals on sensor technologies. Because of the increasing importance of microfabricated sensors, a brief discussion of microsensors is also given.

TERMINOLOGY AND BACKGROUND

Potential applications of chemical sensors are diverse and numerous, and the environment where the sensor is used varies. Therefore, chemical sensor often requires to be tailor-made or semi-tailor-made to meet the needs in the special circumstance. For example, sensing of oxygen in an automobile exhaust or in water or in blood can be accomplished by using an electrochemical-based sensor. However, the selection of electrolyte and a diffusion-limited layer or protective membrane will be different in each case. Therefore, the platform chemical sensor technology is discussed in general. Special applications of a chemical sensor under a particular circumstance need to be addressed separately.

Differing from a typical analytical or sensing instrument, chemical sensors are relatively small in size, mobile or portable. If possible, chemical sensor should require minimum or no additional reagents, and also minimum sample transportation or preparation. For many applications, the possibility of producing the sensors at modest cost, and making disposable sensor a reality, is extremely attractive. This is particularly true in many biological and medical sensing applications.

The essential properties of a chemical sensor include the sensitivity, selectivity, response time, long-term stability, and others. Sensitivity defines the detecting range of the sensor, and it can be in the needs of parts per billion (ppb) or in high concentration percentage. Because the sensor is often employed in a complex environment, potential interference by the other species presented can lead to error in quantifying the analyte. The need to have a reasonable response time for a sensor can vary from a fraction of a second to minutes depending on the applications. The long-term stability is also an important consideration for a chemical sensor to have practical application. For example, the common carbon monoxide sensor for home safety should be operable for a year, if not years, with good long-term stability. There are properties of the sensor, such as temperature dependence, operable temperature range, and others, which can be crucial. Obviously, a specific application of a chemical sensor defines the requirements of its sensitivity, selectivity, response time, and others. Consequently, this leads to adaptation or

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007698

modification of a specific platform technology for the chemical sensor development.

ELECTROCHEMICAL SENSORS

An electrochemical sensor is generally an electrochemical cell containing two electrodes, an anode and a cathode, and an electrolyte. Electrochemical sensors in general are classified, based on the mode of its operation, and they are conductivity sensors potentiometric sensors, and voltammetric sensors. Amperometric sensors can be considered as a special type of voltammetric sensors. The fundamentals of these sensors' operational principles are described exceptionally well in several excellent electroanalytical books.[3–5] In this entry, only the essential features are included.

Conductivity Sensor

In an electrochemical cell, the conductivity is inversely related to the resistance in the electrolyte/test medium. The presence of certain chemical or ionic species may affect the resistance of the electrochemical cell. This change in resistance or conductivity can then be used to quantify the amount of the analyte presented. Molar and equivalent conductivities are commonly used to express the conductivity in an electrochemical cell. The conductivity measurement can be made relatively straightforward, using a DC mode or with a potential or current excitation. However, any faradaic or change transfer process occurring at the electrode surface will affect the conductivity measurement in an electrochemical cell. Furthermore, conductivity measurement in general does not provide sufficient specificity or sensitivity to quantify the analyte. This limits the use of conductivity of an electrochemical cell for sensing applications.

Potentiometric Sensor

Potentiometric sensor is based on a redox reaction that occurs at the electrode–electrolyte interface in an electrochemical cell. If a redox reaction $Ox + Ze \rightarrow Red$ takes place at an electrode surface, it is called a half-cell reaction. In the above reaction, Ox is the oxidant, Red is the reduced product, e in the electron, and Z is the number of electrons transferred in the reaction. At thermodynamic quasiequilibrium conditions, the Nernst equation is applicable and can be expressed as:

$$E = E^{\circ} + \frac{RT}{FZ} \ln \frac{[a_{ox}]}{[a_{red}]}$$

where E and E° are the electrode potential and electropotential at standard state, respectively, a_{ox} and a_{red} are the activities of Ox and Red, respectively, F is the Faraday constant, R is the gas constant, and T is the operating temperature in absolute scale. The Nernst equation shows that the electrode potential E can be used to quantify the ratio of the activities of oxidant and the reduced product. The equation also suggests that at ambient temperature, 298°K (25°C), and $Z = 1$, the slope of the linear relationship of E versus the $\ln([a_{ox}]/[a_{red}])$ is predictable with a value of 59.8 mV.

In a potentiometric sensor, two half-cell reactions will take place simultaneously. However, only one of the two half-cell reactions should involve the sensing species of interest, whereas the other half-cell reaction should be preferably reversible and non-interference. Thus, a reference electrode, such as Ag/AgCl, is often used for the other half-cell electrode. The redox reaction for the reference electrode is highly reversible in an appropriate sensing environment and does not contribute interference to the sensing half-cell reaction. The sensing electrode of a potentiometric sensor can be inert or active. An inert electrode provides a surface for the electron transfer or a catalytic surface for the reaction, and the electrode does not actively engage in the half-cell reaction. On the other hand, an active electrode can be either an ion donor or an acceptor in the sensing reaction. There are three common types of active electrodes and they are the metal/metal ion, the metal/insoluble metallic salt or oxide, and the metal/metal chelate electrode.

Potentiometric sensors using inert electrode have been applied as pH sensors and electrochemical gas sensors including oxygen sensors in liquid and gas phases. Noble metals, such as platinum and gold, graphite, and glassy carbon have been used. In the potentiometric oxygen sensor, the sensor operates as a concentration cell. In this cell, one half-cell is in contact with the test medium, which the oxygen concentration is to be sensed, and the other is exposed to a known oxygen concentration reference gaseous mixture. Potentiometric sensors with active electrodes include ion-selective electrode type sensors. The active electrode often incorporates a specific membrane that may have ion-selective, ion-permeable, or ion exchange properties. These membranes minimize possible interference from other ions and provide the specificity for the desired sensing ions.

Measurement of the cell potential of a potentiometric sensor should be carried out under zero-current or quasiequilibrium conditions. A high input impedance electrometer is commonly used. The advantage of potentiometric sensor is that the sensor output and the cell potential do not depend on the electrode surface area. This can make the manufacturing of practical sensors simpler. A major disadvantage of

potentiometric sensor is its limited sensitivity. The Nernst equation shows a linear relationship between the cell potential and the logarithmic value of the activity of sensing species. Thus, for practical application of any potentiometric sensor, its advantages and limitation should be carefully assessed.

Voltammetric Sensor

A voltammetric sensor is characterized by the current and potential relationship of an electrochemical cell. Voltammetric sensor utilizes the concentration effect on the current-potential relationship. This relationship depends on the rate by which the reactant (commonly the sensing species) is brought to the electrode surface (mass transfer) and the kinetics of the faradaic or charge transfer reaction at the electrode surface. In an electrochemical reaction, the interdependence between the reaction kinetics and the mass transfer processes establishes the concentration of the sensing species at the electrode surface relative to its bulk concentration and, hence, the rate of the faradaic process. This provides a basis for the operation of the voltammetric sensor.

Unfortunately, simultaneous analytical solution of the mass transfer and kinetic equations of an electrochemical cell is usually complex. Thus, the cell is usually operated with definitive hydrodynamic characteristics. Operational techniques, relating to controlling either the potential or the current, have been developed to simplify the analysis of the electrochemical cell. Description of these operational techniques and their corresponding mathematical analyses are well discussed elsewhere.[6,7]

For a voltammetric sensor, the current or potential peak shift that may relate to the concentration of the sensing species is an important measurement. In a dynamic situation in which polarization characteristics are obtained, it is essential that the mass transfer characteristics are reproducible for both calibration and actual measurements. In the case of a stationary planar sensor, stagnant solution or steady flow conditions in a flow cell provides good reproducibility. Or in another case, a sufficiently high concentration of an electrolyte is used to maintain a constant ohmic drop in the cell, regardless of the concentration of the pertinent sensing component. Under these conditions, the mass transfer can be purely diffusional and adequately described by Fick's law of diffusion.

The cell current, a measure of the rate of the faradaic process at an electrode, usually increases with an increase in the electrode potential. The cell current approaches a limiting value, when the rate of the faradaic process at the electrode surface equals the maximum possible mass transfer rate. Consequently, the cell is defined as mass transfer limited, and the cell current is defined as diffusional limited current, which can be used to quantify the sensing species presented. However, in many cases, the cell current does not tend to a limiting value with an increase in the electrode potential. This is because as the electrode potential increases, other faradaic or nonfaradaic processes may become active, and the cell current represents the cumulative rates of all the active electrochemical cell is complex, and the limiting current approach becomes ineffective. The increase in the electrode potential may accelerate the cell reaction to an extent that it would lead to a substantial decrease in the bulk concentration of the sensing ions. Under such conditions, the current will reach a maximum and then decrease with further increase of the potential. In this case, the sensor should not be operated under limiting current condition.

Amperometric sensors are considered to be a sub-class of voltammetric modes. In this case, the current-sensing species concentration relationship is obtained at a fixed electrode potential. At this fixed potential, the cell current can then be used to quantify the amount of the sensing species presented. In addition to amperometric mode of operation, other modes of voltammetric sensor operation include linear sweep and cyclic voltammetry. Linear sweep voltammetry involves increasing the imposed potential linearly at a constant scanning rate from an initial pre-set value to a given upper limited potential. Cyclic voltammetry is similar to the linear sweep potential with the exception that the electrode potential is returned to its initial value at the same scanning rated. The cathodic and anodic sweeps normally produce two current peaks, corresponding to the redox couple in the simplest form of a voltammogram. However, the characteristics of a voltammogram can be complex. The effects of the scanning rate, diffusional properties of the sensing species, operating temperatures can also contribute to the voltammogram and its interpretation, and consequently its assessment of the quantity of the sensing species.

Voltammetric sensors, including amperometric sensors, are very effective and applicable in many sensing circumstances, if it is properly applied. It is recognized that voltammetric sensor is an important sensing element in electrochemical sensors. With appropriate assessment of the needs, platform electrochemical sensor technologies, including voltammetric sensors, can be used to meet our specific needs in sensing technology.

METAL OXIDE SEMICONDUCTIVE SENSORS

Metal oxide semiconductive sensors are an important class of chemical sensors particularly for gaseous sensing. Among the metal oxide semiconductive materials,

tin oxide is most widely studied, and commercial sensors based on tin oxide have been available over the years. Metal oxides are general *n*-type semiconductive materials, and they can be used as chemical and gaseous sensors based on the change of the electronic conductivity, when the oxides are exposed to the gases. The intrinsic conductivity comes from the nonstoichiometric composition of the metal oxide. The oxygen vacancies act as donor defect. Oxygen may be either physisorbed or chemisorbed as charged species on the metal oxide surface. The chemisorbed oxygen may interact with the physisorbed oxygen or interact directly with gaseous oxygen. The chemisorbed oxygen ionic species are dioxygen O_2^- and mono-oxygen, O^-. These ionic species are presented at room temperature. With increasing temperatures, the O_2^- can dissociate from O^- and O^- becomes the dominant species at higher temperature. It is also recognized that O^- is more reactive than O_2^-. When a reducing gas, such as H_2 or CO, reacts with a metal oxide semiconductive material, the O^- and the O_2^- will react with the reducing gas releasing the electrons from the O^- and O_2^-. Consequently, the conductivity of the metal oxide will increase. The change in conductivity can then be used to quantify the reducing gas presented.

The seminal research by Taguchi[8] and Seiyama et al.[9] led to the successful commercialization of tin oxide based gas sensors. The tin oxide can be sintered, forming a disk, on which electrical conductivity metal contacts can be formed. The MOS can also be formed by other techniques, such as sputtering or sol–gel techniques.

Different electron conduction mechanisms of a MOS have been proposed including neck controlled (bulk trap and surface trap limited) conduction, and barrier controlled (barrier limited) conduction.[10] A better understanding of the conduction mechanisms will be helpful in developing more effective MOS based sensors.

Metal oxide semiconductive materials exhibit a relatively low conductivity at ambient temperature. Thus, it will be very difficult to observe a small conductivity change because of its reaction with a reducing gas. Therefore, it is common to operate a MOS based sensor at elevated temperature. At higher temperature, the conductivity of the MOS increases substantially, and a change caused by the reaction with reducing gas is now observable.

Metal oxide semiconductive sensors are not limited to tin oxide only. Many other metal oxides, such as zinc oxide, tungsten oxide, and others can also be used for chemical and gas sensing. It is understandable that an incorporation of a selective catalyst or a dopant may enhance the selectivity of the MOS sensors. Palladium, platinum, and others have been used as catalytic dopants for these sensors. The processes of incorporating the catalysts and dopants are many. For instance, the selected dopant may be in the form of a precursor adding into the sol–gel solution of the MOS material.

It is recognized that the particle size and the size distribution of the particles of MOS materials can affect directly to the sensor performance. It is also suggested that the grain boundaries of the particles provide the sites for the reaction between the sensing gas and the metal oxide. Therefore, a MOS film that can provide large number of grain boundary will be more sensitive. Hence, the possibility of using nanocrystalline MOS materials as sensing films offers opportunity of developing higher sensitivity MOS sensors.

QUARTZ CRYSTAL MICROBALANCE

Among piezoelectric based sensors, QCM represents a major device. A quartz crystal with a noncentrosymmetric space group will have a dipole associated with the orientation of the atoms. When under stress, the crystal exhibits a charge separation because of the displacement of its atoms. The converse effect has also been proven. It has been demonstrated that an applied alternating electric field will cause a vibration in a quartz crystal that in turn results in the generation of acoustic standing waves. Also, the crystal shows a tendency to vibrate at a characteristic resonant frequency.

Also, it has been observed that a mass adsorption at the surface of a quartz crystal will lead to a linear shift of the resonant frequency. Sauerbrey[11] provides a theoretical basis of this phenomenon, and this results in using quartz crystal as a microbalance. It shows a high degree of sensitivity and can detect a very small quantity of the adsorped mass. In more recent years, special coatings are applied to the surface of the quartz crystal. The coating will specifically and selectively adsorb a species resulting in the increase in mass on the QCM, serving as a sensing mechanism for the adsorbed species. This approach has been proposed by King,[12] and much research has also been directed to develop various organic and inorganic coatings for this application.

Practical QCM devices are AT-cut alpha quartz crystals that have excellent mechanical and piezoelectric properties. The AT-cut that is cut at a 35°15 angle from the *Z*-axis, is commonly used because of its minimal temperature effect.

Quartz crystal microbalance is operated in typical resonant frequencies ranging from 1 to 10 MHz, with most of them operating in 5–10 MHz. A typical QCM is a disk in the size of 10–16 mm in diameter with a thickness of approximately 0.15 mm. A thin metal film, gold, aluminum, or others, is deposited onto the surface of the quartz serving as electrodes. The metal

film electrode is approximately 3–10 mm in diameter with a thickness of about 1000–3000 Å.

In the use of a QCM as a sensor, oscillator circuits are the most common electrical interface. A frequency counter can then measure the frequency output from the oscillator, which is identical to the resonant frequency of the quartz crystal. There are two general classifications for the oscillator circuits operation in series resonance and operation in parallel resonance. The performance of these circuits and the choice of the proper circuit are discussed extensively elsewhere.

Quartz crystal micro balance shows promise in its applications for chemical sensing. A proper and selective coating on the surface of a QCM can be used to selectively absorb a chemical species. The mass of the absorbed species, even in very minute quantity, can be used to quantify the species present. It is an effective means for chemical sensing under appropriate circumstance.

CONCLUSIONS

As mentioned, in addition to these described technologies for chemical sensor, there are other basic technologies that can be used for chemical sensing. It would not be feasible to describe each of these technologies, and researchers are encouraged to first carefully assess the needs of the desired chemical sensor, and then choose the potentially applicable platform technology.

In recent years, silicon based microfabrication and micromachining technology provide a new venue for the manufacturing of micro sized chemical sensors. This leads to new applications of chemical sensors in various scientific and commercial endeavors. Details of the microfabrication technologies are given elsewhere in this encyclopedia and references in microelectronic processing. Micro fabricated chemical sensors can be produced in geometrically well-defined highly uniform structure and at a modest cost. This can be important, for instance, for amperometric sensors that require uniform and reproducible electrode surface structure. The modest cost permits the sensor to be disposable. Micro chemical sensors can also be fabricated into an array, making multiple sensing feasible. Micro chemical sensor arrays will find increasing usage in various fields in the years to come.

Electroplating

Helen H. Lou
Department of Chemical Engineering, Lamar University, Beaumont, Texas, U.S.A.

Yinlun Huang
Department of Chemical Engineering and Materials Science, Wayne State University, Detroit, Michigan, U.S.A.

INTRODUCTION

Electroplating is an electrodeposition process for producing a dense, uniform, and adherent coating, usually of metal or alloys, upon a surface by the act of electric current.[1] The coating produced is usually for decorative and/or protective purposes, or enhancing specific properties of the surface. The surface can be conductors, such as metal, or nonconductors, such as plastics. Electroplating products are widely used for many industries, such as automobile, ship, air space, machinery, electronics, jewelry, defense, and toy industries. The core part of the electroplating process is the electrolytic cell (electroplating unit). In the electrolytic cell (electroplating unit) a current is passed through a bath containing electrolyte, the anode, and the cathode. In industrial production, pretreatment and posttreatment steps are usually needed as well.

BACKGROUND

The workpiece to be plated is the cathode (negative terminal). The anode, however, can be one of the two types: sacrificial anode (dissolvable anode) and permanent anode (inert anode).[2] The sacrificial anodes are made of the metal that is to be deposited. The permanent anodes can only complete the electrical circuit, but cannot provide a source of fresh metal to replace what has been removed from the solution by deposition at the cathode. Platinum and carbon are usually used as inert anodes.

Electrolyte is the electrical conductor in which current is carried by ions rather than by free electrons (as in a metal). Electrolyte completes an electric circuit between two electrodes. Upon application of electric current, the positive ions in the electrolyte will move toward the cathode and the negatively charged ions toward the anode. This migration of ions through the electrolyte constitutes the electric current in that part of the circuit. The migration of electrons into the anode through the wiring and an electric generator and then back to the cathode constitutes the current in the external circuit. The metallic ions of the salt in the electrolyte carry a positive charge and are thus attracted to the cathode. When they reach the negatively charged workpiece, it provides electrons to reduce those positively charged ions to metallic form, and then the metal atoms will be deposited onto the surface of the negatively charged workpiece.

Fig. 1 illustrates a typical plating unit for plating copper from a solution of the metal salt copper sulfate ($CuSO_4$). The cathode, which is the workpiece to be plated, is charged negatively. Some of the electrons from the cathode bar transfer to the positively charged copper ions (Cu^{2+}), setting them free as atoms of copper metal. These copper atoms take their place on the cathode surface and copper plate it. Concurrently, the same number of sulfate ions $SO_4^{2-}$is discharged on the copper anodes, thereby completing the electrical circuit. In so doing, they form a new quantity of copper sulfate that dissolves in the solution and restores it to its original composition. This procedure is typical of ordinary electroplating processes with sacrificial anodes; the current deposits a given amount of metal on the cathode and the anode dissolves to the same extent (of the same electrical charge), maintaining the solution more or less uniformly.

ELECTROCHEMISTRY FUNDAMENTALS

When a direct electric current passes through an electrolyte, chemical reactions take place at the contacts between the circuit and the solution. This process is called electrolysis. Electrolysis takes place in an electrolytic cell. Electroplating is one specific type of electrolysis. Besides electroplating, electrolysis has also been widely used for preparation of halogens and notably chlorine, and refining of metals, such as copper and zinc. Understanding the electrochemical principles of electrodeposition is essential to the development of electroplating technologies. Some basic concepts are presented below.[3]

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007747

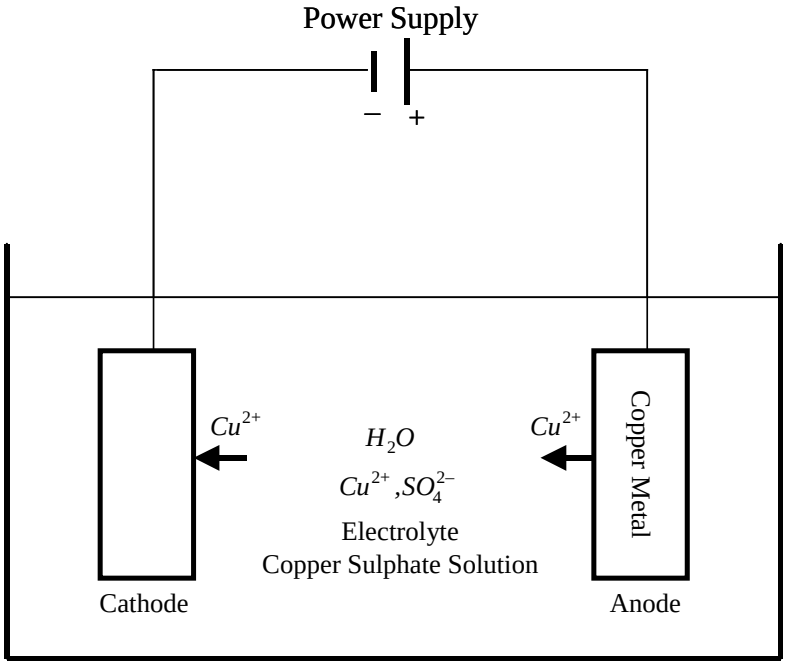

Fig. 1 Principle of electroplating.

Oxidation/Reduction

In a wider sense, all electron-transfer reactions are considered oxidation/reduction. The substance gaining electrons (oxidizing agent, or oxidant) oxidizes the substance that is losing electrons (reducing agent, or reductant). In the process, the oxidizing agent is itself reduced by the reducing agent. Consequently, the reduction process is sometimes called electronation, and the oxidation process is called ''de-electronation.'' Because a cathode is attached to the negative pole of the electric source, it supplies electrons to the electrolyte. On the contrary, an anode is connected to the positive pole of the electric source; therefore, it accepts electrons from the electrolyte. Various reactions take place at the electrodes during electrolysis. In general, reduction takes place at the cathode, and oxidation takes place at the anode.

Anode and Cathode Reactions

Electrodeposition or electrochemical deposition (of metals or alloys) involves the reduction of metal ions from electrolytes. At the cathode, electrons are supplied to cations, which migrate to the anode. In its simplest form, the reaction in aqueous medium at the cathode follows the equation:

$$M^{n+} + ne^- \rightarrow M \quad (1)$$

with a corresponding anode reaction. At the anode, electrons are supplied to the anions, which migrate to the anode. The anode material can be either a sacrificial anode or an inert anode. For the sacrificial anode, the anode reaction is:

$$M \rightarrow M^{n+} + ne^- \quad (2)$$

In this case, the electrode reaction is electrodissolution that continuously supplies the metal ions.

Faraday's Laws of Electrolysis

In 1833, the English scientist, Michael Faraday, developed Faraday's laws of electrolysis. Faraday's first law of electrolysis and Faraday's second law of electrolysis state that the amount of a material deposited on an electrode is proportional to the amount of electricity used. The amount of different substances liberated by a given quantity of electricity is proportional to their electrochemical equivalent (or chemical equivalent weight).

In the SI system, the unit quantity of electricity charge and the unit of electric charge are coulomb (C); one coulomb is equivalent to one ampere flowing for one second ($1\,C = 1\,A \cdot sec$). The electrochemical equivalent of an element is its atomic weight divided by the valence change involved in the reaction. For example, for the reaction, $Fe^{2+} \rightarrow Fe^0$, the valence change is 2, and the electrochemical equivalent of iron is $55.85/2 = 27.925$ in this reaction. Depending on the specific reaction, one element may have different equivalent weights, although it has only one atomic weight.

In detail, to reduce one mole of a given metal from a metal ion with the valence charge of $n+$, n moles of electrons are required. That is, the total cathodic charge used in the deposition, Q(C), is the product of the number of gram moles of the metal deposited, m, the number of electrons taking part in the reduction, n, Avogadro's number, N_a (the number of atoms in a mole), and the electrical charge per electron, Q_e(C). Thus, the following equation gives the charge required to reduce m moles of metal:

$$Q = mnN_aQ_e \tag{3}$$

The product of the last two terms in Eq. (3) is the Faraday constant, F. Therefore, the number of moles of the metal reduced by charge Q can be obtained as:

$$m = \frac{Q}{nF} \tag{4}$$

The Faraday constant represents the amount of electric charge carried by 1 mol, or the Avogadro's number of electrons. The Faraday constant can be derived by dividing Avogadro's number, or the number of electrons per mole, by the number of electrons per coulomb. The former is approximately equal to 6.02×10^{23} and the latter is approximately 6.24×10^{18}. Therefore,

$$F = \frac{(6.02 \times 10^{23})}{(6.24 \times 10^{18})} = 9.65 \times 10^4\,\mathrm{C/mol} \tag{5}$$

On the other hand, the total charge used in the deposition can be obtained as the product of the current, I(A), and the time of deposition, t(sec), if the deposition current is held constant. Or, if the current varies during the deposition,

$$Q = \int I\,\mathrm{d}t \tag{6}$$

The weight of the deposit, W(g), thus can be obtained by multiplying the number of moles of metal reduced with the atomic weight, M_w, of the deposited metal:

$$W = \frac{M_w}{nF}\int I\,\mathrm{d}t \tag{7}$$

Ideally, the deposition thickness, δ (cm), can be solved by:

$$\delta = \frac{W}{\rho A} = \frac{M_w}{nF\rho A}\int I\,\mathrm{d}t \tag{8}$$

where ρ is the density of the metal (g/cm^3) and A is the area of deposition (cm^2).

Current Efficiency, Current Density, and Current Distribution

Faraday's laws give theoretical prediction of electrodeposition in an ideal situation. In a real application, many factors influence the coating quantity and quality.[4]

Current efficiency

It is stated in Faraday's laws that the amount of chemical charge at an electrode is exactly proportional to the total quantity of electricity passing. However, if several reactions take place simultaneously at the electrode, side reactions may consume the product. Therefore, inefficiencies may arise from the side reactions other than the intended reaction taking place at the electrodes. Current efficiency is a fraction, usually expressed as a percentage, of the current passing through an electrolytic cell (or an electrode) that accomplishes the desired chemical reaction. Or,

$$\text{Current efficiency} = 100 \times W_{Act}/W_{Theo} \tag{9}$$

where W_{Act} is the weight of metal deposited or dissolved, and W_{Theo} is the corresponding weight to be expected from Faraday's laws [Eq. (7)] if there is no side reaction. Note that the cathode efficiency is the current efficiency applied to the cathode reaction, and the anode efficiency is the current efficiency applied to the anode reaction.

Current density

Current density is defined as current in amperes per unit area of the electrode. It is a very important variable in electroplating operations. It affects the character of the deposit and its distribution.

Current distribution

The local current density on an electrode is a function of the position on the electrode surface. The current distribution over an electrode surface is complicated. Current will tend to concentrate at edges and points, and unless the resistance of the solution is very low, it will flow to the workpieces near the opposite electrode more readily than to the more distant workpieces. It is desired to operate processes with uniform current distribution. That is, the current density is the same at all points on the electrode surface.

Potential Relationships

In electroplating, sufficient voltage should be provided by the power source. The voltage–current relationship

follows Ohm's law. The concepts of electrode potentials, equilibrium electrode potential, overpotential, and overvoltage are of fundamental importance.

The voltage–current relationship: Ohm's law

The current is driven by a potential difference, or voltage through the conducting medium, either electrolytic or metallic. The voltage necessary to force a given current through a conductor is given by Ohm's law:

$$E = IR \tag{10}$$

where E is the e.m.f (electromotive force) volts (V) and R the resistance of the conductor (Ω).

Electrode potentials

The electrode potential is the electrical potential difference between an electrode and a reference electrode. The absolute potential of an electrode is not directly measurable. Therefore, the electrode potential must always be referred to an arbitrary zero point that is defined by the potential of the reference electrode.

Equilibrium electrode potential

When a metal is immersed into a solution containing ions of that metal, equilibrium is set up between the tendency of the metal to enter solution as ions and the opposing tendency of the ions to lose their charge and deposit on or in the metal.

$$\mathrm{M} \leftrightarrow \mathrm{M}^{n+} + n\mathrm{e}^{-} \tag{11}$$

Depending on the conditions of the system, this can occur in either direction. At equilibrium, the driving forces for metal ions being discharged and metal atoms being ionized are equal. The potential difference between the metal and the solution phases under these conditions is the equilibrium potential difference.

The equilibrium electrode potential is the electrical potential of an electrode measured against a reference electrode when there is no current flowing through the electrode. It is also called open circuit potential (OCP). The equilibrium potential between a metal and a solution of its ions is given by the Nernst equation as follows:

$$E = E^0 + \frac{RT}{nF} \ln a \tag{12}$$

where E^0 is the standard electrode potential, which is a constant characteristic of the material of the electrode; R the gas constant ($8.3143\,\mathrm{J/k \cdot mol}$); T the absolute temperature (K); F the Faraday constant; n the valence change; a the activity of the metal ion. In approximation, the concentration of the metal ion can be used instead of the activity.

If numerical values are substituted for R and F, and T is at 25°C (298 K), and base 10 logarithm is used instead of base e, the Nernst equation can be expressed as:

$$E = E^0 + \frac{0.059}{n} \log a \tag{13}$$

In the above equation, if $a = 1$, then $E = E^0$. The standard potential of an electrode E^0 is the potential of an electrode in contact with a solution of its ions of unit activity. The standard potentials are always expressed against the standard hydrogen electrode (SHE), the potential of which is zero by definition. The standard potentials are a function of temperature; they are usually tabulated for 25°C. Standard electrode potential is also called normal electrode potential.

Overpotential and overvoltage

The equilibrium is dynamic with metal ions being discharged and metal atoms being ionized, but these two effects cancel each other and there is no net change in the system. For the realization of metal deposition at the cathode and metal dissolution at the anode, the system must be moved away from the equilibrium condition. An external potential must be provided for the useful electrode reactions to take place at a practical rate; this external potential may have several causes.

Overpotential is the difference in the electrode potential of an electrode between its equilibrium potential and its operating potential when a current is flowing. The overpotential represents the extra energy needed to force the electrode reaction to proceed at a required rate (or its equivalent current density). Consequently, the operating potential of an anode is always more positive than its equilibrium potential, while the operating potential of a cathode is always more negative than its equilibrium potential. The overpotential increases with increasing current density. The value of the overpotential also depends on the inherent speed of the electrode reaction. A slow reaction (with small exchange current density) will require a larger overpotential for a given current density than a fast reaction (with large exchange current density). Overpotential is also referred to as polarization of the electrode.

An electrode reaction always occurs in more than one elementary step, and there is an overpotential associated with each step. Even for the simplest case, the overpotential is the sum of the concentration overpotential and the activation overpotential.

Overvoltage is the difference between the cell voltage (with a current flowing) and the open-circuit voltage (OCV). The overvoltage represents the extra energy needed to force the cell reaction to proceed at a required rate. Consequently, the cell voltage of an electrolytic cell is always more than its OCV, while the cell voltage of a galvanic cell (e.g., a rechargeable battery during discharging) is always less than its OCV. Occasionally, it is also referred to as polarization of the cell.

The overvoltage is the sum of the overpotentials of the two electrodes of the cell and the ohmic loss of the cell. Unfortunately, the terms overvoltage and overpotential are sometimes used interchangeably.

SURFACE PREPARATION

Workpieces to be plated may be put through a variety of pretreating processes, including surface cleaning, surface modification, and rinsing.[4] A schematic flowsheet of a typical electroplating plant, including surface treatment and waste treatment, is depicted in Fig. 2.

The purpose of surface pretreatment is to remove contaminants, such as dust and films, from the substrate surface. The surface contamination can be extrinsic, composed of organic debris and mineral dust from the environment or preceding processes. It can also be intrinsic, such as a native oxide layer. Contaminants and films interfere with bonding, which can cause poor adhesion and even prevent deposition. Therefore, surface pretreatment is important to ensure plating quality. Most (metal) surface treatment operations have three basic steps: surface cleaning, surface treatment, and rinsing.

Surface Cleaning

Cleaning methods should be able to minimize substrate damage while removing the contaminants, dust, film, and/or debris. Cleaning processes are based on two approaches: chemical approach and mechanical approach.

Chemical approaches

A chemical approach usually includes solvent degreasing, alkaline cleaning, (soak cleaning), and acid cleaning (acid pickling).

Solvent Degreasing. Contaminants consist of oils and grease of various types, waxes, and miscellaneous organic materials. These contaminants can be removed by appropriate organic solvents, either by dipping the workpieces in the solvent or by vapor decreasing.

Alkaline Cleaning. Workpieces are immersed in tanks of hot alkaline cleaning solutions to remove dirt and solid soil. A special type of alkaline cleaning is electrocleaning. In electrocleaning, the workpiece can be either the cathode (namely direct cleaning) or the anode (reverse cleaning). Electrocleaning adds to the chemical action of the cleaner the mechanical action caused by plentiful gas evolution at the surface of the workpiece.

Acid Cleaning. Acid cleaning can move heavy scale, heat-treat scale, oxide, and the like. The most commonly used acids include sulfuric and hydrochloric. Pickling can also be combined with current to be more effective.

Mechanical approaches

Mechanical preparations include polishing, buffing, and some variations. Polishing is to remove small amounts of metal by means of abrasives. It produces a surface that is free of the larger imperfections left by grinding, and is a preliminary to buffing. Buffing is similar to polishing, but uses finer abrasives to remove very little metal. Buffing can produce an extremely smooth surface.

Surface Modification

Surface modification includes change in surface attributes, such as application of (metal) layer(s) and/or hardening.

Rinsing

In wet plating, when workpieces are transferred from one treating solution to another, or when they leave the final treating solution, they carry some of the solution in which it has been immersed. This solution is called drag-out. In most cases, this residue solution should be removed from the workpieces surface by rinsing before the workpieces enter the next step in sequence, or come out of the final processing solution. The dirty rinse water will be sent to the wastewater treatment facilities before being discharged to a public sewage system.

ELECTROLYTIC METAL DEPOSITION

There are three types of electrolytic metal deposition processes: direct current electrodeposition, pulse plating, and laser-induced metal deposition.[2]

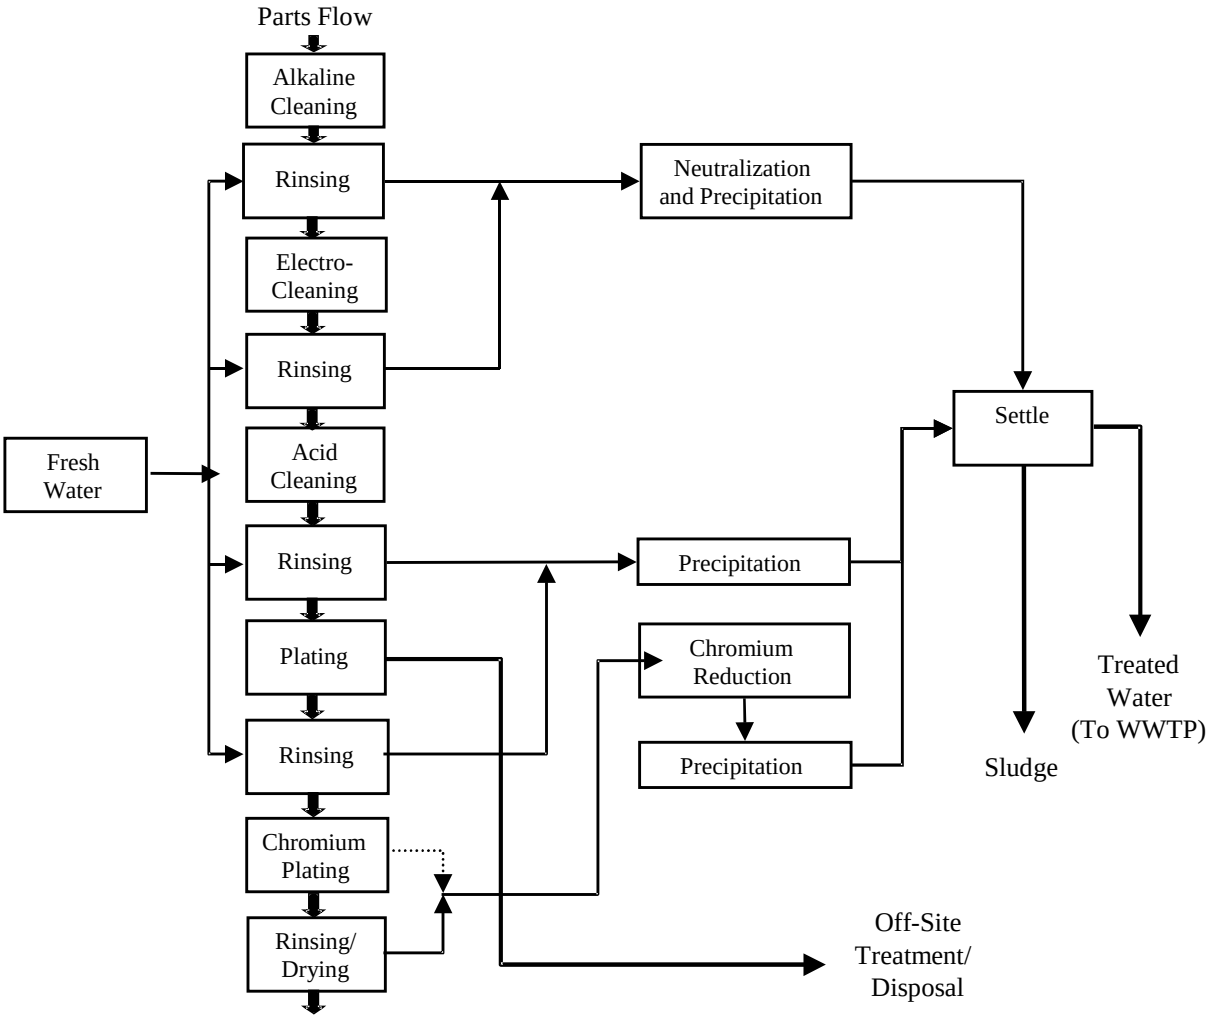

Fig. 2 Process flowsheet of a typical electroplating plant.

Direct Current Electrodeposition

In the direct current (DC) electrodeposition, the current source is a DC power source. A power source in the form of a battery or rectifier (which converts alternating current electricity to regulated low-voltage DC current) provides the necessary current.

Electroplating is performed in a plating unit. Electrodes, immersed in the electroplating bath (electrolyte), are connected to the output of a DC current source. The workpiece that is to be plated acts as a negatively charged cathode. The positively charged anode(s) completes the electric circuit. This type of circuit arrangement directs electrons (negative charge carriers) into a path from the power supply (rectifier) to the cathode (the workpiece to be plated).

The geometric shape and contour of a workpiece to be plated affect the thickness of the deposited layer. In general, workpieces with sharp corners and features will tend to have thicker deposits on the outside corners and thinner ones in the recessed areas. The cause of this difference in the resulting layer thickness is that the DC current flows more densely to sharp edges than to the less accessible recessed areas. In other words, the current distribution is not uniform. Therefore, a judicial placement of the anode(s) as well as modifications of the current density are required to overcome the thickness irregularity effects.

Pulse Plating

Electrodeposition using pulsed currents is known as pulse plating. The pulsed currents can be unipolar (on–off) or bipolar (current reversal). Pulses can be used along or be superimposed on a DC feed. By using the bipolar pulse, metal deposition occurs in the cathodic pulse period, with a limited amount of metal being

redissolved in the anodic period. This repeated deposition and partial redissolution could improve the morphology and the physical properties of the deposit.

Laser-Induced Metal Deposition

In laser-induced metal deposition, a focused laser beam is used to accelerate the metal deposition. Experiments have shown that the deposition rate can be increased by 1000 times. The plating equipment mainly consists of a laser head with focusing optics and the electrolytic cell. The focused laser beam can pass through a hole in the anode through the electrolyte and impinge on the cathode surfaces.

ELECTROLYTE

Different metals may need different types of electrolyte. The composition and properties of the electrolyte is very important for the coating quality.

Types and Components

Types of electrolytes include water solutions of acids, bases, or metal salts, certain pure liquids, and molten salts. Gases may act as electrolytes under conditions of high temperature or low pressure. In addition to metal salts, electrodeposition electrolytes usually contain a number of additives for various purposes. Some agents are used to increase electrolyte conductivity (supporting electolytes). Others may be used for increasing bath stability (stabilizers), activating the surface (surfactants or wetting agents), improving leveling or metal distribution (leveling agents), or optimizing the chemical, physical, or technology properties of the coating. These coating properties include corrosion resistance, brightness or reflectivity, hardness, mechanical strength, ductility, internal stress, wear resistance, or solderability.[2]

Properties of Electrolyte

The properties of electrolyte are usually characterized by electrolytic conductance, covering power, macrothrowing power, and microthrowing power.[4]

Electrolytic Conductance

Electrolytic conductance is different from electrical conductance in metal. Electronic conductance is called a ''Class I'' conductor, while electrolytic conductance is a ''Class II'' conductor. Both inorganic and organic salts, acids or alkalis can be used to increase the electrolytic conductance. The conductivity of an electrolyte is a function of the degree of dissociation, the mobility of the individual ions, the temperature and viscosity, and the electrolyte composition.

Covering Power

Covering power describes the extent to which an electrodeposition electrolyte can cover the entire surface of a workpiece being plated, with reasonable uniform thickness. Covering power is influenced by the nature of the substrate surface, the electrolyte composition, the temperature and viscosity, and the current density.

Macrothrowing Power

Macrothrowing power predicts the ability of an electrolyte to lay down as nearly as possible a uniformly thick deposit across the surface of a workpiece. A good covering power is a prerequisite for good macrothrowing power. Other factors that affect macrothrowing power include the current distribution and current density, electrolyte composition, electrolytic conductance, and electrolyte agitation.

Microthrowing Power

Microthrowing power indicates the extent to which metal electrodeposition occurs at the outer plane of the substrate or at the base of valleys or cracks. Microthrowing power can be improved by activating the surfaces at the base of valleys or cracks to promote electrodeposition there, while inhibiting the outer surfaces by using inhibitors preferentially. In many cases, microthrowing power is inversely related to macrothrowing power.

TYPES OF ELECTROPLATING PROCESSES

Depending on the size and geometry of the workpieces to be plated, different plating processes, including mass plating, rack plating, continuous plating, and in-line plating, may be adopted.[2]

Mass Plating

Mass plating is used for small workpieces to be plated in large quantities, such as nuts and bolts, but it is not used for delicate workpieces. The most widely used mass plating system is called barrel plating, where the workpieces are loaded into a plating barrel. Other mass plating containers include plating bells and vibratory units.

Rack Plating

Some workpieces cannot be mass plated because of their size, shape, or special features. Rack plating means workpieces are mounted on a rack for the appropriate pretreatment plating and posttreatments. Racks are fixtures suitable for immersion in the plating solution. Rack plating is sometimes called batch plating.

Continuous Plating

Continuous plating means the workpieces to be plated move continuously passing either one row or between two rows of anodes. Continuous plating is usually used for a workpiece of simple and uniform geometry, such as metal strip, wire, and tube.

In-Line Plating

In-line plating is used to integrate the plating and finishing processes into a main production line. The benefit of in-line plating includes exclusion of pretreatment steps and a significant reduction in material, chemical and energy consumption, and waste discharge.

TYPES OF METAL COATINGS

Plating metals can be roughly classified into the following categories with the typical applications.[4]

Sacrificial Coatings

Sacrificial coatings are primarily used for the protection of the base metal, usually iron and steel. Another name for sacrificial coating is anodic coating, because the metal coatings are anodic to the substrate metal, so the coatings sacrifice themselves to protect the base metal from corrosion. Zinc (Zn) and cadmium (Cd) coatings can be used as sacrificial coatings. Because of high toxicity, cadmium plating is now forbidden by law in many countries.

Decorative Protective Coatings

Decorative protective coatings are primarily used for adding an attractive appearance to some protective qualities. Metals in this category include copper (Cu), nickle (Ni), chromium (Cr), zinc (Zn), and tin (Sn).

Engineering Coatings

Engineering coatings (sometimes called functional coatings) are used for enhancing specific properties of the surface, such as solderability, wear resistance, reflectivity, and conductivity. Metals for engineering purpose include precious gold (Au) and silver (Ag), six platinum metals, tin, and lead (Pb). The six platinum metals are ruthenium (Ru), rhodium (Rh), palladium (Pd), osmium (Os), iridium (Ir), and platinum (Pt). These six metals are noble, i.e., with positive electrode potentials and they are relatively inert.

Minor Metal Coating

Minor metals here refer to iron (Fe), cobalt (Co), and indium (In). They are easily plated but have limited applications in electroplating.

Unusual Metal Coating

The unusual metals are rarely electroplated and can be divided into the following categories: 1) easily platable from aqueous solutions but not widely used, such as arsenic (As), antimony (Sb), bismuth (Bi), manganese (Mn), and rhenium (Re); 2) platable from organic electrolyte but not aqueous electrolyte, such as aluminum (Al); and 3) platable from fused-salt electrolyte but not aqueous electrolyte, including refractory metals (named because of their relatively high melting points), such as titanium (Ti), zirconium (Zr), hafnium (Hf), vanadium (V), niobium (Nb), tantalum (Ta), molybdenum (Mo), and tungsten (W). The periodic table in Fig. 3 shows that the metals that can be electrodeposited from aqueous solutions are those inside the frame.

Alloy Coatings

An alloy is a substance that has metallic properties and is composed of two or more chemical elements, at least one of which is a metal. The elements composing the alloy are not distinguishable by the unaided eye. Examples of alloy coating include gold–copper–cadmium, zinc–cobalt, zinc–iron, zinc–nickle, brass (an alloy of copper and zinc), bronze (copper–tin), tin–zinc, tin–nickle, and tin–cobalt. Alloy coatings are produced by plating two metals from the same solution.

Multilayered Coatings

Multilayered coatings are produced by plating different metals from the same solution at different potentials. A pulse train-shaped potential is enforced, resulting in the multilayer deposition. For example, multilayered coatings based on copper, nickle, chromium, in that order, can be applied to either metal or plastic components for visual appearance, corrosion and wear resistance, and weight saving.

Composite Coatings

Composite materials can be defined as coatings consisting of minute second-phase particles dispersed throughout a metal matrix. The size of the second phase particles may range from 10 μm down to nanoscale and the particles can be inorganic, organic, or occasionally metallic. The presence of fine particles in a metal matrix generally improves its mechanical and chemical properties, resulting in a wide range of applications. Composite coatings with an electrodeposited metal matrix and nonmetallic inclusions have excellent wear resistance and permit emergency dry running of machinery.

Conversion Coatings

Conversion coatings are formed by a reaction of the metal on the surface of the substrate with a solution.[5] For example, chromate coatings are formed by the reaction of water solutions of chromic acid or chromium salts. The chromate coatings can be applied to aluminum, zinc, cadmium, and magnesium. The coatings usually have good atmospheric corrosion resistance. Chromate coatings are widely used in protecting common household products, such as screws, hinges, and many hardware items with the yellow-brown appearance.

Anodized Coatings

Anodizing is produced by electrochemical conversion. In an anodizing process, the metal workpiece to be plated is the anode in a suitable electrolyte. With the electric current passing through the electrolyte, the metal surface is converted to a form of its oxide. An anodizing process is usually used on aluminum for protection and cosmetic purposes. The electrolyte provides oxygen ions that react with metal ions to form the oxide, and hydrogen is released at the metal or carbon cathode. Anodizing differs from electroplating in two aspects. In electroplating, the workpiece to be plated

is the cathode, and the metallic coatings are deposited on the workpiece. In anodizing, the workpiece is the anode, and its surface is converted to a form of its oxide.

RELATED PROCESSES

The related processes for metal deposition include electroless deposition, immersion plating, and electroforming.[4] They follow the basic principles of electrochemistry.

Electroless Deposition (Autocatalytic Plating)

A special type of electroplating is called electroless deposition, autocatalytic plating, or ''chemical deposition.'' In electroless plating, there is no external power source. The deposited metal is reduced from its ionic state in solution by a chemical reducing agent. The reducing agent supplies the electrons for the following reaction:

$$M^{n+} + ne^{-} \rightarrow M \quad (14)$$

This reaction takes place only on a catalytic surface. Therefore, once deposition is initiated, the metal deposited must itself be catalytic for the deposition to continue.

Not all metals can be plated autocatalytically. The reducing agents are usually more expensive electron sources as compared with the electric current. The major advantages of electroless deposition are as follows:

1. It can be used to deposit metal on nonconductive surfaces, such as plastics, glass, or ceramics. Some proper pretreatment steps are needed to activate these surfaces. The metallizing of printed circuit board is one such example.
2. The throwing power is perfect. Deposits are laid down on the surface with no excess buildup on projections or edges.

Immersion Plating

Immersion plating is the deposition of a metallic coating on a substrate by chemical replacement from a solution of salt of the coating metal. It requires no electric circuitry or source of power, but it differs from autocatalytic plating in not requiring a chemical reducing agent to reduce the metal ions to metal. Immersion deposition stops when the substrate is completely covered by a layer of coating.

The major advantages of immersion plating include simplicity, minor capital expense, and the ability to deposit in recesses and on the inside of the tubing. But, the applicability of immersion plating is limited.

Electroforming

Electroforming is to produce or reproduce a metal workpiece by electrodeposition in a plating bath over a base form (mold) or mandrel, which is subsequently removed. In some cases, the mandrel or mold may remain within the finished metal workpiece. A mandrel is a form used as a cathode in electroplating.

The advantage of the process is that it faithfully reproduces a form of mandrel exactly, to within one micrometer, without shrinkage and distortion associated with other metal forming techniques, such as casting, stamping, and drawing. Because the mandrel is machined as an outside surface, close dimensional tolerances and high surface finishes can be held and maintained on complex interior configurations. The disadvantage of electroforming includes slow production, relatively high cost, design limitations of the geometry, and the separation of workpieces from the mold or mandrel.

CONCLUSIONS

The electroplating industry has been experiencing continuous innovations and also facing significant challenges from economic and environmental perspectives. The purpose of electroplating is to produce a qualified coating with the desirable attributes. Based on the specifications of the coating and the substrate, one may select a specific electroplating process for a given application.

Electrostatic Precipitation

Kenneth R. Parker
Ken Parker Consultant APC, West Midlands, U.K.

INTRODUCTION

Although electrostatic precipitators have been employed almost for a century to remove particulates, fumes, and mists from a wide range of industrial processes, the main approach for assessing the size and design of a new plant has been based on measurements from units operating under similar conditions. Recent developments using computerized fluid dynamics approaches have enabled the physics to be theoretically studied in greater detail, which leads to an improved understanding of precipitation. In this entry, the precipitator operation is reviewed from theoretical and practical aspects and some of the gas and particulate characteristics, which have to be considered when designing a precipitator for a specific duty, have been indicated. While it is mainly used currently for pollution control purposes, where efficiencies of 99.8%+ are required to comply with emission legislation, the precipitator can be used for the recovery of valuable materials, cleaning process gases for subsequent reuse, air cleaning duties, and the cleaning of process oil streams. The recent issue by the EPA of the ESPVI Series 4W precipitator program enables power station precipitators to be proactively studied to speedily evaluate low-cost enhancement scenarios for precipitators that require upgrading to meet more stringent emission regulations.

BACKGROUND

Electrostatic precipitators have been used commercially for almost a century for the collection of particulates present in the gas streams on many industrial processes. The early plants were installed to recover valuable material that, otherwise, would have been lost to atmosphere, rather than in preventing atmospheric pollution. These plants, mainly in the sulfuric acid, bullion, and nonferrous smelting industries, were designed and priced to produce a commercial ''pay back'' in the order of 3–5 years. In recent years, with the increasing awareness and worldwide recognition of the problems associated with atmospheric pollution, most industrialized nations have enacted legislation to limit emissions from all sources. This legislation is continuously reviewed and is becoming steadily more stringent, such that, in general, particulate emissions are presently controlled to a maximum of $50\,mg/Nm^3$ for inert materials and a maximum of $10\,mg/Nm^3$ for substances that are considered hazardous to health.

The features of the electrostatic precipitation process that make it an ideal vehicle for the removal of particulates are

1. Versatility and effective performance on a wide range of industrial processes. Can be designed to satisfy any required efficiency and gas flow rate.
2. Designs can be produced to cover a temperature range from ambient up to 850°C.
3. Can collect particles over the complete size range spectrum.
4. Material is usually recovered in its original state. (Plants can be designed to operate as a wet phase device if required.)
5. Low pressure loss; typically less that 1 mbar.
6. Acceptable electrical power consumption for required efficiency level.
7. Robust and reliable construction and a life expectancy of more than 20 years.
8. Low maintenance requirements.

BASIC OPERATING PRINCIPLES

The basic principle of operation is that the particulates are passed through an electric field where they initially receive an electric charge to become charged particles and are deflected across the field to be retained on the counter electrode. Most industrial precipitators are based on a single-stage approach where both charging and migration (precipitation) take place within the same set of electrodes, as illustrated in Fig. 1. Another type of unit, particularly used for air cleaning duties, is two-stage precipitation, where there is a separate charging field followed by a collection field, as illustrated in Fig. 2.

In general, the basic components of any precipitator consist of some form of small diameter discharging element and, for a parallel flow unit, a flat plate counter electrode, or, in the case of vertical flow mist type of installation, a large diameter tube.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007748

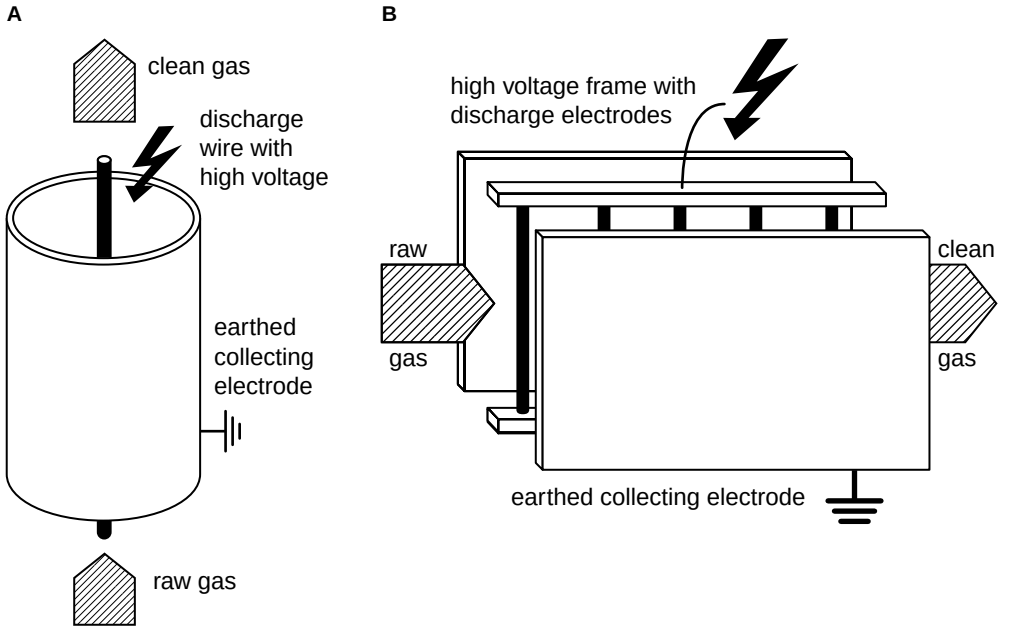

Fig. 1 Basic single-stage ESP arrangements: (A) a wire tube arrangement and (B) and parallel plate arrangement.

In practice, the form of discharge element ranges from a simple weighted wire, typical of tubular units, to specially designed controlled emission electrodes, used in a number of industries, not only to mitigate corona suppression from high concentrations of fine particulates but also to provide a long and trouble-free operating life.[1] The receiving, or collecting, electrodes range from stiffened flat plates to some form of channel construction for multifield high efficiency parallel flow applications. The size and the form of receiving electrode depend on the supplier's preference, but plates with a length of 5 m and a height of 15 m can be found in power station precipitators.[2] While for vertical flow mist type units, tubes with a diameter of 300 mm and a length of 6 m can be found.

Until the recent development of switched mode power supplies (SMPS), most industrial precipitators were energized from some type of 50–60 Hz rectified high voltage equipment. This basically comprised a suitably designed and insulated step-up transformer, the output from which can be controlled by employing silicon controlled rectifiers to modulate the incoming supply voltage. The transformer output is then rectified using silicon rectifiers to produce the high negative direct current (DC) voltage required for the necessary ionization for charging and the electric field for particle migration.

Recent developments in switched mode or high frequency direct current supplies have been applied to new and some older plants where performance enhancement is required.[3] In this form of equipment, the normal three-phase supply is first rectified and converted to a 25–50 kHz square wave, which can be modulated to supply the HT transformer, which, having a ferrite core, is much smaller and lighter than its conventional counter part. The output of the HT transformer is then rectified to produce the high voltage requirement. This form of supply has a number of advantages over the conventional (50–60 Hz) frequency supply, in that it produces almost a pure DC voltage, which enables the precipitator to operate at higher voltages and performance levels, while being much more efficient in terms of power conversion (95% as against 85%) and a power factor of 0.94 as

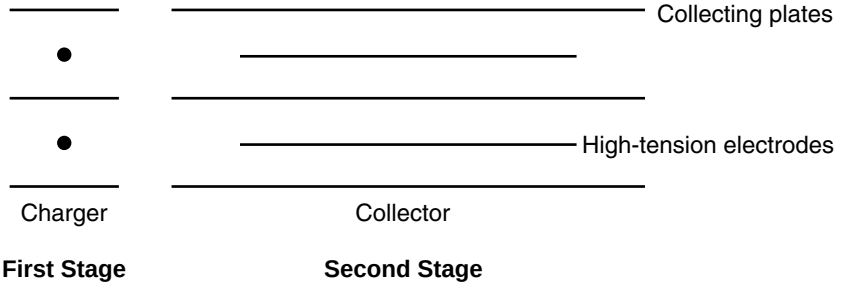

Fig. 2 Two-stage ESP arrangement.

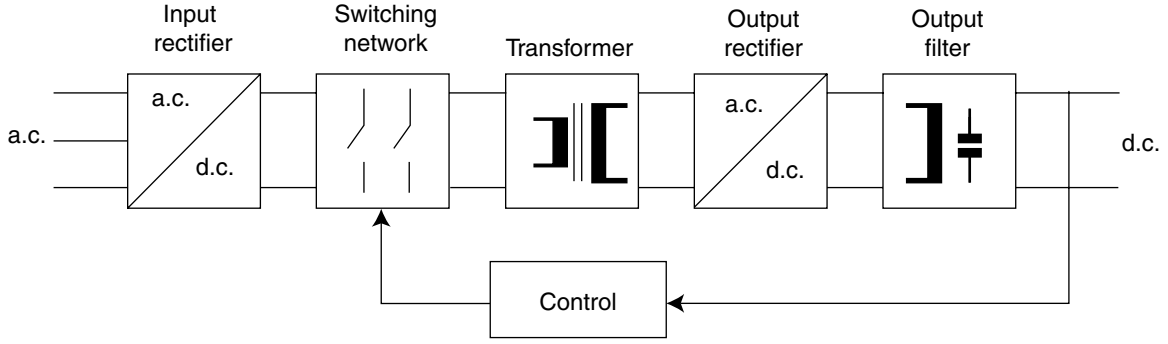

Fig. 3 Basic building block for a switch mode power supply.

against 0.63. The SMPS basic building block is shown in Fig. 3.

For air cleaning duties, although energization is normally derived from conventional supplies, the voltages are much lower, 6–12 kV, and typically positive, because of a lower ozone production, resulting from the reaction between the ions and the oxygen in the air.

In operation, the high electrical field adjacent to the energized electrode elements ionizes the gas molecules, forming both positive and negative ions. With negative energization, the positive ions are immediately captured, while the negative ions and any electrons, generally referred to as a corona discharge, migrate under the influence of the electric field into the interelectrode space. As the gas borne particles pass through the interelectrode space, the larger particles receive an electric charge either by collision with the ions/electrons or by diffusion charging for the smallest particles. The charged particles then move under the influence of the electric field and migrate to the collecting electrodes, where the charge subsequently leaks away to earth. In the interim, before becoming neutral, the charged particles are retained on the collector surface by a combination of van der Waals and electric forces.

In a dry precipitator to ensure that the collection process is continuous, after a period of time the collector electrodes are generally mechanically rapped to remove the deposited material. This time aspect, together with the frequency and intensity of the rapping, is important to minimize rapping re-entrainment and hence maximize collection efficiency. In wet precipitators, the particles are deposited on a film of running water or removed by flushing, while for mist precipitators, the droplets are usually selfdraining.

THE PHYSICS OF PRECIPITATION

Ion Production

Although there are various methods of particle charging, for example, triboelectric, ultraviolet, and radiation effects, for industrial precipitator applications corona charging is universally used, as it is the most efficient and cost-effective approach. The physics of corona or ion production therefore occupies an essential position in the practice of electrostatic precipitation. Investigations into the physics of ionization date back to the middle of the last century and are still ongoing, particularly since the development and application of computational fluid dynamics (CFD) using fast computers capable of deriving satisfactory solutions to the Poisson and La Place equations.

Early investigations were concerned with developing voltage–current relationships of corona discharge and the effects of positive and negative energization systems using wire and tube arrangements. Gaugain[4] found that the breakdown potential for a given outer diameter R depends on the diameter of the central discharge element r and derived the following relationship:

$$E = A + (C/r)^{1/3} \tag{1}$$

where E is the electrical breakdown field, r, the radius of inner electrode, and A and C are experimental constants (for $r \ll R$).

Rőentgen,[5] working with point/plane electrodes, found that a certain voltage had to be applied to initiate a corona current flow. This corona onset voltage was dependent on the sharpness of the point, gas pressure, and polarity of the point electrode. Further investigations produced a parabolic relationship for negative corona current flow as:

$$I = AV(V - M) \tag{2}$$

where I is the corona current flow, V the applied voltage, and A and M are experimental constants.

Townsend[6] noted that, with negative ionization of the discharge electrode, the appearance of the corona discharge was very different to when it was positively energized, when the corona appeared as a diffuse glow surrounding the emitter. With negative energization,

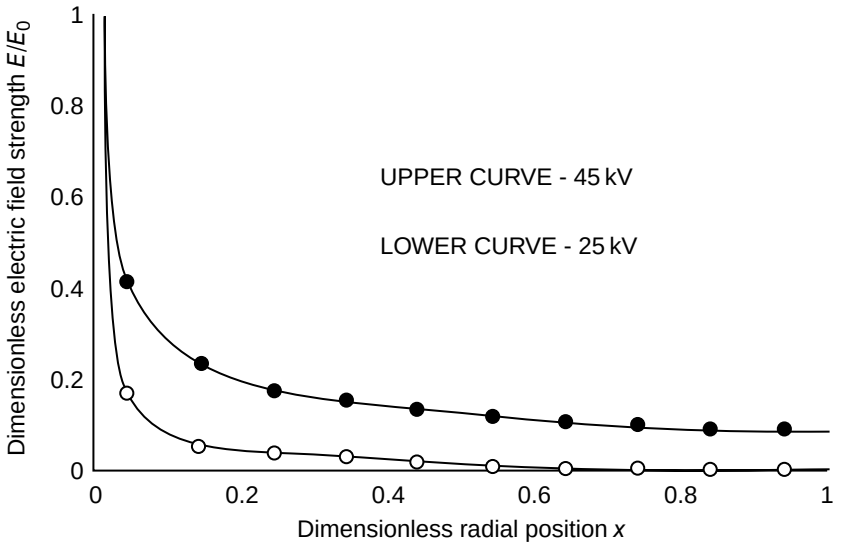

Fig. 4 Relative field strength between the electrodes of a tubular precipitator arrangement. *(View this art in color at www.dekker.com.)*

the corona appeared as bright flares, which tend to move across the surface of the electrode, and had a distinctive hissing sound, a lower initiation voltage, and a higher breakdown potential. The visual appearance of negative corona takes the form of ''tufts''—bright glow points—or Trichel pulses.[7] The number of tufts and their luminescence increase as the energizing voltage is raised, producing a higher corona current discharge.

The conduction of electricity through gases is fundamentally different to that in solids and liquids, which contain ''charge carriers'' that move under the influence of the electric field to produce the current flow. With gases, however, ions need to be provided from some outside force or agency to induce a current flow. For precipitators, this outside agency is high voltage applied across the electrode system. In Fig. 4, a typical electric field distribution between a small diameter emitter and a much larger passive electrode is shown (i.e., $r \ll R$).

This shows the electric field adjacent to the emitter is extremely high and it is this stress that excites any free electrons in the immediate vicinity. These fast moving electrons acquire sufficient energy from the applied electric field so as to collide with other gas molecules to produce further free electrons and positive ions. Townsend,[6] working in this area, proposed the concept of a chain reaction or electron avalanche, in which each new electron produced generates new electrons by ionization in ever increasing numbers.

The number of ions at a distance x from the active zone can be represented by:

$$n = n_0 e^{ax} \tag{3}$$

where n_0 represents the number of ions at a distance $x = 0$ and a is the Townsend ionization coefficient, which varies with the gas temperature, pressure, and electric field strength.

In general terms, the field strength varies with distance across the field, x, as in a precipitator. Hence the equation takes the integral form:

$$n = n_0 e^{\int_0^x a\,dx} \tag{4}$$

The term $1/a$ is the mean free electron path between collisions.

In Fig. 5, the relationship between the Townsend ionization coefficients (ion pair production) for air at atmospheric pressure at different temperatures and field strengths is given.

In the figure, it can be seen that, at 20°C, doubling of the field strength results in the number of ion pairs,

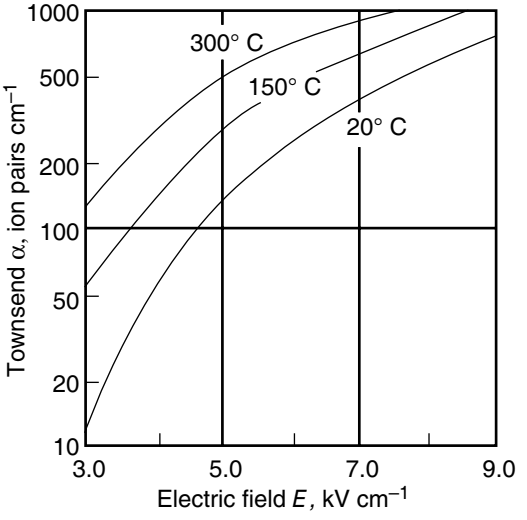

Fig. 5 Effect of electric field strength and temperature on ion pair production.

or Townsend coefficient, increasing by a factor of 20. The impact of a rise in gas temperature, which increases the mean free electron path and produces significantly increased ionization, is also indicated.

In practice, when the system is negatively energized, the electrons collide with and attach themselves to gaseous molecules to produce negative ions as they rapidly move across the field area, although there are a large number of ion pairs immediately adjacent to the discharge element. Concurrently, the positive ions are attracted toward the discharge element and, although during transit they produce further ion pairs on reaching the element take no further part in the process. As the distance from the element increases, because of attachment, the number of electrons decreases, and there is a corresponding increase in the number of negative ions. The net number of electrons at a distance x from the electrode is represented by the following equation:

$$n = n_0 e^{\int_0^x (a-\eta)dx} \tag{5}$$

where η is the coefficient of ion attachment or the Townsend second coefficient.

In the case of positive energization, normally found in air cleaning applications, the primary electrons produced at the boundary of the visible glow are attracted toward the emitter. In moving through the field, they collide with and produce new ion pairs by impact ionization, with the positive ions migrating toward the passive earthed electrode. Except for the collection of electrons, the emitter by itself plays little part in the ionization phenomenon, which is essentially a gas process with the primary electrons being released from the gas molecules through photoelectric effects in the plasma region.

Particle Charging

Particle charging occurs in the area between the active plasma region and the passive electrode surface. This area comprises a high space charge having neutral ions, negative ions, and some free electrons, all moving toward the passive electrode as a result of the electric field. As the gas borne particles enter the corona derived space charge region of the field, two charging mechanisms occur: the first is by ion attachment, i.e., field or impact charging, and the second by ion diffusion charging. The field or impact charging predominates for particles with a diameter greater than 1 μm ($1\mu m = 1 \times 10^{-6}$ m), while diffusion charging is essential for particles with a diameter less than 0.2 μm; both processes occur in the intermediate size range.

While field charging requires the presence of an electric field to drive the free mobile charge carriers, the diffusion process is based on randomly moving gas ions arising through temperature effects as described by the kinetic theory of gases, i.e., Brownian motion, which plays a significant and important role in the collection of particles in the submicron size range, in spite of their saturation charge being much smaller than that of the larger particles.

Over recent years, a great deal of numerical modeling work has been carried out using computational fluid dynamics to derive particle charging models;[8–10] however, the basic models need experimental support because the equations cannot be analytically solved. A reasonable alternative to modeling is proposed by Cochet,[11] who developed an equation, which appears to give reasonable correlation to actual precipitator measurements in the critical size range, as tested and reported by Hewitt.[12]

The particle saturation charge Q_p^{∞}, according to Cochet, is given by the following formula:

$$Q_p^{\infty} = \left\{ \left(1 - \frac{2\lambda}{d_p}\right)^2 + \frac{2}{1 + 2\lambda/d_p} \times \left(\frac{\varepsilon_r - 1}{\varepsilon_r + 2}\right) \right\} \times \pi \varepsilon_o d_p^2 E \tag{6}$$

where ε_r is the electrical permittivity of the particle, ε_o the electrical permittivity of the gas, d_p the particle diameter, E the electric field strength, and λ the mean free path electron path.

The equation can be rewritten in simplified terms:

$$Q_p^{\infty} = pEd_p^2 \tag{7}$$

where p is a constant, which varies between 1 and 3 fornonconductive particles and is 2 for conductive particles.

In practice, both field and diffusion charging occur simultaneously and are basically inseparable. It can be shown that all particles reach around 90% of their full saturation charge in less than 0.1 sec. Hence, for all practical conditions, it can be assumed that on entering the precipitation field, having a typical exposure/treatment time of 3–5 sec, the particles rapidly achieve their saturation charge.

Particle Migration

Within the precipitation field, a particle experiences the following forces acting upon it: a momentum force, $F_m = ma$; an electrical force, $F_e = Q_p E$; and a drag force, $F_d = \mathrm{Re}AC_o$ (Re is the Reynolds number and C_o the Cunningham coefficient).

Under a steady state condition

$$F_m + F_e + F_d = 0 \quad (8)$$

Prior to solving this equation, the drag force F_d has to be calculated.

In the case of low Reynolds number, the drag coefficient is given by

$$C_o = 24/\mathrm{Re} \quad (9)$$

As the particle size d_p reduces and approaches the region where the fluid loses its continuum (mean free path of molecules $= \lambda$), Stokes law needs to corrected by the Cunningham correction factor, C_o.

$$C_o = 1 + 1.246 \times 2\lambda/d_p + 0.42 \times 2\lambda/d_p \times e^{(0.87d_p/2\lambda)} \quad (10)$$

This relationship is plotted in Fig. 6, in which the significant correction factor that arises for submicron sized particles is shown.

The drag force (or Stokes law) can be written as

$$F_d = 3\pi\eta d_p \omega_{th} \times \frac{1}{C_o} \quad (11)$$

where η is the gas viscosity, d_p the particle diameter, C_o the Cunningham correction, and ω_{th} the theoretical particle migration velocity.

Assuming the fluid has no component acting toward the passive electrode and all particles achieve their saturation charge, the equation of motion of a charged spherical particle in an electric field is characterized by

$$\frac{d\omega_{th}}{dt} + \frac{3\pi\eta d_p \omega_{th}}{mC_o} = \frac{Q^{\infty}{}_p E}{m} \quad (12)$$

Taking $\omega_{th} = 0$ at $t = 0$, the solution of the above equation can be readily found, i.e.,

$$\omega_{th} = \frac{Q^{\infty}{}_p E}{3\pi\eta d_p} \times C_o \quad (13)$$

As $Q^{\infty}{}_p = pEd_p{}^2$,

$$\omega_{th} = E^2 \times d_p \times C_o \quad (14)$$

The significance of this relationship is

a. As the limiting charge on the particle is proportional to the radius squared, the migration velocity of the particle will increase with particle size.
b. As the electric field is proportional to the applied voltage, the migration velocity is proportional to the voltage squared.

It will be appreciated from this fundamental approach that the operation of an electrostatic precipitator requires a voltage high enough to produce an electric field to precipitate the particles and deliver sufficient corona current to satisfy ion production for initially charging the particles.

In Fig. 7, the relationship between the theoretical migration velocity ω_{th} against particle size for three different field strengths in a typical flue gas at 150°C, for particles having an electrical permittivity of 10, is given. Because of the logarithmic scale, the effect of

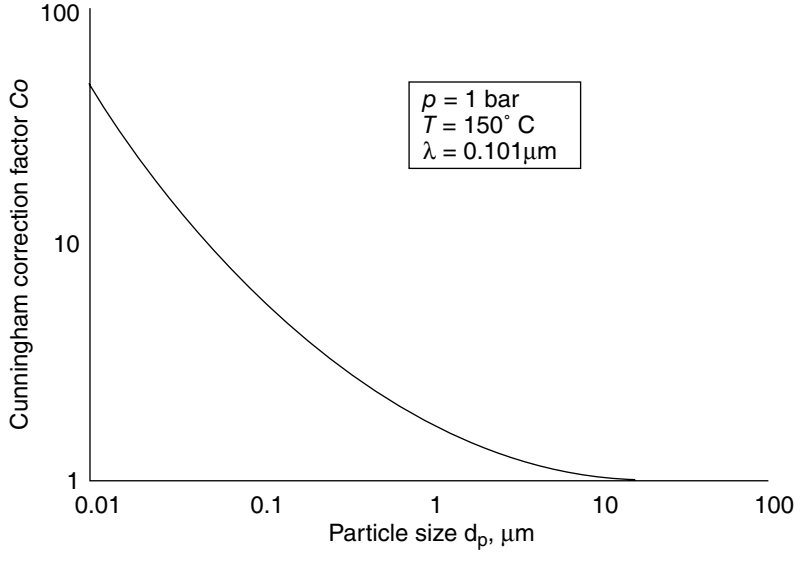

Fig. 6 Relationship between particle size and the Cunningham correction factor.

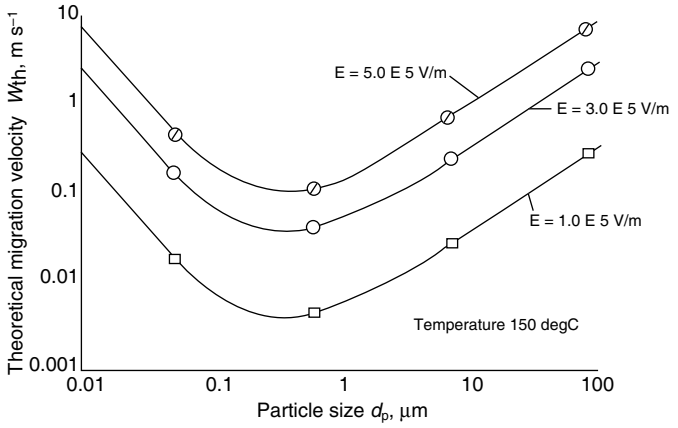

Fig. 7 Relationship between the theoretical particle migration velocity and particle size.

the field strength squared factor is not apparent, unless one examines the actual migration velocity figures.

Although the foregoing portrays the theoretical approach to the migration of charged particles through an electric field, the theoretical migration velocity should not be confused with the Deutsch ''effective migration velocity,'' which is derived from plant efficiency measurements and the specific surface area of the precipitator. The effective migration velocity derived from measured efficiencies and the specific collection area for the precipitator should more realistically be considered as a measure of a ''performance factor'' because it applies to the material that has been collected and not to the finer material that invariably forms the major part of the emission.

Regardless of which method is considered, the general trend of a much reduced migration velocity/efficiency at around 0.5 μm region is apparent. The subsequent increase in efficiency of smaller particles is the result of Brownian motion, which aids their charging and migration. To derive a fractional efficiency curve in practice, it is necessary to determine the particle sizings at both the inlet and the outlet of the precipitator and then evaluate separate grade efficiencies from the overall mass precipitator efficiency. The separate grade efficiencies can then be transposed into effective migration velocities from the Deutsch relationship.

In Fig. 8, a typical particle size penetration (1 – efficiency) relationship is illustrated through penetration curves based on both particle mass and number relationships; both demonstrate the high penetration window in the 0.5 μm region.

Particle Deposition and Removal from the Collector Electrodes

When considering the motion of a charged particle in an electric field, until the particle has been removed from the collector plate and transferred to the receiving hopper, it should not be considered as being collected. This is one of the many reasons why the theoretical values of migration velocity are usually far higher than those based on actual measured efficiency/plate area calculations. The theoretical approach also assumes that the particle on arriving at the collector losses its charge and plays no further part in the process. In practice, charged particulates arriving at the collector can cause a serious impact on the electrical operating conditions and hence the performance.

As the particle arrives at the collector, the first reaction is that it is held by a combination of van der Waals and electrical forces. Depending on the thickness of the deposited layer and the electric resistance of the layer, the charge on the particle leaks away to earth, leaving the particle to be retained only by van der Waals forces. Unless the deposit is periodically removed, the precipitation process slowly degrades, as the deposit has a deleterious impact on the electrical operating conditions. In the case of a dry precipitator, this is achieved by some form of

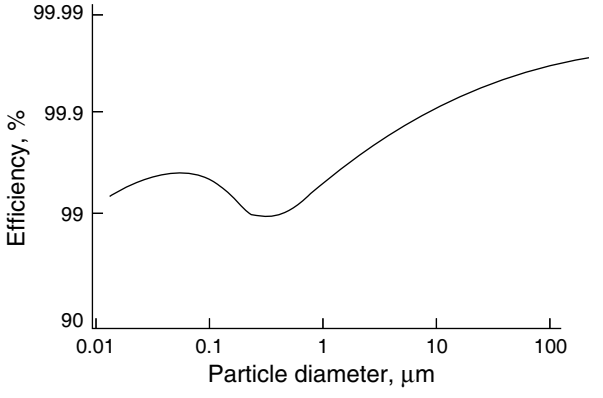

Fig. 8 Precipitator fractional efficiency curve.

mechanical rapping, and in the case of a wet precipitator, depending on the design, this is achieved by periodic water washing (flushing), a continuous spray irrigation system, or having a film of water continuously flowing over the collectors (film flow).

For a dry application, the frequency and the intensity of the rapping must be such as to shear the deposit as a layer from the plates, rather than attempting to disintegrate the layer completely, as this would lead to severe rapping re-entrainment. Ideally for the particles to reach the hopper and to overcome the horizontal component of velocity, the effective size of agglomerate should be in the order of at least 500 μm in diameter.[13]

As the rate of deposition varies along the length of the precipitator, the frequency of rapping reduces from the inlet to the outlet fields. This enables the deposited layer between blows to achieve a thickness, such that it can be sheared from the plates as an optimum sized agglomerate to reach the hoppers with the minimum of re-entrainment. Because the mean particle size of the deposited material decreases along the length of the precipitator, ideally, and because of the increased packing density and cohesion between particles, the intensity of the rapping blow should increase as the particle size becomes smaller toward the outlet.

Although the majority of the dust is deposited on the collectors, some is deposited on the discharge electrodes, and, to optimize corona production, the discharge electrodes should be kept deposit free. On a dry plant, this is achieved by rapping systems similar to those employed for the collectors, while on wet systems, water washing of the internals is usually effective in maintaining corona emission.

The relationship, indicated in Eq. (14), is important in practice, because to optimize performance it is important that the voltage applied across the electrode system is maintained at the maximum possible level. The actual operating voltage across the electrode system is largely dependent on the properties of the gas, the material suspended in the gas, the layer of deposited material, and the design of the electrode system. Though it would be ideal to consistently operate just below the electrode breakdown potential, as the complete system is dynamic and the conditions are constantly changing, an automatic voltage control system is used to maintain the voltage and, hence efficiency, as high as possible.

FACTORS AFFECTING THE DESIGN AND PERFORMANCE OF PRECIPITATORS

To obtain a better understanding of the factors that affect precipitator design and operation, one must examine the characteristics of both the gas and particulates as they are presented to the precipitator.

Gas Composition

The main requirement of the gas carrying the particulates is that it must be capable of maintaining as high an electric field as possible and permit the flow of corona current. The composition of some gases can, however, affect the electric operating conditions of the precipitator; generally the corona characteristics are modified by the presence of electropositive or electronegative gases, i.e., gases that readily absorb or reject negative ions.

Although one normally thinks of electrostatic precipitators only being applied for the removal of particulates from gas streams, the process has been satisfactorily applied for the removal of particulates from oil streams; again the main criterion is that the oil must be sufficiently insulating to maintain an electric field. The arrangement of the plant is somewhat different to a conventional gas application. Because the electrodes are normally perforated and the oil passes freely through them, the particles are contact charged before they migrate to the area of maximum field intensity between the electrode edge and casing wall. Here they are allowed to agglomerate to a sufficient size to fall under gravity into the base of the processing vessel from where they can be removed. Some installations use high voltage AC for initial treatment, followed by high voltage DC for final cleaning of the oil stream; others use DC treatment only.

Gas Temperature

The gas temperature has impacts mainly on the materials of construction; ordinary carbon steel is adopted as the cost-effective material for most applications, which limits the operating temperature to approximately 400°C, while for higher temperatures, stainless or high nickel alloys need to be used. In the case of plants operating close to acid dew point temperature, particularly for wet type environments, when choosing the material for fabrication, one must take corrosion into account to ensure durability.[14]

The main advantage of the dry type of precipitator is that the gas in most applications can be delivered directly to the precipitator from the process without the need for additional cooling or pretreatment. This means that the collected material is usefully captured in a dry state for subsequent disposal/reuse and that the cleaned gases are emitted from the chimney buoyant and usually at a temperature high enough to result in a steam free discharge.

Gas Pressure

Because most process plants operate close to ambient pressure conditions, gas pressure is not a major effect, except that one has to ensure the casing is ''gas tight'' and will withstand the operating conditions, i.e., to prevent either the egress of process gas or the in leakage of ambient air.

Gas Flow Rate

In the initial sizing of a precipitator, while it is important to have accurate knowledge of the total gas flow such that the correct contact time can be assessed to meet the required efficiency, there is also an optimum operating gas velocity to be considered. This optimum velocity is determined to some extent by the particle characteristics; too high a design velocity for a dry application can result in particle scouring and potential rapping re-entrainment, while too low a velocity will detract from the overall collection efficiency, as the deposition along the collector plate, most being collected close to the inlet, adversely distorts the electric precipitation field.

Generally with wet or mist applications, as the deposited material is retained on a wetted surface, operational gas velocities can be appreciably higher than that of a dry precipitator, as the risk of particle scouring is significantly reduced.

It is important that, to optimize the collection efficiency, the gas distribution across the frontal area of the precipitator must be as uniform as possible, although some recent work has indicated that for certain conditions a ''skewed'' velocity profile can be advantageous.[15] It is not easy to produce a typical operational gas velocity of around 1.5 m/s, which has been decelerated from approximately 15 m/s in the inlet approach ductwork, and an acceptable standard of distribution is an RMS deviation of 15%.[16] This standard can be achieved through field corrective testing, large-scale model tests, or the more recent CFD approaches.[17]

Viscosity and Density

These parameters are determined by the compositionand temperature of the gases and affect the precipitation process as follows:

a. As the charged particles migrate through the interelectrode space, they are retarded by the effects of gas viscosity and density.
b. As the temperature rises, although the gas density decreases assisting ion movement, the viscosity rises and hinders the particle transportation mechanism.

Particle Concentration

For many applications, the main effect of inlet fly ash concentration is minimal and normally has impact only on the overall removal efficiency requirement. Generally, increases in the inlet loading over that specified tend to arise from an ''upset condition'' on the process plant and are normally associated with the carryover of larger sized particles, which are more readily precipitated than the finer ones. Nevertheless, it is possible that the upset condition can modify other characteristics of the gas and result in an unacceptable emission transgression.

Particle Composition and Electrical Resistivity

For most dry process applications, the major impact of particle composition and precipitator performance is related to the electrical resistivity of the deposited material. The value of the electrical resistivity of the deposited particles can result in the required exposure/contact time within the precipitation fields varying by a factor of 4 or more.

For resistivities greater than approximately 10^{12} Ω cm, a phenomenon known as back or reverse ionization arises, which severely detracts from the overall efficiency. Because of the increasing resistance of the deposited material as the precipitation process proceeds, particles subsequently arriving only slowly lose their charge. Consequently, a voltage begins to build up on the deposit and in the worst case reaches a point where positive ions begin to be emitted from the surface of the layer. These positive ions not only neutralize any negative charge on the arriving particles but also considerably modify the electric field such that the overall efficiency is compromised. The onset of reverse ionization can be readily recognized by a significant increase in current flow and an apparent fall in average operating voltage.

With fly ash having a slightly lower dust resistivity, an alternate operational condition arises, where instead of the voltage continuing to build up on the surface of the deposited layer to initiate positive ion flow, it reaches a value where electrical break down occurs within the deposited material, producing a ''leader,'' which results in flashover across the interelectrode area. This condition produces an electrical condition typified by a slightly reduced operating voltage with a significant fall in corona current; any attempt to increase the current into the plant only results in further sparking and a decreasing performance level.

With conductive materials having electrical resistivities below 10^8 Ω cm, such as unburnt carbon or metallic particles, the particles are readily charged by the corona, and, as they reach the collector, they lose their charge so rapidly as to be repelled back into the gas stream. Although the charging and repelling process can occur several times during their transit through the precipitator, some particles can leave the plant without being captured.

An important thing as regards chemical composition and format is to know if the material is likely to produce a sticky deposit, or is in a liquid phase, when it reaches the collector electrode, such that the correct type of precipitator can be supplied. For wet or mist type applications, the materials of construction need to be corrosion resistant to protect it from either the gas or the particulate components.

Another difficulty, usually associated with particulate composition, is the cohesive strength of the deposited layer. If, on a dry plant, the material lacks cohesion and is only lightly bonded together, it is likely to be readily re-entrained during rapping and thus detract from the overall performance.

Particle Sizing

The electrostatic precipitator can effectively collect particulates having diameters from 0.01 μm to approximately 100 μm. The fractional efficiency, however, is not constant, as there is a higher penetration window in the 0.5 μm diameter range, which, coincides with the change from collision to induction charging of the particles (Fig. 8). This in itself, provided the particle sizing is available for a specific application/duty, means that the precipitator size needs to be increased to cater for particles falling in this range. This is of prime importance in enhancing existing precipitator performance levels since the emitted material, because the penetration window contains a major proportion of the finer particles.

Particle Shape

For most applications, the particle shape can be either granular resulting from the comminution of the feed material by grinding, milling, etc., or, in the form of a fume. These usually result from the material being initially volatilized in the high temperature zone of the process to subsequently condense into a spherical fume upon cooling. Neither of these forms, provided they are known or assessed beforehand and the size aspect has been considered in the design parameters, has a serious impact on the overall performance. For those processes producing a large mass of fine fume, space charge effects need to be addressed in the form of discharge element used to overcome potential corona suppression effects.

Operational problems can arise with platelet type materials, which have a fairly large surface area but virtually no thickness. These are very light in terms of mass and tend to attach themselves on to the collectors and each other, thereby reducing electrical clearance, which leads to flashover.

The presence or carryover of siliceous cenospheres, which sometimes arise during combustion, is understood to result from burning carbon particles, which are being trapped within a larger fused siliceous particle, producing sufficient gas to inflate the molten mass into a hollow sphere. This problem is not because of their shape, which is usually spherical, but because being hollow; they have little mass and poor cohesive properties, so can be readily re-entrained by rapping after being deposited.

Particulate Surface Properties

As far as precipitator performance is concerned, the surface condition/properties of the particle are generally more important than the chemical composition of the actual matrix. In many combustion applications using sulfur bearing carbonaceous fuels, the waste gases on cooling can pass through an acid dew point temperature, and any resultant sulfuric acid mist produced subsequently uses the particles as condensation nuclei depositing a thin layer of highly conductive material on their surface. At higher temperatures of operation, e.g., above 300°C, there is little possibility of reaching any dew point temperature and it is the chemical matrix of the particle that primarily governs the electrical resistivity.

Where high resistivity particles are met in practice, the electrical operating characteristics and the difficulties of the reverse ionization phenomenon can be mitigated by the injection of chemical reagents into the flue gases ahead of the precipitator to modify the electrical resistivity.[18] (Other reagents can be used to increase the cohesive properties of easily re-entrained materials if necessary to minimize re-entrainment.)

An alternative approach to flue gas conditioning is to modify the method of electrical operation, either by intermittent energization or by pulse charging. In these, instead of the continuous production of corona, the precipitator is pulsed, such that ions are only produced during the application of the voltage, thereby enabling the charge on the particles reaching the collector to discharge prior to the next set of ions arriving.[19] The capacitive component of the precipitator maintains the field voltage high enough to precipitate particles during the nonpulsing phase.

SIZING OF ELECTROSTATIC PRECIPITATORS

The development of computerized programs for resolving the Poisson and La Place equations has greatly assisted in gaining a better understanding of the physics of precipitation. To date, however, no computer program is commercially available for determining precipitator design/sizing parameters from first principles. In practice, most precipitators are sized by the suppliers from interpretation of test data from plant operating under similar duties.

Deutsch,[20] working in the mid-1920s, proposed that the performance or collection efficiency of a precipitator took the form of an exponential equation:

$$\text{Efficiency} = 1 - e^{-x} \tag{15}$$

where x is dependent on factors related to the precipitator design and physical properties of the gas and dust.

In deriving the above relationship Deutsch assumed, with infinite turbulence producing a homogeneous distribution of the particles within the gas stream, that the particles were fully charged and the gas velocity was uniform, as was the corona current distribution on the collector plates; none of which are strictly true in practice. During his investigations, Deutsch, by changing the gas velocity through the precipitator and keeping all other factors constant, derived the following efficiency relationship:

$$\text{Efficiency} = 1 - e^{-2l/v} \tag{16}$$

where l is the field length and v the gas velocity. It should be recognized that l/v is the reciprocal of the precipitation contact time.

The above relationship was later transposed by the precipitation industry and used for many years to relate the size of the precipitator, collection efficiency, and gas flow rate for plants operating on similar duties and inlet conditions. Although the formula is often assumed to be theoretically based, it is no more than a useful method of comparing precipitator performance levels.

The relationship is probably more recognizable in the following form:

$$\text{Efficiency} = 1 - e^{-(A\omega/V)} \tag{17}$$

where ω is the effective migration velocity (m/s), A the area of collecting plate (m^2), and V the gas flow rate, (m^3/s).

Rearranging

$$\omega = \log_e\left(\frac{1}{1 - \text{efficiency}}\right) \times V/A \tag{18}$$

It is important to note that the value ω, the effective migration velocity, derived from Deutsch, is not equal to the theoretical value ω_{th}, derived from Eq. (14).

PRACTICAL APPROACH TO INDUSTRIAL PRECIPITATOR SIZING

Although the Deutsch relationship was used for many years as a design tool for comparing and sizing precipitators to cater for different gas flow rates and efficiencies, it was not until the 1960s, when difficulties arose in meeting more stringent emission requirements, that modifications to the traditional Deutsch relationship were considered. The lower emission requirements demanding more of the finer, more difficult, particulates were collected.

One of the better known modifications was that derived by Matts and Onhfeldt,[21] who produced the following relationship, termed the modified Deutsch formula, for deriving an improved working figure:

$$\omega_k = \log_e\left(\frac{1}{1 - \text{efficiency}}\right)^2 \times V/A \tag{19}$$

where ω_k is termed the modified effective migration velocity.

An alternative approach is that proposed by Petersen,[22] who developed the following relationship:

$$\log_e\left(\frac{1}{1 - \text{efficiency}}\right) = (1 + b\omega A/V)^{1/b} \tag{20}$$

where b is an empirically derived constant (=0.22), which holds true for both the power and cement industry applications.

The practical implication of these modified approaches is that, for a change in efficiency, based on an installed plant whose operational data is known, the required plate area increase is significantly higher than that derived from the straight Deutsch formula, because the need to remove the finer particulates in the penetration window.

The recently updated and released Precipitator Computer Programme ESPVI Series 4W[23] for power plant applications can accurately track the performance of existing precipitators, because its algorithms use the established mathematical physics reviewed earlier. In its operation, the program divides the particle sizing into 27 discrete fractions and derives

the charging and migration velocity for each, before summating them to derive the overall efficiency. By using theplant's design and operating data as input, the program can be used to quickly investigate any upgrade scenario and hence derive a low-cost approach to enhance the performance of any existing installation.[24]

VERSATILITY OF THE ELECTROSTATIC PRECIPITATOR

The use and versatility of the electrostatic precipitator can be appreciated from the following generalized applications.

1. Steam raising: utility and industrial boilers; firing (e.g., anthracite, bituminous, sub-bituminous, lignite and brown coals, heavy and light fuel oils, orimulsion, petroleum coke, etc.); biomass (wood, straw, chicken litter, grain husks, etc.).
2. Iron and steel manufacturing: blast furnace gas cleaning for combustion (basic iron and ferromanganese units); steel converters, ladles, and electric arc furnaces; scarfing and deseaming machines; sinter plants and iron ore pelletizers; foundry and cupola applications.
3. Metallurgical process plant: dryers, smelters, roasters, and refining on nonferrous plants (e.g., copper, lead, nickel, and zinc); gold and silver bullion refining operations.
4. Coal and gas operations: coal drying, carbonization and treatment, milling, and grinding; detarring, coal gasification, and distillation processes.
5. Cement and lime manufacture: vertical and rotary kilns—wet, semidry, and dry processing; clinker coolers, limestone crushing, etc.; raw meal mills, grinders, and general feed preparation units.
6. Waste incineration: municipal, chemical, clinical, and hazardous waste disposal units; sewage sludge fired installations.
7. Pulp and paper manufacture: black liquor and Kraft recovery furnaces.
8. Chemical processing and production: dust and fume from roasters, crushers, and dryers; fumes arising during the production of fine chemicals and dyes; mist collection from sulfuric and phosphoric acid plants; gas cleaning ahead of acid production units.
9. Miscellaneous applications: carbon black collection; catalyst recovery on refinery "cat crackers;" penultimate gas cleaning stage on uranium reprocessing plant; capture and recovery of oil mists; "clean room" applications.

This list does not cover all possible applications but relates to many common industrial processes. As each application produces different waste gas flows, temperatures, particulate inlet loading, etc., the precipitator size and its design tend to be site specific for a given duty.

As indicated, the performance of the electrostatic precipitator, whether it is in material recovery or for prevention of pollution, can deliver emissions down to the mg/Nm^3 region and, for air cleaning, emissions in the low $\mu g/Nm^3$ region.

CONCLUSIONS

Electrostatic precipitation is perhaps the most versatile and cost effective of all particulate collecting devices and can be applied to any process where there is a need to remove solid particulate and mist of fume sized particles from the gas stream, whether it be for recovery or pollution control duties. It can be designed to deliver any efficiency for any gas flow rate and temperature and has a low pressure drop and a life span of more than 20 years.

The process of collection can be considered in the following stages:

- The production of a corona field to create ions.
- The charging of the particles by the ions.
- The migration of the charged particles through the field.
- The arrival of the charged particle at the receiving electrode.
- The removal of the deposited particles from the receiving electrode.

Each of these has been addressed from both theoretical and practical aspects, as they relate to the design and performance of any installation, so as to give even a nonspecialist an idea of the role played by electrostatic precipitation, particularly for controlling emissions from coal fired electricity generation plant where collection efficiencies in the order of 99.8%+ are now required to satisfy environmental legislation.

Emulsion Polymerization

Vincent G. Gomes
University of Sydney, Sydney, New South Wales, Australia

INTRODUCTION

A polymer [poly (many) + meros (particles)] consists of a large number of structural units formed by covalent bonding of monomer units to create larger molecular chains having relatively high molecular weights. The polymer industry is a multibillion dollar business globally (OECD countries alone produce over 100 MT/pa), growing at a relatively fast rate. Polymers are used in almost every major market sectors including construction, packaging, automobiles, aerospace, shipping, electrical/electronics, food, medical, sporting, and a variety of consumer goods, just to mention a few. Emulsion polymerization is a versatile process and is one of the several fundamental routes to produce nano- to microstructured materials. It is one of the principal techniques for polymerization among bulk, solution, suspension, and emulsion. In bulk and solution polymerization all reactions proceed in a single phase.

Bulk polymerization is the simplest, involving monomer and monomer-soluble initiator, without solvents or dispersion media. Monomer conversion causes rapid increases in viscosity, making reactor agitation and heat transfer inefficient. This may cause reactor thermal runaway. The difficulties associated with bulk polymerization can be overcome by solution polymerization, which is carried out with a solvent to reduce mixture viscosity, thereby ensuring better heat removal and mixing. However, chain transfer to solvent may reduce the chain length and, hence, the degree of polymerization. The complete removal of solvent from the final product is difficult and economically impractical. Thus, solution polymerization is mainly used where the polymer is required in a solution. An effective means of reducing the problems with bulk polymerization is to use emulsion polymerization, which is carried out in monomer droplets suspended by colloid stabilizers in water. The process facilitates heat and mass transfer and is used in industrial scale. Suspension polymerization has similar advantages as for emulsion; however, the particles generated are larger (10–1000 μm), while monomer conversion, and heat and mass transfer efficiencies are lower. An emulsion is a discontinuous liquid phase dispersed within a different continuous liquid phase. Emulsion polymerization is based on a system consisting of water as the continuous phase, one or more monomer(s), emulsifier(s) dispersed in immiscible monomer(s), and an initiator that initiates the reaction by producing highly reactive radicals in the aqueous phase. The end product of this process is a finely divided latex comprising polymer particles (0.05–0.3 μm) dispersed in a continuous phase. The particles form a colloid that can be used either in latex form (adhesives, surface coatings, etc.) or coagulated and dried for other applications (fibers, tires, etc.). In the related dispersion polymerization, the monomer and the initiator are soluble in the continuous phase and the polymer particles produced, precipitate from the mixture.

Emulsion polymerization is the basis of many industrial processes, and the production volume of latex technologies is continually expanding—a consequence of the many environmental, economic, health, and safety benefits the process has over solvent-based processes. A wide range of products are synthesized by emulsion polymerization, including commodity polymers, such as polystyrene, poly(acrylates), poly (methyl methacrylate), neoprene or poly(chloroprene), poly(tetrafluoroethylene), and styrene–butadiene rubber (SBR). The applications include manufacture of coatings, paints, adhesives, synthetic leather, paper coatings, wet suits, natural rubber substitutes, supports for latex-based antibody diagnostic kits, etc.[1]

Scope

Emulsion polymerization is in wide commercial use because of its substantial advantages:

- Heat generated by polymerization can be readily absorbed and dissipated by the aqueous phase, making it safer.
- The rate of polymerization is high compared to other processes, and a relatively high conversion can be achieved.
- The polymer is formed as low-viscosity latex rather than as the solid or viscous solution as in bulk and solution polymerization.
- Molecular weight of polymer is readily controlled in emulsion polymerization, where the average number of radicals, $\bar{n}$, can be kept constant over an extended period of the reaction, and higher molecular weights

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007749

can often be achieved because of the compartmentalization of growing chains.
- The process itself and the resulting polymer latex are water-based rather than solvent-based, which reduces both safety hazards and environmental impact.

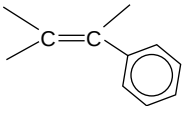
The disadvantages of emulsion polymerization are:

- Stabilizers and other additives may impair the quality of the final product.
- It may be necessary to separate the polymer from the water for further processing (e.g., by coagulation/dewatering) at increased expense.
- As the polymerization process is heterogenous and involves a minimum of two phases, mechanisms are complex and may pose operational challenges.

REAGENTS

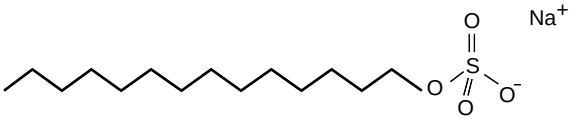
Most emulsion polymerization is based on free-radical reactions, involving monomers (e.g., styrene, butadiene, vinyl acetate, vinyl chloride, methacrylic acid, methyl methacrylate, acrylic acid, etc.), surfactant (sodium dodecyl diphenyloxide disulfonate), initiator (potassium persulfate), water (18.2 MΩ/cm), and other chemicals and reagents such as sodium hydrogen carbonate, toluene, eluent solution, sodium chloride, and sodium hydroxide.

Monomers must be bifunctional, e.g., styrene:



Surfactants or emulsifiers help stabilize the emulsion and are classified into four broad categories: anionic, cationic, nonionic, and zwitterionic. Surfactants are dissolved in water at low concentrations, where they form aggregates or micelles. At a concentration greater than their critical micelle concentration (CMC), all excess molecules form micelles.

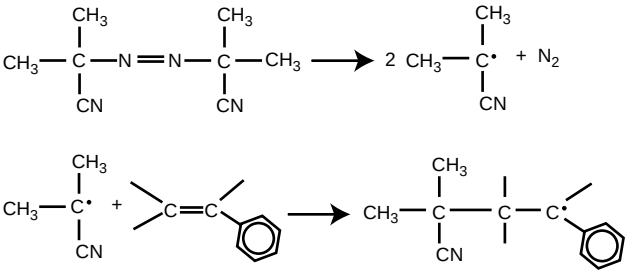
Typical surfactant: Sodium dodecyl sulfate (CMC of 6×10^{-3} mol/L at 80°C), a common alkyl sulfate of the anionic surfactant family.



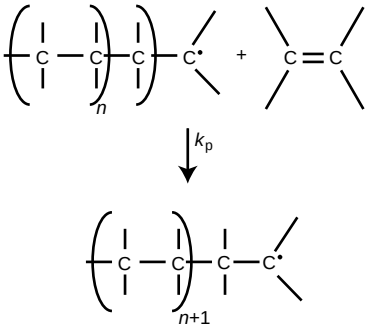
Typical initiator: $K_2S_2O_8$ or potassium persulfate.

Typical polymerization chemistry:

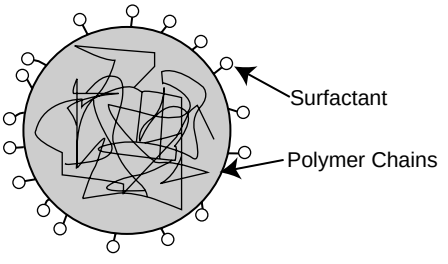
Free-radical polymerizations begin with initiation for example, for AIBN as initiator and styrene as monomer:



This is followed by propagation:



Product latex particle:



Magnified Latex Particle

A typical emulsion polymerization recipe includes specific proportions of the added ingredients, e.g. (in wt%): monomer, 100; water, 150; initiator, 0.5; surfactant, 5. Because the monomer has low water solubility, it is clear that there will be two separate phases referred to as the monomer phase and the aqueous phase. The aqueous phase, containing the surfactant in the form of micelles, can be considered as consisting of two phases, the micellar phase and the true aqueous phase. The emulsifier helps disperse the monomer in the aqueous phase with droplets in the order of a few micrometers in size. The hydrophobic interior of the micelles contains solubilized monomer, which is apportioned by diffusion out of the emulsified monomer droplets and through the aqueous phase.

REACTION KINETICS

The kinetics of emulsion polymerization is complex, involving a large number of species and at least two phases. The first quantitative approach to emulsion polymerization kinetics led to extensions by many others.[2] The important events to consider are: 1) the free-radical reactions of chain formation: initiation, propagation, chain transfer, and termination and 2) the phase transfer events that control particle formation: radical entry into particles from the aqueous phase, radical exit into the aqueous phase, radical entry into micelles, and the aqueous phase coil–globule transition. In free-radical emulsion polymerization, the fundamental steps are shown schematically in Fig. 1

Initiation

Initiation is the reaction step when free radicals are formed. In emulsion polymerization, the initiator is usually soluble in the aqueous phase, e.g., potassium persulfate. In the following reaction, the initiator decomposes to make two identical free-radical entities, denoted by $I^{\bullet}$:

$$I \xrightarrow{k_d} 2I^{\bullet}$$

where I stands for initiator and k_d is the rate coefficient for initiator decomposition. The initiation reaction is as follows:

$$I + M \xrightarrow{k_1} R_1^{\bullet}$$

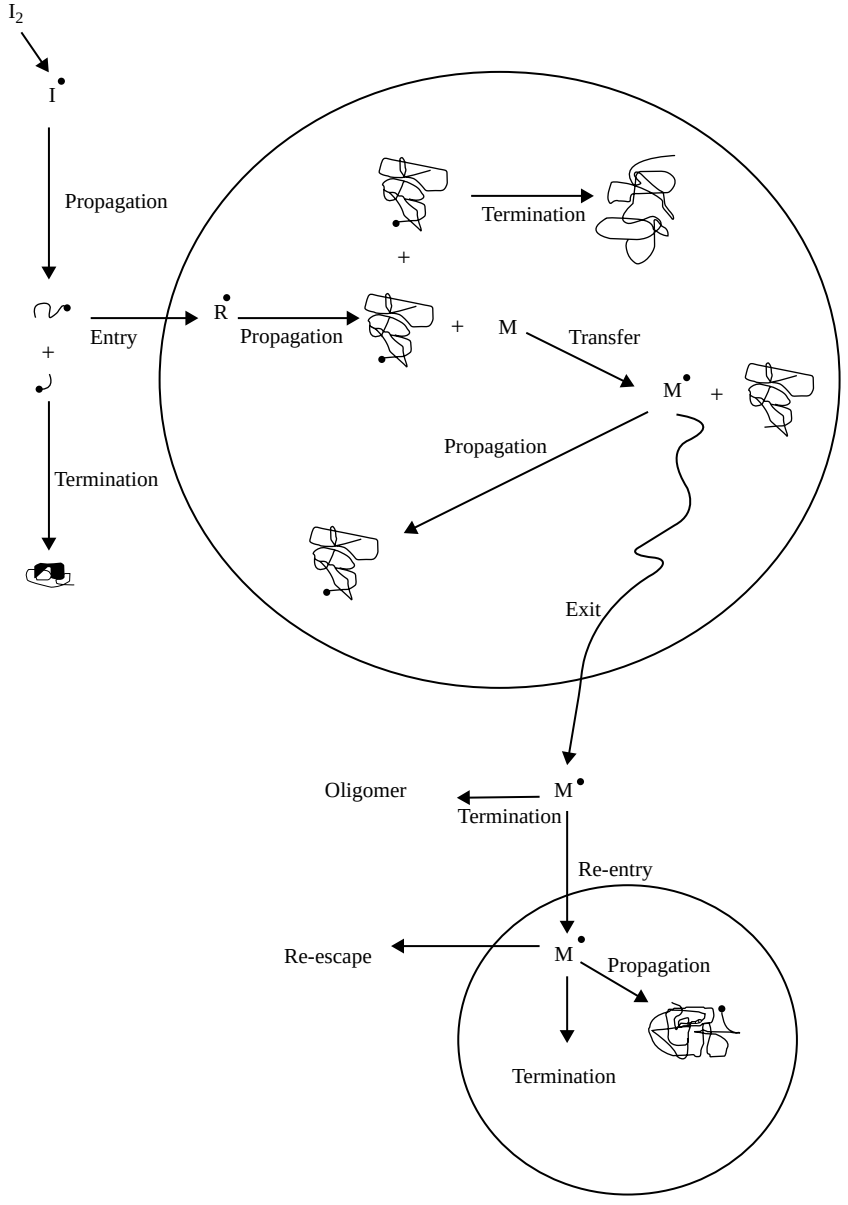


Fig. 1 Subprocesses occurring during emulsion polymerization. (From Ref.[3].)

where M is a monomer unit, $R_1^\bullet$ is a monomeric radical, and k_1 is the rate coefficient for the propagation of an initiator radical with a monomer molecule.

Propagation

Following the radical formation step, the propagation step takes place with the addition of polymer radicals to the monomers. The chemical equation for propagation is:

$$R_n^\bullet + M \xrightarrow{k_P^n} R_{n+1}^\bullet$$

where $R_n^\bullet$ is a radical of degree of polymerization n (i.e., a polymeric radical comprising n monomer units), and k_p^n is the rate coefficient for propagation of a polymeric radical having the degree of polymerization n.

Chain Transfer

Transfer occurs when radical activity is transferred from a polymeric radical to a monomer, polymer, initiator, solvent (or a chain transfer species). The mechanism of transfer to a monomer is given as:

$$R_n^\bullet + M \xrightarrow{k_{tr}} P_n + M^\bullet$$

where P_n is a dead polymer chain of degree of polymerization n, and k_{tr} is the rate coefficient for transfer to a monomer unit. The reaction takes place via hydrogen abstraction.

Termination

Termination occurs by two distinct mechanisms: combination and disproportionation. In combination, a polymeric radical of degree of polymerization n adds to a polymeric radical of degree of polymerization m, forming a dead polymeric chain of degree of polymerization $n + m$:

$$R_n^\bullet + R_m^\bullet \xrightarrow{k_{tc}} P_{n+m}$$

where k_{tc} is the rate coefficient for termination by combination.

The second mechanism, disproportionation, takes place as a result of a hydrogen atom abstraction from one radical to another. This results in two dead polymer chains:

$$R_n^\bullet + R_m^\bullet \xrightarrow{k_{td}} P_n + P_m$$

where k_{td} is the rate coefficient for termination by disproportionation.

Accurate kinetic models provide insight into the relationship between process variables and the product characteristics that they influence. Different emulsion polymerization theories, although controversial, were used over the years to aid in interpreting polymerization experiments. These models at the early stages focused only on the emulsion kinetics until recent research began to couple these kinetic models with reactor dynamics. These studies have helped to elucidate the various competing mechanisms involved, and led to mathematical models (with varying degrees of complexity) that are able to predict the key product attributes.[4–10]

The rate coefficient for propagation (k_p), essential for quantitative interpretation of rate data, is studied by pulsed laser polymerization, a technique that has now become well established. Termination coefficients are established by relaxation experiments performed with γ-radiolysis initiated free-radical polymerization with large latex particles, while analysis of the molecular weight distribution (MWD) under transfer-dominated conditions yields rate coefficients for chain transfer. Radical exit rate coefficients from small particles are measured by γ-radiolysis relaxation experiments, and in combination with the steady-state reaction rate and previously measured exit rate coefficients can be used to determine the rate of radical entry.[11] Pulsed laser polymerization uses periodic flashes of laser light to generate bursts of radicals. At each burst, a number of chains are initiated, and the growing chains are terminated by the small free-radical species. If a sufficient number of chains are initiated and terminated by successive laser pulses, the point of inflection on the gel permeation chromatography (GPC) trace of the polymer product corresponds to the molecular weight of these chains.[12]

Termination rate coefficients can be measured using the γ-radiolysis relaxation method. This involves initiation using γ-radiation, followed by removal of the reaction vessel from the γ-source. Conversion during the relaxation period is monitored by dilatometry, and the decay in polymerization rate over time is related to the rate of radical loss.[12] When large particles are used, radical loss is dominated by intraparticle termination, rather than exit into the aqueous phase, and the rate coefficient for termination can be determined from the decay curve. By using multiple insertions and removals, the termination rate coefficient is determined over a wide range of polymer mass fraction (w_p).

Most kinetic studies focus on batch emulsion polymerization. These studies enable estimation of important polymer properties. Only recently, the control of particle size and MWD described by population balance models has been achieved.[13–17] The differences between emulsion polymerization and copolymerization

behavior in batch and semibatch processes have remained unexplored in the literature until recently. It has been accepted that polymer particle formation and growth in batch or semibatch modes obey the same kinetics. No significant difference in average particle size has been reported.[18] However, recent work noted an increase in particle number with a decrease in the monomer feed rate in semibatch emulsion polymerization.[2,19] It was observed that increasing the feed rate results in a larger particle size and at sufficiently low rates, multimodal distributions are produced.

The early kinetic model by Smith and Ewart was based on Harkin's mechanistic understanding of the batch process.[11] The particle population balances were written for a stationary state assuming that the rate of formation of particles with n radicals equals the rate of their disappearance (see equation at the bottom of this page). Where R_i is the rate of radical entry into a particle (m^{-3}/sec); k_0 is the rate constant for radical exit (m/sec); S is the particle surface area (m^2); k_{tp} is the rate constant for bimolecular termination in the particles (m^3/sec) and υ is the particle volume. According to Smith and Ewart three limiting cases can be identified:

Case I: Where the rate of radical exit from the particle is greater than the rate of radical entry

$$\frac{k_0 S}{\upsilon} \gg \frac{R_i}{N_c}$$

In this case the number average radicals per particle $\bar{n}$ is less than unity:

$$\bar{n} = \frac{\sum nN_n}{\sum N_n}$$

Case II: The rate of termination is greater than the rate of entry and greater than the rate of exit

$$\frac{k_{tp}}{\upsilon} \gg \frac{R_i}{N_c} \gg \frac{k_0 S}{\upsilon}$$

This case gives $\bar{n} = 1/2$ on the basis that entry of a radical into an empty particle will result in a particle having one propagating chain, whereas the entry into a particle containing a radical will cause instantaneous termination. Therefore, the number of radicals in a particle can be either zero or one.

Case III: The particles contain more than one radical and

$$\frac{k_{tp}}{\upsilon} \leq \frac{R_i}{N_c} \gg \frac{k_0 S}{\upsilon}$$

Thus, the kinetics in the particles resembles bulk polymerization.

With these sets of equations the reaction rate, R_p, is calculated from:

$$R_p = k_p M_p \frac{N_c \bar{n}}{N_A}$$

where k_p is the reaction rate coefficient (m^3/mol/sec), N_A is Avogadro's number, and M_p is the monomer concentration in the particles (mol/m^3).

In a similar manner, the particle number N_c can be calculated via two models:

Model I: Where all the radicals generated by the initiator in the aqueous phase nucleate the micelles. Therefore, the rate of formation of particles equals the initiation rate. Consequently,

$$N_c = 0.53\left(\frac{R_{i,w}}{\mu}\right)^{2/5}(a_s[S])^{3/5}$$

where μ is the volume growth rate of the particle (m^3/sec), $R_{i,w}$ is the rate of initiator decomposition (mol/m^3/sec), a_s is the emulsifier covering capacity per mole of emulsifier, and [S] is the surfactant concentration (mol/m^3).

Model II: Where particles and micelles absorb radicals at a rate proportional to their current interfacial areas. Thus,

$$N_c = 0.37\left(\frac{R_{i,w}}{\mu}\right)^{2/5}(a_s[S])^{3/5}$$

Extensions of the early model employed mass balances across all components.[20] The model agreed well with experimental data for the production of polystyrene. However, as in most traditional models it was a particle number model, based on all particles being identical. These models helped analyze polymerization in terms of the number concentration of polymer particles containing "i" actively polymerizing radicals of number, $N_i(t)$. As a result, they contained no particle size

$$\underbrace{\frac{R_i}{N_c}N_{n-1}}_{\text{(entry)}} + \underbrace{\frac{k_0 S}{\upsilon}(n+1)N_{n+1}}_{\text{(exit)}} + \underbrace{\frac{k_{tp}}{\upsilon}(n+2)(n+1)N_{n+2}}_{\text{(termination)}} = \underbrace{\frac{R_i}{N_c}N_n}_{\text{(entry)}} + \underbrace{\frac{k_0 S}{\upsilon}nN_n}_{\text{(exit)}} + \underbrace{\frac{k_{tp}}{\upsilon}(n)(n-1)N_n}_{\text{(termination)}}$$

parameter and failed to take into account the volume dependence of the rate coefficients.

Later research extended the Smith–Ewart theory and developed models incorporating the complete particle size distribution (PSD).[21] In particular, the volume of latex particles was included, enabling computation of the density of polymer particles (containing "*i*" radicals) as a function of volume and time. The particles were then compartmentalized into discrete volumes studied over a discrete time interval. These models relied on mass balances over the concentration of particles of a specified diameter at a given time. They included terms for nucleation, growth, and coagulation of particles. The result was a series of coupled partial differential equations, which were solved numerically. Recent advances in the understanding of the physicochemical mechanisms have eliminated the controversy and uncertainties accompanying previous findings. These models incorporated the competing events, such as aqueous phase propagation and termination, and micellar and secondary nucleation.[4,22]

MECHANISTIC MODELS FOR DESIGN AND SCALE-UP

Mathematical modeling is an essential tool for design and scale-up. As emulsion polymerization involves a minimum of two phases, the kinetics is complex and makes it difficult to:

- Predict the effect of changes in process variables on product.
- Optimize the process to achieve the desired product characteristics and efficient use of raw materials.
- Control reaction in a safe and cost-effective manner.

The emulsion polymerization process is analyzed in terms of the stages or intervals it involves: typically represented by Intervals I, II, and III.

Interval I

Particle formation is the defining event of Interval I (Table 1, Fig. 2). Micelles may be present (if the surfactant concentration is sufficiently high for micelles to form), monomer droplets are present, and particle number and particle size are both increasing. Particles form by two competing mechanisms: micellar nucleation or homogenous nucleation. Micellar nucleation occurs when an oligomeric radical from a radical enters a micelle, and a particle forms. Homogenous nucleation occurs when an oligomeric radical is no longer soluble in the aqueous phase and collapses to form a particle. Largely because of the increasing number of particles the rate of polymerization increases. Interval I is the first stage of ab initio polymerization (i.e., where no particles are initially present) and can be avoided by using a preformed latex to give a seeded system, in which case, polymerization may begin in Interval II or III.

During Interval I, the initiator decomposes in the water phase to generate active radicals. The most commonly used initiator is potassium persulfate, $K_2S_2O_8$, which decomposes as follows:

$$S_2O_8^{2-} \rightarrow 2SO_4^{-\bullet}$$

The active radical propagates with the monomer dissolved in water to form oligomeric radicals, soluble in water

$$2SO_4^{-\bullet} + M \rightarrow {}^{\bullet}MSO_4^{-}$$
$${}^{\bullet}MSO_4^{-} + M \rightarrow {}^{\bullet}M_2SO_4^{-}$$

This may undergo termination with another radical:

$${}^{\bullet}MSO_4^{-} + {}^{\bullet}M_2SO_4^{-} \rightarrow M_3(SO_4^{-})_2$$

When an oligomeric radical enters a micelle, it propagates rapidly with solubilized monomer to form a polymer particle. Similarly, new polymer particles are continuously formed with the new particles being small compared to the larger early particles. Thus, the PSD is broad at this early stage. As the total interface area of micelles is much larger than that of the monomer droplets, the oligomeric radicals in the aqueous phase are much more likely to diffuse into a micelle swollen with monomer rather than into the monomer droplet. Polymerization thus occurs mainly in the micelles (which gradually transform into polymer particles) and the polymer latex particles, while

Table 1 Description of the three intervals of emulsion polymerization

Interval	Conversion range (%)	Micelles	Monomer droplets	Particle number	Particle size	Comments
I	0–10	Present	Present	Increases	Increases	Nucleation period
II	10–40	Absent	Present	Constant	Increases	C_p constant
III	40–100	Absent	Absent	Constant	Roughly constant	C_p decreases

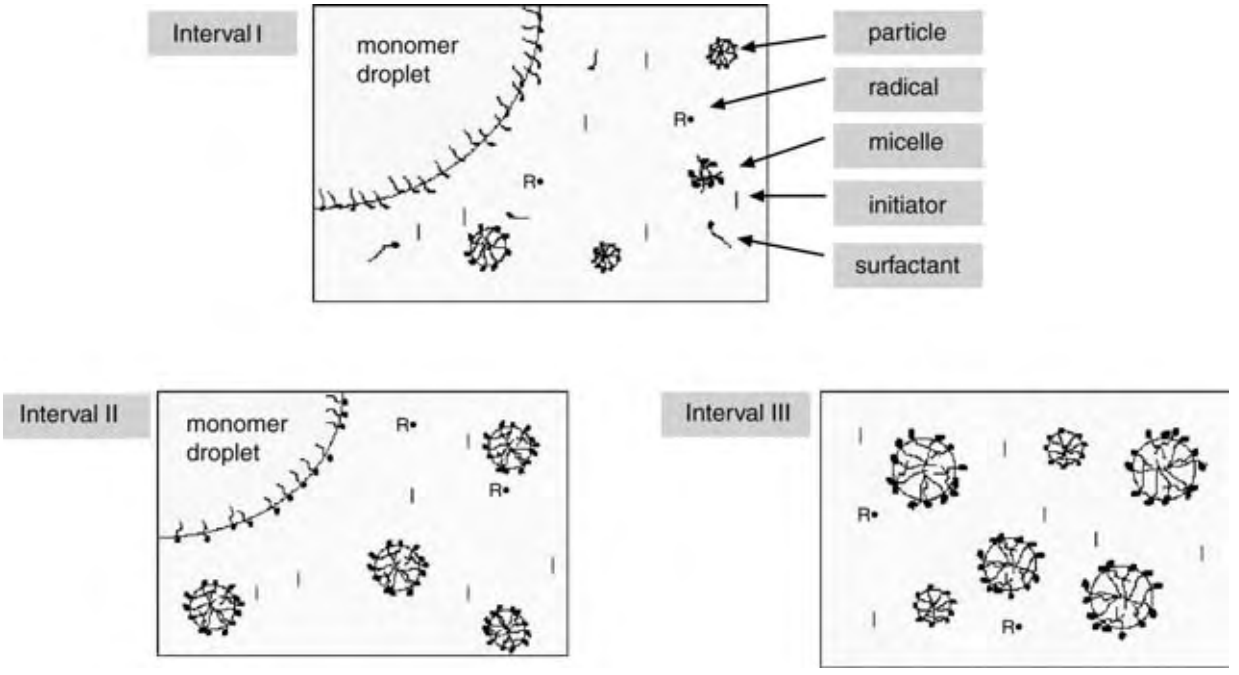

Fig. 2 Three intervals during emulsion polymerization. *(View this art in color at www.dekker.com.)*

continually consuming monomers, delivered via diffusion from the droplets through the aqueous phase. There are eventually a sufficient number of large-size particles so that all newly formed aqueous phase radicals enter preexisting particles rather than nucleating new ones. At the completion of this stage, all micelles are consumed by nucleation and the when surfactant concentration falls below the CMC, particle formation ceases and the number of latex particles stabilizes.

Interval II

When particle formation ceases, Interval II begins. At this point both surfactant-stabilized monomer droplets and polymer particles are present in the emulsion. Polymerization continues in the particles with the process of initiation and termination maintaining a stable or a slowly increasing $\bar{n}$. The particles continue to grow during this interval, as monomers continue to migrate from the monomer droplets into the particles to replenish that which is being polymerized. This migration of monomer normally maintains the concentration of monomer in the particles at the saturation level, C_P^{sat}. As C_P and N_c do not change in Interval II, this interval is associated with a relatively constant rate of polymerization.

The polymer chain within the particle keeps growing by propagation and eventually undergoes radical transfer forming a new monomeric radical:

$$M_n^{\bullet} + M \rightarrow M_n + M^{\bullet}$$

The monomeric radical continues to propagate, or escape from the particle into the aqueous phase. The exited radical may enter another particle and terminate the growth of a propagating chain in this particle, or propagate if the particle contains no growing chains. As a result of these processes of entry, transfer, and exit, the particle contains a large number of dead polymer chains with a high molecular weight (of the order of 10^6).

Interval III

When the monomer droplets are depleted, Interval III commences. The majority of the remaining monomer is in the latex particles with some dissolved in the aqueous phase. Particles are still able to grow, but the decreasing concentration of the monomer leads to a gradual decrease in the rate of polymerization (unless reduced diffusion of radicals because of the increasing weight fraction of polymers leads to an increase in $\bar{n}$). Polymerization will usually continue until all the monomer has reacted.

The heterogenous nature of emulsion polymerization processes, and the stepwise mechanisms involved add complications to the understanding of the kinetics. Despite the investigations conducted in emulsion polymerization over the last few decades, the scientific representation of these complex processes remains incomplete. With recent advances in fundamental chemistry and colloid science, model uncertainties have diminished.

KINETIC REGIMES

Two types of systems are identified in emulsion polymerization: the pseudo-bulk system and the zero–one system.[1]

Pseudo-Bulk System

In this system the number of radicals in a particle is relatively so high that the polymerization resembles bulk polymerization. The average number of radicals per particle, $\bar{n}$, is, almost, always greater than 0.5. Compartmentalization has no effect on the kinetics of a pseudo-bulk system, and termination, which is rate determining, is always diffusion controlled.

Zero–One System

The term zero–one designates that all latex particles contain either zero or one active free radical. The entry of a radical in a particle that already contains a free radical will instantaneously cause termination. Thus, the maximum value of the average number of radicals per particle, $\bar{n}$, is 0.5. In a zero–one system, compartmentalization plays a crucial role in the kinetic events of emulsion polymerization processes. In fact, a radical in one particle will have no access to a radical in another particle without the intervention of a phase transfer event. Two radicals in proximity will terminate rapidly; however, the rate of termination will be reduced in the process because of compartmentalization, as the radicals are isolated as separate particles. Consequently, the propagation rate is higher and the molecular weight of the polymer formed is larger than in the corresponding bulk systems. Which model is more appropriate depends primarily on the particle size. Small particles tend to satisfy the zero–one model, as termination is likely to be instantaneous.[1]

Mass balances on the aqueous radical species lead to the following set of rate equations:

$$\frac{d[I^\bullet]}{dt} = 2k_d[I] - k_{p1}[I^\bullet]C_w \quad (1)$$

$$\frac{d[IM_j^\bullet]}{dt} = k_{p1}[I^\bullet]C_w - k^1_{p,aq}[IM_1^\bullet]C_w - k_{t,aq}[IM_1^\bullet][T^\bullet] \quad (2)$$

$$\frac{d[IM_i^\bullet]}{dt} = k^{i-1}_{p,aq}[IM_{i-1}^\bullet]C_w - k^i_{p,aq}[IM_i^\bullet]C_w - k_{t,aq}[IM_i^\bullet][T^\bullet], \quad i < z \quad (3)$$

$$\frac{d[IM_i^\bullet]}{dt} = k^{i-1}_{p,aq}[IM_{i-1}^\bullet]C_w - k^i_{p,aq}[IM_i^\bullet]C_w - k_{t,aq}[IM_i^\bullet][T^\bullet] - k^i_e[IM_i^\bullet]\frac{N_{tot}}{N_A} - k^i_{e,micelle}C_{micelle}[IM_i^\bullet], \quad i = z, \ldots, j_{crit} - 1 \quad (4)$$

In the equations above, C_w is the monomer concentration in the water phase, N_{tot} is the total number of latex particle per litre of aqueous phase, and N_A is Avogadro's number.

Furthermore, the monomeric radicals formed by radical transfer to the monomer, $M^\bullet$may desorb from the particle with such "exited" radicals denoted by $E^\bullet$. Once such a desorbed radical meets the surface of a particle, it will immediately penetrate the particle because of its lipophilic nature. This adsorption–desorption process is reversible, as illustrated below:

$$E^\bullet + \text{particle} \underset{k_{dM}}{\overset{k_{cE}}{\rightleftarrows}} (\text{particle} - M^\bullet)$$

Hence, the total radical concentration in the aqueous phase $T^\bullet$ becomes:

$$[T^\bullet] = \sum_{i=1}^{z-1}[IM_i^\bullet] + [E^\bullet] \quad (5)$$

The rate of surfactant consumption determines the micelle concentration, $C_{micelle}$. The amount of adsorbed surfactant onto the particle surface is defined as

$$S_{ads} = \frac{4\pi r_s^2 N_{tot}}{N_A a_s} \quad (6)$$

and hence

$$C_{micelle} = \text{maximum}\left[0, \frac{[S_{added}] - S_{ads} - [CMC]}{n_{agg}}\right] \quad (7)$$

where $[S_{added}]$ is the total concentration of surfactant added, a_s is the area occupied by an adsorbed surfactant molecule, n_{agg} is the average number of surfactant molecules in a micelle (known as the micellar aggregation number), and [CMC] is the critical micelle concentration. Eq. (7) designates that particle formation via micelles stops when the surfactant concentration falls below the CMC. This equation also shows the critical relationship existing between the surfactant concentration and the number of particles, N_{tot}. Fig. 3 shows a schematic diagram of radical transfer between particles of unswollen volumes based on the zero–one kinetics.

Fig. 3 depicts the dominant mechanisms of micellar and homogenous nucleation, where an oligomer of degree greater than or equal to the critical degree of polymerization for entry, z, creates the latex particle containing a polymeric radical. The critical degree of polymerization is the degree in which the monomer while propagating in the aqueous phase acquires enough hydrophobicity to enter into micelles. For micellar nucleation a particle containing a radical of

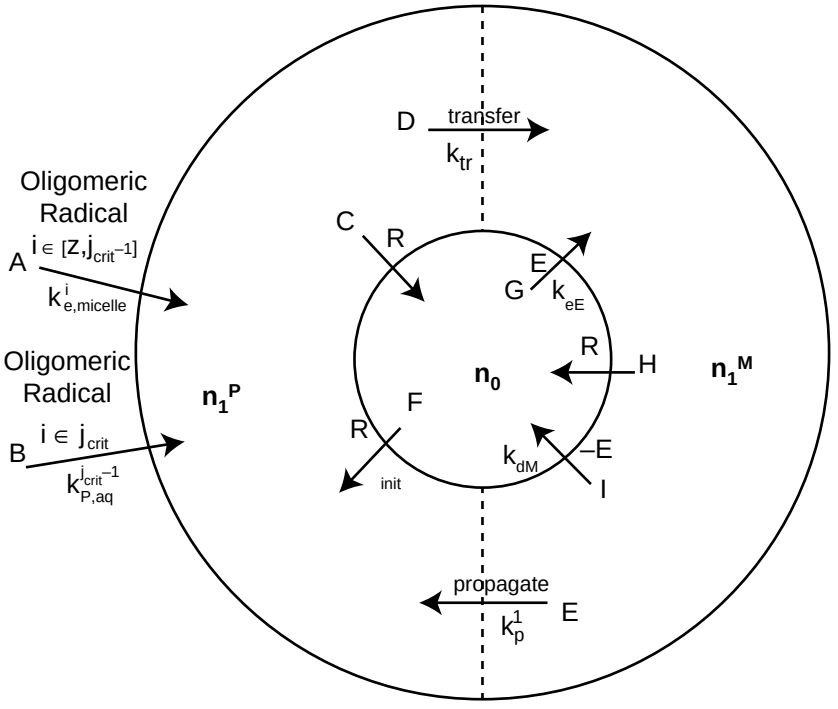

Fig. 3 Schematic representation of radical transfer between particles of unswollen volume based on zero–one kinetics.

degree $i \in [z, j_{crit}-1]$ is formed, with rate constant $k^{i}_{e,micelle}$(section A). Homogenous nucleation occurs on the formation of an oligomeric radical of degree j_{crit}, and hence forms with rate constant $k^{j_{crit}-1}_{p,aq}$ (section B).

Polymeric radical containing particles are also formed when an oligomeric radical enters an n_0-type particle with rate constant ρ_{init} (section F) and when an n_1^M-type particle propagates (rate constantk^1_p) to convert the monomeric radical into a polymeric radical (section E). Particles with polymeric radicals are consumed when either an exited or an oligomeric radical enters an existing n_1^P particle, causing termination (section C). This occurs with rate constant ρ, the pseudo first-order rate constant that accounts for all entry events. Alternatively, chain transfer to a monomer (section D) consumes them.

POPULATION BALANCES

The main assumptions in developing dynamic model equations are:[23]

- Polymerization occurs only within latex particles.
- Particles are formed through both homogenous and micellar nucleation.
- ''Competition'' occurs between the processes of particle growth, homogenous nucleation, and micellar nucleation.
- Three types of particles may be identified: 1) those containing no radicals—referred to as type n_0 particles; 2) those containing one monomeric radical—type n_1^M particles; and 3) those containing one polymeric radical—type n_1^P particles.
- Compartmentalization plays a crucial role in the overall kinetics, as a radical in one particle will have no access to a radical in another particle without the intervention of a phase transfer event.
- Two radicals in close proximity will terminate rapidly.
- The entry of a radical into a particle that already contains a free radical will instantaneously cause termination. Thus, the maximum value of the average number of radicals per particle, $\bar{n}$, is 0.5.
- Monomer diffusion inside a particle is a function of the polymer volume fraction.
- At low monomer concentration (that is, at high monomer conversion), entry, propagation, and termination become diffusion-controlled processes.
- Particle coagulation follows the DLVO theory.

Given these assumptions, the population balance equations for the three particles types (n_1^P, n_0, and n_1^M) are as follows:

$$\frac{\partial n_1^P(V,t)}{\partial t} = k_P^1 C_P n_1^M + \rho_{init} n_0 - \rho n_1^P - k_{tr} C_P n_1^P - \frac{\partial (K n_1^P)}{\partial V} + \delta(V - V_0) \times \left[C_{micelle} \sum_{i=z}^{j_{crit}-1} \left[k^i_{e,micelle} [IM_i] \right] - k^{j_{crit}-1}_{p,aq} C_w [IM_{j_{crit}-1}] \right]$$

$$+ \int_0^\infty B(V, V - V')[n_0(V')n_1^{\mathrm{P}}(V - V') + n_1^{\mathrm{P}}(V')n_0(V - V')]\mathrm{d}V' - n_1^{\mathrm{P}}(V) \times \int_0^\infty B(V, V')[n_0(V') + n_1^{\mathrm{P}}(V')]\mathrm{d}V' \tag{8}$$

$$\frac{\partial n_0(V,t)}{\partial t} = \rho[n_1^{\mathrm{P}} + n_1^{\mathrm{M}} - n_0] + k_{\mathrm{dM}}n_1^{\mathrm{M}} + \int_0^\infty B(V, V - V')[n_0(V')n_0(V - V') + n_1^{\mathrm{P}}(V')n_1^{\mathrm{P}}(V - V')]\mathrm{d}V' - n_0(V) \times \int_0^\infty B(V, V')[n_0(V') + n_1^{\mathrm{P}}(V')]\mathrm{d}V' \tag{9}$$

$$\frac{\partial n_1^{\mathrm{M}}(V,t)}{\partial t} = k_{\mathrm{tr}}C_{\mathrm{P}}n_1^{\mathrm{P}} + k_{\mathrm{eE}}[\mathrm{E}]n_0 - \left(k_{\mathrm{p}}^1 C_{\mathrm{P}} + k_{\mathrm{dM}} + \rho\right)n_1^{\mathrm{M}} \tag{10}$$

$$n(V,t) = n_1^{\mathrm{P}}(V,t) + n_0(V,t) + n_1^{\mathrm{M}}(V,t) \tag{11}$$

These coupled partial integrodifferential equations comprise the ''evolution equations'' for the latex particles in an emulsion polymerization process. In this mathematical description, an n_1^{P}-type particle is formed when an oligomeric radical enters an n_0-type particle and the monomeric radical propagates in an n_1^{M}-type particle to form a polymeric radical. Particles containing such polymeric radicals are consumed when an oligomeric radical enters an existing n_1^{P}-type particle, causing instantaneous termination. This process occurs with a rate constant ρ, the pseudo first-order rate constant, which describes all entry events. Alternatively, radical transfer to a monomer molecule transfers radical activity, and the resulting monomeric radical may undergo subsequent propagation or termination.

The population of n_0-type particles is increased by the entry of radicals (oligomeric or exited) into $n_1^{\mathrm{M}}$and n_1^{P}-type particles. They are also formed when monomeric radicals exit an n_1^{M}-type particle (a process that occurs with a rate constant k_{dM}). The population of n_0-type particles is decreased when oligomeric radicals enter an existing particle (to form an n_1^{P}-type particle), or when an exited radical enters to form an n_1^{M}-type particle.

Finally, n_1^{M}-type particles may be formed by chain transfer within particles containing a polymeric radical, and via the entry of exited monomeric radicals into n_0-type particles. These n_1^{M} particles are consumed through the propagation of radicals in existing particles, by the desorption of monomeric radicals from existing n_1^{M} particles, and by the entry of any type of radical into existing n_1^{M}-type particles.

Growth only significantly affects n_1^{P}-type particles, as radicals propagate without changing the particle's identity.

The entry processes, and hence the rate coefficients, k_{e}^i and $k_{\mathrm{e,micelle}}^i$, are assumed to be diffusion controlled (with an exponent of $\frac{1}{2}$ describing the chain length-dependent diffusion coefficient of small radicals). Given that oligomeric radicals (of degree greater than or equal to z) can only enter a micelle or preexisting particle, the entry coefficients can be calculated as follows:

$$k_{\mathrm{e}}^i(V) = 4\pi r_{\mathrm{s}}N_{\mathrm{A}}e_{\mathrm{e}}\frac{D_{\mathrm{W}}}{i^{1/2}} \quad i \geq z, \qquad k_{\mathrm{e}}^i(V) = 0 \quad i < z \tag{12}$$

$$k_{\mathrm{e,micelle}}^i(V) = 4\pi r_{\mathrm{micelle}}N_{\mathrm{A}}\frac{D_{\mathrm{W}}}{i^{1/2}} \quad i \geq z, \qquad k_{\mathrm{e,micelle}}^i(V) = 0 \quad i < z \tag{13}$$

In these equations, D_{W} is the diffusion coefficient for a monomeric radical in water, e_{e} is the entry efficiency, r_{micelle} is the radius of a micelle, and r_{s} is the radius of a latex particle swollen with monomer. Note that r_{s} is related to the unswollen radius, r, of a particle as follows:

$$\frac{r_{\mathrm{s}}}{r} = \left[\frac{d_{\mathrm{m}}}{d_{\mathrm{m}} - C_{\mathrm{P}}M_0}\right]^{1/3} \tag{14}$$

where d_{m} is the monomer density, M_0 is the monomer molecular weight, and C_{P} is the concentration of monomer in the latex particle. The entry coefficient for exited radicals can be defined in a similar fashion, as follows:

$$k_{\mathrm{eE}}(V) = 4\pi r_{\mathrm{s}}N_{\mathrm{A}}e_{\mathrm{e}}D_{\mathrm{W}} \tag{15}$$

The rate coefficient for desorption of monomeric radicals may be written as a function of the diffusivity of monomer both in the water phase and inside the particle, the aqueous monomer concentration, the monomer concentration in the particle, and the swollen radius:

$$k_{\mathrm{dM}}(V) = \frac{3D_{\mathrm{W}}D_{\mathrm{mon}}}{\left(\frac{C_{\mathrm{P}}}{C_{\mathrm{w}}}D_{\mathrm{mon}} + D_{\mathrm{W}}\right)r_{\mathrm{s}}^2} \tag{16}$$

The overall rate for entry, ρ, is derived from the following equation:

$$\rho = k_{\mathrm{eE}}[\mathrm{E}^\bullet] + \rho_{\mathrm{initiator}} \tag{17}$$

where $\rho_{\text{initiator}}$ is the rate of formation of ''z-mers'' obtained from

$$\rho_{\text{initiator}} = \sum_{i=z}^{j_{\text{crit}}-1} k_{\text{e}}^{i}[\text{IM}_i] \tag{18}$$

The propagational growth rate, $K(V)$, is defined by

$$K(V) = \frac{k_{\text{p}} M_0 C_{\text{P}}(V)}{N_{\text{A}} d_{\text{p}}} \tag{19}$$

where d_{p} is the density of the polymer.

The average number of radicals per particle, $\bar{n}$, is given by

$$\overline{n} = \frac{1}{\sum_{i=1}^{G} n(V_i)} \left(\sum_{i=1}^{G} n_1^{\text{P}}(V_i) + \sum_{i=1}^{G} n_1^{\text{M}}(V_i) \right) \tag{20}$$

while the total number of particles per unit volume, N_{tot}, can be calculated from

$$N_{\text{tot}} = N_{\text{A}} \int_0^{\infty} n(V)\mathrm{d}V \tag{21}$$

At high monomer conversion, the viscosity inside the polymer particles increases sharply and further polymerization becomes diffusion controlled. The particles are referred to as a glassy polymer and the kinetics for a zero–one system is no longer valid. To account for these changes, the propagation rate coefficient can be expressed as follows

$$k_{\text{p}} = 1/\left(1/k_{\text{p}_0} + 1/k_{\text{diff}}\right) \tag{22}$$

where k_{p_0} is the propagation rate coefficient at low conversion, while k_{diff} is the diffusion-controlled rate coefficient defined as

$$k_{\text{diff}} = 4\pi\sigma N_{\text{A}}(D_{\text{mon}} + D_{\text{rd}}) \tag{23}$$

where $D_{\text{rd}} = (1/6)\left(k_{\text{p}} C_{\text{p}} \alpha^2\right)$. The diffusion coefficient for the monomer (styrene in this case), D_{mon}, was expressed as a function of the polymer volume fraction inside the particle

$$\begin{aligned} D_{\text{mon}} &= 10\,\hat{}\,(0.417 - 29.51\phi_{\text{p}} + 53.14\phi_{\text{p}}^2 \\ &\quad - 36.03\phi_{\text{p}}^3) \quad \text{for } \phi_{\text{p}} < 0.8 \\ D_{\text{mon}} &= 9 \times 10^{-8} \exp(-19.16\phi_{\text{p}}) \quad \text{for } \phi_{\text{p}} \geq 0.8 \end{aligned} \tag{24}$$

An additional entry phenomenon can be brought forward at high ϕ_{p}, that is, entry of a z-mer into a glassy particle, is impeded because of slow diffusion through the interface. The hindered z-mer then desorbs back into the aqueous phase and may propagate to a j_{crit}-mer and cause secondary nucleation. Therefore, an empirical equation for the entry efficiency, $e_{\text{e}} = (1 - \phi_{\text{p}})^{C_{\text{p-sat}}}$, was used to model these changes. In a similar fashion, the termination rate coefficient is calculated from the empirical equation:

$$k_{\text{t}} = k_{\text{to}} \exp\left(-19\phi_{\text{p}}^{2.1}\right) \tag{25}$$

The instantaneous MWD can be calculated (over the conversion range) using:[24–27]

$$\begin{aligned} \frac{\partial \overline{P}(M)}{\partial t} &= P(M) = (k_{\text{tr}} C_{\text{P}} + \rho)\bar{n} \\ &\quad \times \exp\left(\frac{-(\rho + k_{\text{tr}} C_{\text{P}})}{k_{\text{P}} C_{\text{P}}} \frac{M}{M_0}\right) \end{aligned} \tag{26}$$

where M is the molecular weight of the polymeric chain.

For a semibatch process (as considered here), the rate of accumulation of monomer in the reaction vessel can be obtained from a molar balance equation

$$\frac{\mathrm{d}N_{\text{m}}}{\mathrm{d}t} = F_{\text{m}} - R_{\text{P}} V_{\text{r}} \tag{27}$$

where $R_{\text{P}} = k_{\text{p}} C_{\text{p}} (\bar{n} N_{\text{tot}}/N_{\text{A}})(V_{\text{w}}/V_{\text{r}})$ is the reaction rate and V_{r} is the total reaction volume, the latter being described by

$$\frac{\mathrm{d}V_{\text{r}}}{\mathrm{d}t} = M_0 R_{\text{p}} V_{\text{r}} (1/d_{\text{p}} - 1/d_{\text{m}}) + F_{\text{m}} M_0/d_{\text{m}} \tag{28}$$

Here, F_{m} is the monomer feed rate. At high feed rates, monomer droplets accumulate inside the reactor and the monomer concentration inside the particles reaches its saturation value. Therefore, C_{p} may be estimated as follows:

$$V_{\text{d}} = (N_{\text{m}} M_0 - C_{\text{w}} M_0 V_{\text{w}} - C_{\text{p}} M_0 V_{\text{p}})/d_{\text{m}}$$

where

$$\text{C}_{\text{p}} = \text{C}_{\text{p\_sat}} \quad \text{when } V_{\text{d}} > 0$$

and

$$\text{Cp} = N_{\text{m}}/V_{\text{p}} \quad \text{when } V_{\text{d}} = 0 \tag{29}$$

In Eq. (29), V_{d} is the droplet volume, the monomer concentration in the water phase is given by $C_{\text{w}} = C_{\text{p}} k_{\text{mwp}}$, while k_{mwp} is the partition coefficient of the monomer between the water and the polymer phases. In the same equation, V_{p} is the volume of the

polymer phase as calculated by

$$\frac{dV_p}{dt} = M_0 R_p V_r / d_p \quad (30)$$

Energy balance:

$$MC_p \frac{dT_e}{dt} = \sum_i F_i C_{p_i} (T_{amb} - T_e) + Q_f - Q_{loss} + Q_r + Q_s$$

where $\sum_i F_i C_{p_i}(T_{amb} - T_e)$ is heat flow due to feed input, Q_f is heat flux across the reactor wall, Q_{loss} is heat loss to the surroundings, Q_r is heat generation rate due to the chemical reaction, and Q_s is the heating due to stirring.

REACTOR OPERATION AND CONTROL

The reactor types commonly used for emulsion polymerization are:

- *Batch stirred tank reactor*: Low-volume products; flexibility to produce numerous grades (batch-to-batch variability); and homogenous (narrow MWD) or segregated (broad MWD).
- *Semibatch stirred tank reactor*: Similar to batch reactor but provides greater flexibility in operations and in obtaining the desired product characteristics.
- *Continuous reactor*: Single high-volume product; low operating costs; consistent quality (reduced flexibility); and broad MWD.

The current confidence in the design and scale-up of emulsion polymerization reactors is due to:

- The successful testing of a wide range of data with model predictions. For example, the models can successfully predict monomer conversions (see Fig. 4), molecular weight average and distribution (see Fig. 5), and particle size average and distribution (see Fig. 6) for batch and semibatch reactors. The results have also been verified for continuous reactors.
- The understanding of the dependence of particle diameter on initiator concentration and ionic strength below the CMC, and how the particle diameter varies with surfactant concentration above the CMC.
- The model has been used to analyze and improve performance for a range of emulsion processes.
- The substantial level of details (e.g., kinetics, PSD, MWD) that can be incorporated into reactor operation and control algorithms.[3]

OPTIMIZATION AND CONTROL OF EMULSION POLYMERIZATION

The challenges to be overcome in emulsion polymerization reactor optimization and control include the following considerations:[28–32]

- Multiphase media.
- Inadequate on-line measuring instruments.
- Effect of control on conversion and particle size are strongly interactive.
- Adaptive and decoupling control is needed.
- May exhibit limit cycle behavior.
- Control system must handle large, variable dead times, as well as severe nonlinearities.

Some of these challenges are overcome through the use of sophisticated models, complex algorithm application, and inferential measurements or use of soft-sensors.

MEASUREMENT OF VARIABLES

The relevant variables to be monitored in emulsion polymerization are temperature, flow rate, conversion, molecular weight, particle size, density, viscosity,

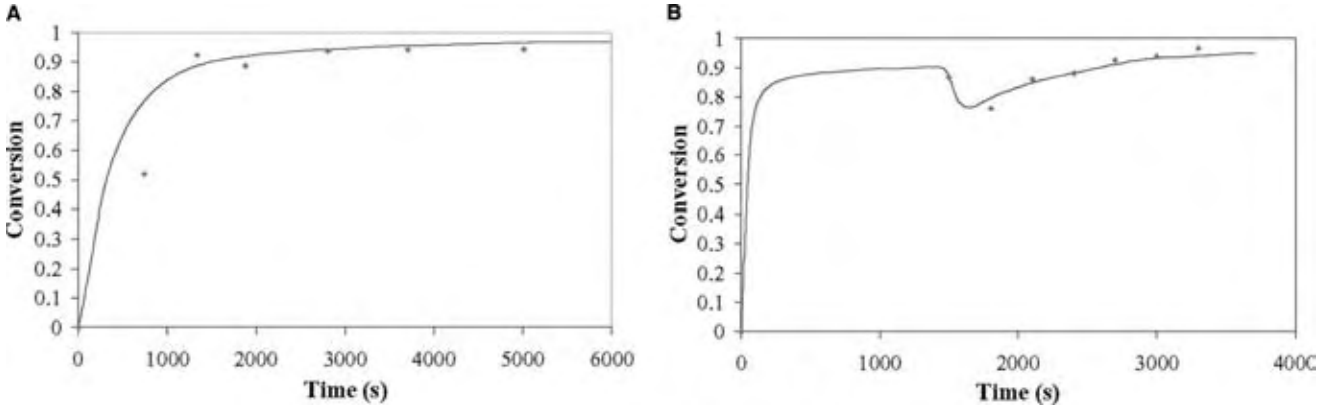

Fig. 4 Conversion profiles as a function of time for (A) batch and (B) emibatch operation. *(View this art in color at www.dekker.com.)*

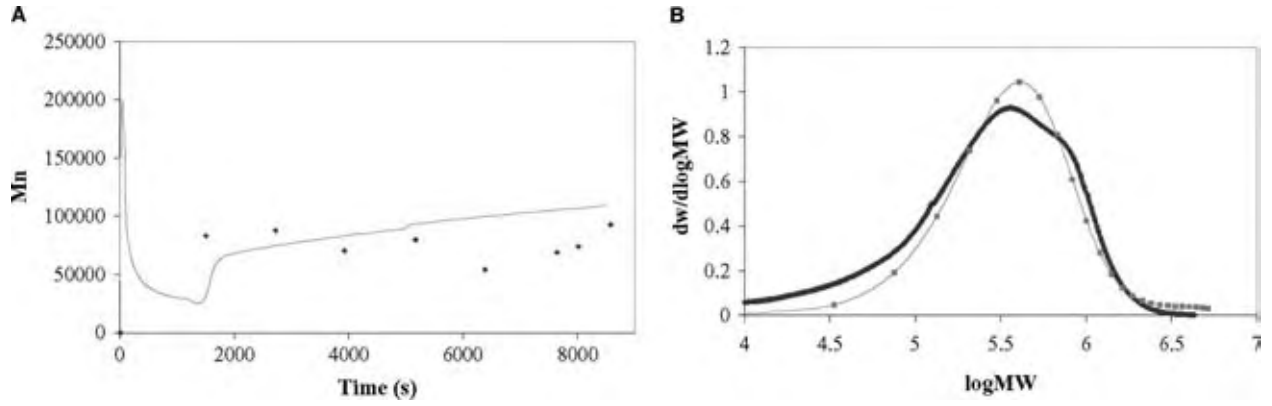

Fig. 5 Molar mass profiles for emulsion polymerizations: (A) number average and (B) distribution. *(View this art in color at www.dekker.com.)*

composition, etc. The measurement of an important process variable such as on-line conversion is a challenging task. Some of the measurement techniques tested, such as gravimetry (mass measurement), densitometry, chromatography, Raman spectroscopy, and NMR are off-line, suffer from inaccuracy, or are relatively expensive. Industrial and laboratory applications often rely on microcalorimetry, which does not share the above-mentioned disadvantages.

The measurement of particle size and molar mass distributions are typically carried out off-line with relatively expensive instruments. Techniques used for particle size include transmission electron microscopy, photon correlation spectroscopy, or capillary hydrodynamic fractionation and molar mass measurement with GPC.

MODEL PREDICTIVE CONTROL

The key polymer properties are heavily related to the polymer PSD and MWD, which are in turn highly sensitive to the process and kinetic history. Any disturbances in the operating conditions during normal operation may cause irreversible changes in the quality of the polymer formed. Therefore, adjustments may have to be made during reaction through an effective on-line control scheme. For this purpose the use of the dynamic matrix control (DMC) algorithm is studied in this entry for the on-line model based control of the PSD and MWD with different control formulations. An intelligent control hierarchy is formulated for such a distributed parameter system incorporating three different levels: off-line optimization, on-line DMC, and regulatory control successively.

At the heart of an model predictive control (MPC) application is the optimization of a variable subject to constraints. A typical MPC cost functional is given as follows:

$$J = \min_{\Delta u} \left[\sum_{i=1}^{P} \delta(y^{\text{setpoint}}(k+i) - y(k+i))^2 + \sum_{i=1}^{M} \lambda(\Delta u(k+M-i))^2 \right]$$

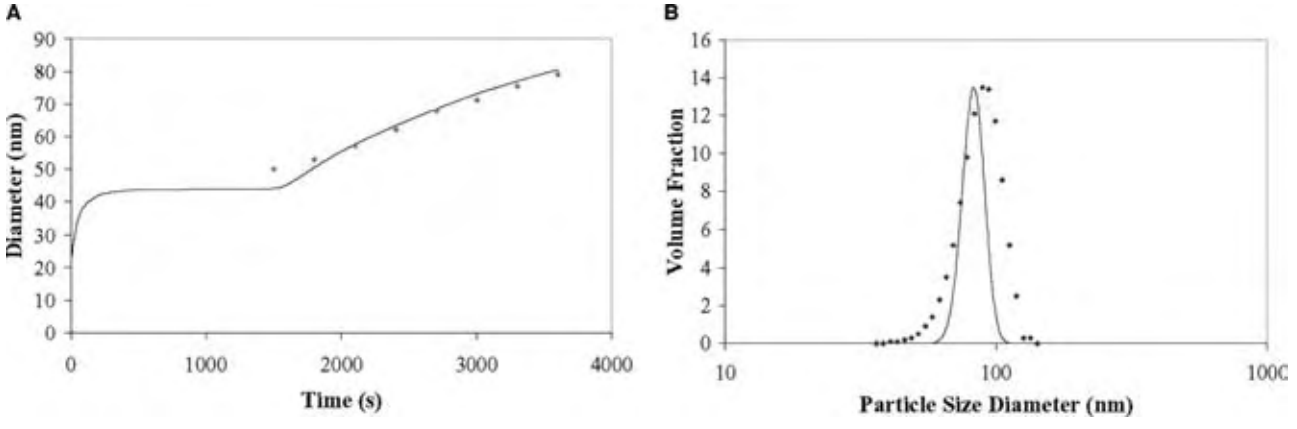

Fig. 6 Particle diameter for emulsion polymerization: (A) number average and (B) distribution. *(View this art in color at www.dekker.com.)*

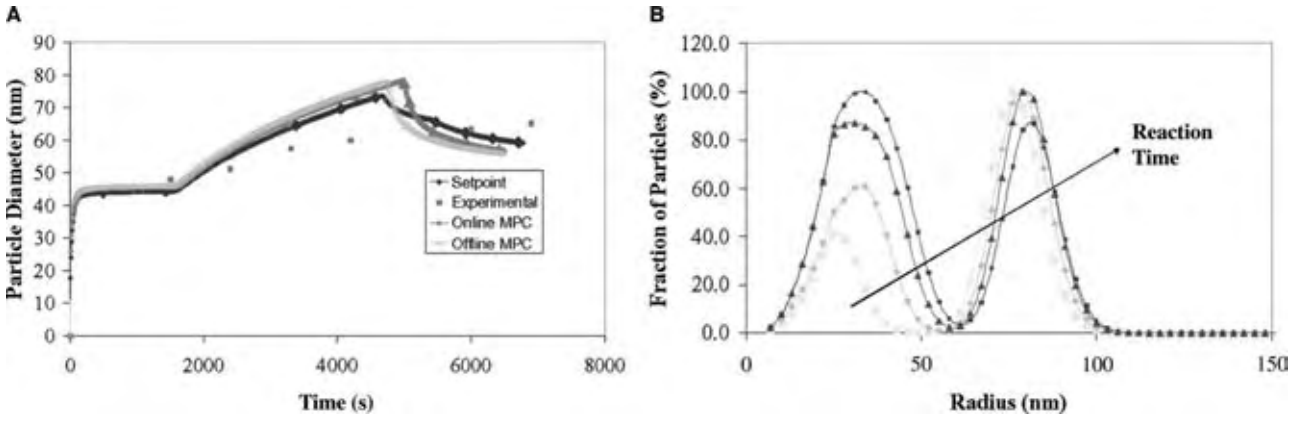

Fig. 7 Particle size control using on-line multivariable constrained MPC: (A) average particle diameter and (B) PSD. *(View this art in color at www.dekker.com.)*

subject to:

Constraints on input moves: $\Delta u(k) \in [\Delta u_{\min}, \Delta u_{\max}]$.

Constraints on input: $u(k) \in [u_{\min}, u_{\max}]$.

Constraints on output: $y(k) \in [y_{\min}, y_{\max}]$.

The weight on the error, δ, is a $P \times P$ diagonal matrix. Similarly, λ is the weight on the input (suppression move) and is an $M \times M$ diagonal matrix. The optimization problem is solved at every sampling time when a new prediction is updated by recent feedback measurements. Here, y^{setpoint} is a matrix of the set point values for the average radius, molar mass, and conversion.

The model predictions have been found to compare well with the experimentally controlled variables as shown in Figs. 7 and 8. Thus, the currently developed models show a high degree of accuracy and are suitable for process operation and control.

CONCLUSIONS

Emulsion polymerization is a powerful technique for developing products for a wide range of industry. The process can be used for the development of structured products in the nano- to microscales. Some of the key advantages of the process are the use of mild conditions, the near-complete conversion of monomers, the minimization of separation and recycling, the improved heat and mass transfer, and the improved environmental benefits due to the use of a water medium. However, the process is complex and requires careful modeling and scale-up. The prediction of process behavior, the key product properties, and the control of emulsion polymerization systems in particu-

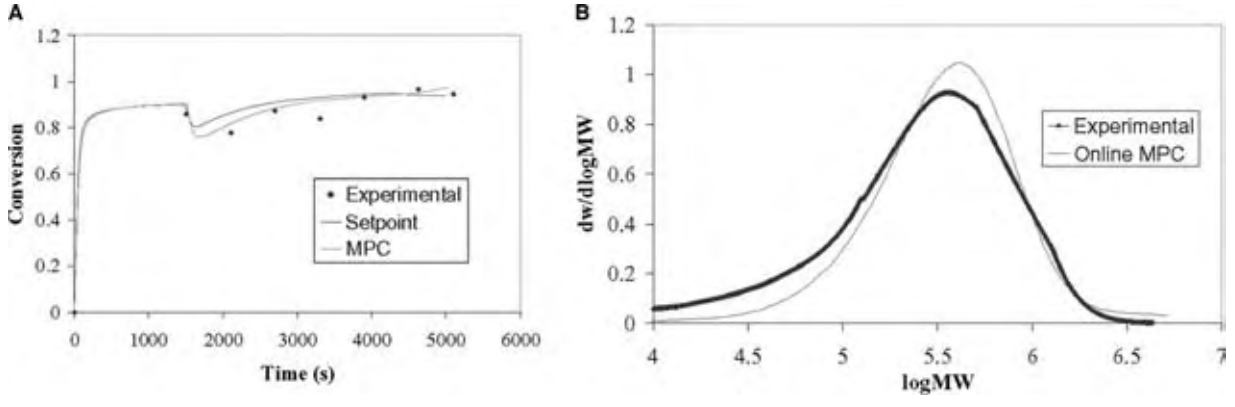

Fig. 8 Molar mass control using on-line multivariable constrained MPC: (A) conversion and (B) MWD. *(View this art in color at www.dekker.com.)*

lar require a thorough understanding of the mechanisms and the chemical subprocesses. In this respect, a good understanding of the reaction kinetics, the process stages or intervals, and the physicochemical transformations is essential.

Apart from the development of models suitable for predictive and control applications, some of the major challenges include accurate measurements of process variables that are particularly difficult to accomplish on-line. In this respect, the PSD and the MWD are particularly important, as they are factors that influence some of the most important properties of polymers, such as the surface coverage of coatings and the mechanical strength of the polymer product. However, the use of soft-sensors, the application of model predictions, and process control implementation for a varied number of systems have shown positive results. Several studies in the literature have demonstrated the efficacy of the model in adequately predicting the full PSD and the MWD of the polymer formed, over a wide range of reactor operating conditions. Further, the PSD and the MWD are controllable by varying the operating regime and the process conditions, such as temperature and flow rates of the monomers, initiators, and surfactants. Thus, the advanced operation and control of the process and some of the key products are now feasible. Consequently, on-line optimal control is gradually being implemented for the process.

NOMENCLATURE

a_s	Surface area of surfactant molecule (dm^{-2})
$B(V,V')$	Rate coefficient for coagulation of two particles of volume V and V and V′ (L/mol/sec)
CMC	Critical micelle concentration (mol/L)
$C_{micelle}$	Concentration of micelles (mol/L)
C_P	Monomer concentration in latex particles (mol/L)
C_{p_sat}	Saturated monomer concentration in latex particles (mol/L)
C_W	Monomer concentration in the water phase (mol/L)
C_{W_sat}	Saturated monomer concentration in the aqueous phase (mol/L)
d_m	Density of monomer (kg/L)
d_p	Density of polymer (kg/L)
D_W	Diffusion coefficient for monomer in water (dm^2/sec)
[E]	Aqueous phase concentration of desorbed radicals (mol/L)
F_m	Monomer feed to the reactor (mol/sec)
$[IM_i]$	Aqueous phase concentration of oligomeric radicals of degree i (mol/L)
j_{crit}	Critical degree of polymerization for homogenous nucleation
K	Rate of propagation (volume growth per particle) (L/sec)
k_d	Rate coefficient for initiator decomposition (s^{-1})
k_{dM}	Rate coefficient for desorption of monomeric radicals from particles (s^{-1})
k_e^i	Rate coefficient, entry of oligomeric radical of degree i into existing particle (L/mol/sec)
k_{eE}	Rate coefficient for reentry of desorbed radicals (L/mol/sec)
$k_{e,micelle}^i$	Rate coefficient for entry of an oligomeric radical of degree i into a micelle (L/mol/sec)
k_p	Long chain limiting propagation rate coefficient in the latex phase (L/mol/sec)
k_p^1	Monomeric radical propagation rate coefficient in the latex phase (L/mol/sec)
$k_{p,aq}^i$	aqueous phase propagation rate coefficient for oligomeric radicals of degree i (L/mol/sec)
k_{mwp}	Partition coefficient for styrene between the water phase and polymer phase
$k_{t,aq}$	Rate coefficient for termination reaction between oligomeric radicals in the aqueous phase (L/mol/sec)
k_{tr}	Rate coefficient for radical transfer to monomer (L/mol/sec)
M_0	Monomer molecular weight (kg/mol)
$\bar{n}$	Average number of radicals per particle
n_{agg}	Surfactant agglomeration number
N_m	Number of moles of monomer
N_{tot}	Total number concentration of particles (1/L)
r	Radius of latex particle (dm)
R_P	Polymerization reaction rate (mol/L/sec)
r_s	Swollen radius of latex particle (dm)
V_d	Volume of monomer in droplets (L)
V_M	Volume of monomer in system (L)
V_P	Volume of polymer in system (L)
V_r	Total reaction volume (L)
V_W	Volume of water in the system (L)
z	Critical degree of polymerization for entry
σ	van der Waals radius of a monomer unit (dm)

INTRODUCTION

More than half the original oil typically remains in oil reservoirs after primary and secondary recovery operations. Primary recovery refers to production of oil because of its natural energy; fluids expand as pressure falls to push out some oil and gas. Expansion of associated aquifers and gas caps also help in pushing out oil. Primary recovery efficiency varies greatly from reservoir to reservoir and is typically in the range of 5%–20%. Secondary recovery refers to injection of immiscible fluids, such as water and gas, to recover oil. These fluids displace oil from the pore space immiscibly. Secondary recovery efficiency is typically another 10–20%. Oil is left behind in bypassed regions as well as in swept zones. Oil is bypassed in certain zones of the reservoir because of permeability heterogeneity, lack of conformance at the wells, pattern orientation, and sometimes-viscous fingering. Oil is also left behind in the swept zones because of capillary forces in immiscible displacements during secondary recovery. Tertiary recovery techniques (also called enhanced oil recovery (EOR) techniques) are needed to recover additional oil from existing fields.

MISCIBLE GAS INJECTION PROCESSES

Process Description

Miscible flooding is one of the commercially successful improved recovery methods. It constitutes the injection of CO_2, hydrocarbon gases, and even nitrogen or flue gas.[1] Typically 10–50% PV of the injectant is injected in the case of CO_2 or hydrocarbon gases. A much larger amount of nitrogen or flue gas can be injected because they are cheaper. These gases can be injected in different modes: miscible gas injection followed by dry gas injection, miscible gas injection followed by water injection or water–alternating-gas (WAG) injection. The individual slug size in the WAG injection is in the range of 1–5% and typical WAG ratio is 0.5–5. Incremental production cost for CO_2 flooding is estimated to be between \$2 and \$8 per barrel of oil.[a]

Recovery Mechanisms

Gas flooding recovers oil by reducing residual oil saturation and oil viscosity, and oil swelling.[2] When two fluids are miscible, interfacial tension disappears and capillary forces do not exist. Thus, residual saturation of a displaced phase is zero in completely miscible floods. Oils can be solubilized by solvents and recovered. When the solvent is a gas, e.g., CO_2 or enriched gas, it develops miscibility at high pressures, often greater than 1200 psi at reservoir temperatures. The pressure needed for miscibility must be lower than the fracture pressure of the formation. The reservoir should be deep enough to accommodate this pressure. Availability of suitable miscible solvents is often a constraint. Large deposits of CO_2, present in the West Texas and mid-continental areas, have promoted many CO_2 floods in that region. Miscible hydrocarbon solvents are available in some reservoirs to a limited extent from its associated gas or gas in neighboring fields, and hydrocarbon gasflood processes are used in those reservoirs. Air and nitrogen are available widely but need very high pressure or depth to develop miscibility.

Gas injection can also recover oil by reducing oil viscosity and residual oil saturation,[2] even when miscibility is not achieved. Reduction in viscosity is more significant if the oil viscosity is large, and this process is attractive in viscous or semiviscous reservoirs, especially when accompanied by some other improved recovery mechanism. Residual oil saturation in three-phase flow in water-wet rock is very low (essentially zero), even at very low capillary numbers.[3] Two main problems in such a process are the low relative permeabilities and sweep efficiencies. This process can be implemented in a highly dipping reservoir to take

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007753

advantage of gravity. Three-phase immiscible residual gasfloods are not that low for other wettability and spreading conditions.[4] The key advantage of immiscible processes is the cost of the solvent, as solvents are cheap.

Phase Behavior and Miscibility

Mixtures of oil and gases form one, two, or even three hydrocarbon fluid phases.[1] This does not include a solid phase or asphaltene, which can also be present. When the mixture is one phase irrespective of the ratio of the oil and gas, the solvent is called first contact miscible (FCM) with the oil. This happens with most gases at very high pressures. If the pressure or enrichment is lower, solvents may not be first-contact miscible, but can still displace the oil in a one-dimensional tube by forming a transition zone of fluid compositions that range from the oil to injection fluid composition, all within a single phase. One of the tielines shrinks to zero length in this composition path. Such a solvent is called multiple-contact miscible (MCM). Multi-contact miscibility can be developed by vaporizing, condensing, or condensing–vaporizing mechanisms.[5] If oil is displaced by a solvent at a lower pressure or enrichment, multiple phases exist at all points of the transition zone, and these are termed immiscible.

The multicontact miscibility development by a vaporizing mechanism is illustrated in Fig. 1. The pseudoternary diagram shows light (L) components (CO_2, CH_4), intermediate (I) gases (C_2–C_5) and heavy (H) components (C_{6+}) in the vertices. The critical point on the two-phase diagram is denoted by C. Oil and solvent compositions are denoted by O and S, respectively. As oil and solvent mix at oil–solvent front, two phases form, as shown by L1 and G1. The gas moves ahead being less viscous and mixes with original oil. This produces a two-phase mixture that forms compositions shown by L2 and G2. G2 moves ahead and mixes with oil. This process repeats itself and the gas composition moves along the phase diagram along the red line, which eventually is first contact miscible with the oil near the critical point. This is possible if the pressure is high enough. The MCM development by a condensing mechanism is illustrated in Fig. 2. Multi-contact miscibility can be developed by a vaporizing or a condensing mechanism if the oil composition and the solvent composition lie on opposite sides of the critical tie-line shown by CA'. This is possible by high enough pressure or enough enrichment of the solvent.

The enrichment (or the pressure) needed to develop miscibility between the injectant and the oil is determined experimentally in one-dimensional slim-tube tests.[1] As the enrichment (or pressure) increases, the slim-tube recovery reaches a plateau long before first contact miscibility is developed. This enrichment is called the minimum miscibility enrichment, or MME, which is a function of reservoir pressure, temperature, and contaminants in the solvent. Similarly, a pressure called the minimum miscibility pressure, or MMP, can be identified for any solvent. Other experimental methods (e.g., rising bubble method) are also available to determine MMP or MME. In vaporizing three component systems, MMP (or MME) corresponds to the pressure (or enrichment) at which the critical tie line passes through the crude oil composition. In condensing three component systems, MMP (or MME) corresponds to the pressure (or enrichment) at which the critical tie line passes through the solvent composition.[5]

Several correlations have been developed in the past to estimate MME and MMP from the compositions of oil and solvent and the reservoir temperature.[1,6] Generally, the MMP increases with the temperature and the molecular weight of the oil heavy fraction. Carbon dioxide must achieve a certain density to develop with a crude oil. This required density is a function of the heavy fraction content. Nitrogen and CH_4 increase CO_2 MMP; H_2S decreases it. The solvency is increased if CO_2 is diluted with an impurity, whose critical

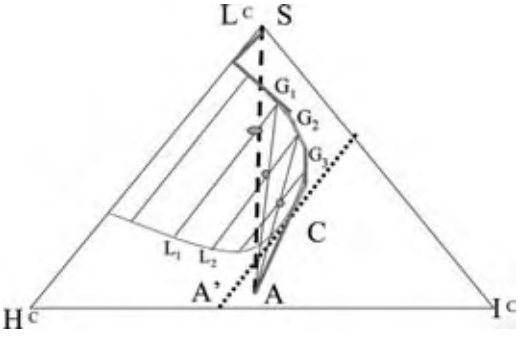

Fig. 1 Compositional path in vaporizing multi-contact miscible flood. *(View this art in color at www.dekker.com.)*

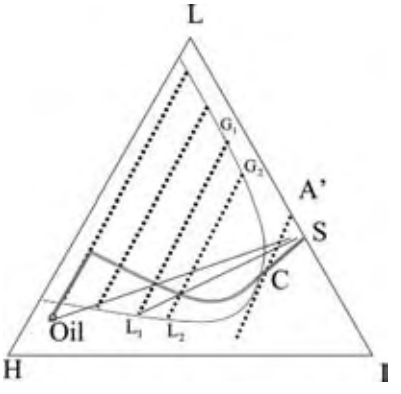

Fig. 2 Compositional path in condensing multi-contact miscible flood. *(View this art in color at www.dekker.com.)*

temperature is higher than that of CO_2. Sebastian[7] has developed a correction to CO_2 MMP in terms of the critical temperatures of the impurities. Benham et al.[8] give correlations of MME or MMP for hydrocarbon gases. The MME depends on the temperature, pressure, and molecular weight of the intermediate components in the solvent and molecular weight of the C_{5+} fraction in the crude oil.

Many relatively shallow reservoirs, especially those in Alaska and some in West Texas, are at temperatures below 50°C. In such reservoirs, three hydrocarbon fluid phases (L1-L2-V) form when oil and solvents mix.[9] Slim tube recoveries greater than 90% can be observed in such fluids with hydrocarbon solvents, even when three fluid phases form. Although true miscibility did not develop, high oil recovery rates were observed through the condensing–vaporizing mechanism. These solvents also had high coreflood recoveries.

Bypassing in Multidimensional Floods

The mobility ratio and density contrast is large in most solvent floods. Sweep efficiency can be low because of rock heterogeneity, viscous fingering, and gravity override, and it plays a crucial role in determining the overall recovery efficiency.[1] To understand this process, one needs to model the amount of bypassing and the resulting mass transfer between bypassed and fingered fluids. In one-dimensional displacements, MME and MMP are the optimum levels of enrichment or pressure for the solvent. However, reservoir flow is three-dimensional and the optimum enrichment (or pressure) can be different from that of the one-dimensional flood in a slim-tube.[10] Injected solvent composition (or pressure) affects not only the local displacement efficiency, i.e., that evaluated by one-dimensional corefloods, but also the sweep efficiency.

Bypassing must be reduced in all gasfloods. There are several techniques to reduce bypassing—WAG, foams, and polymers.[11] Field tertiary gasfloods are often conducted with alternating water, called WAG scheme. Injection of water and solvent slows both the solvent and the water, as they block each other at the pore-scale. Efficiencies of WAG schemes depend on the WAG ratio, slug size, and rock wettability. Optimum WAG ratios are often determined from fractional flows in homogeneous cores. The traditional fractional flow analysis for WAG ratio is not valid in heterogeneous rocks. Stern[12] found that CO_2 WAG displacements were quite effective at high WAG ratios in mixed-wet rocks.

Foams and polymers have been studied in the past without much field-scale success. Surfactant water is injected into the reservoir alternating with the miscible injectant to produce foams. The foams used in the near-wellbore region are designed to be strong and do work. It has been very difficult to design weak foams that propagate through the reservoir and move the solvent banks in a stable manner. Surfactant loss (because of adsorption and otherwise) and cost are some of the major problems. Polymers or other chemicals that are directly soluble in the solvent have been used to increase the viscosity and the density of the solvent. However, cost is the key limiting factor.

Screening Criteria

CO_2 flooding is applicable to reservoirs with relatively light oil (gravity >25 API, viscosity <15 cp, and high amounts of C_5–C_{20} in oil).[13] The formation can be either sandstones or limestones. The reservoir pressure should be high (>1200 psi for high gravity oil to >4500 psi for low gravity oil). This implies that the reservoir should be deep enough. The reservoir should be relatively thin or dipping. A high degree of heterogeneity lowers the efficiency of the process. The temperature is not that critical, but the minimum pressure required for miscibility increases with pressure. Hydrocarbon gas injection works in similar reservoirs except with slightly lighter oils (gravity >35 API). Nitrogen and flue gas require much higher pressure to develop miscibility. Thus, they are applied to deeper reservoirs (>4500 ft) with light oils (>35 API for nitrogen and 25 API for flue gas).

Field Experience

CO_2 and hydrocarbon gas flooding remain popular methods to recover oil. Between 1982 and 1992, oil production from gas floods increased from 72,028 to 296,020 b/d in the United States.[14] The latest data can be found in the review of EOR projects published by *Oil & Gas Journal* every two years. In 1992, there were 45 active CO_2 miscible projects in the USA.[15] About 2.4 BCF/D of CO_2 was being injected into these reservoirs. About 40% of this gas was being produced and reinjected. The incremental production response was about 142,000 b/d of oil. The industry had booked about 1.9 billion barrels of oil because of CO_2 flood. Hydrocarbon flooding has been used in Prudhoe Bay field in Alaska, Block 31 field in West Texas, and Hassi-Messaoud field in Algeria, to give a few examples.

One of the key factors for feasibility of a CO_2 flooding project is the availability of large amounts of CO_2. The 45 projects discussed here are located near large natural deposits of CO_2 gas. The main area of activity has been the Permian Basin area of the West Texas and New Mexico. The main sources of CO_2 supply for these projects have been McElmo Dome, Sheep Mountain, and Bravo Dome, which contain between 20 and 40 TCF of

CO_2. In northwest region, LaBarge field, which supplies to several CO_2 floods, contains about 20–60 TCF of CO_2.

Oil recovery has been significantly enhanced by the injection of CO_2 and hydrocarbon gases. The typical incremental oil is about 8–14% OOIP for tertiary injection. For example, the SACROC field quadrupled the oil production rate and produced more than 10% of the OOIP. In secondary injections, for example, in Block 31 field in Texas, the oil recovery is close to 60% of the OOIP. Improved reservoir management in the preparation of CO_2 flood also added to improved recovery. For example, in the Means field, well spacing was changed from 20 acre/pattern to 10 acre/pattern and five-spot to inverted nine-spot. These changes increased oil production rate from 7,000 to 10,000 b/d, even before CO_2 injection. 35% of the EOR oil was produced because of improved reservoir management.

CO_2 injection leads to early breakthrough, but the oil production continues beyond breakthrough. CO_2 utilization was about 7–10 MCF/BBL. Two-thirds of the injected CO_2 was recovered. CO_2 production can be curtailed by the use of WAG and polymers and foams. CO_2 utility rate in the field are often in line with the simulation indicating that CO_2 displaces the trapped residual oil. CO_2 injectivity in WAG floods was an industry concern. The field tests have shown that loss of injectivity is minor and manageable. Post CO_2 flood-water injectivity was higher than the original water injectivity in several reservoirs. Water blocking is not found to be an issue in WAG floods. Corrosion problems are manageable if separate CO_2 injection line, SS wellheads and fiberglass gathering system are used. Asphaltene problems are negligible, except during early CO_2 breakthrough.

THERMAL METHODS

Process Description

The two main thermal recovery processes are steam injection and in situ combustion. In the steam injection process, steam of 80% quality is injected into the reservoir to displace oil. The steam can be injected continuously (called ''steam drive'') or intermittently (called ''cyclic steam injection''). In the steam drive process, steam is injected in several injection wells and the oil is produced in several production well. In cyclic injection process, steam is injected in several (previously producing) wells for 2–6 weeks, soaked for 3–7 days, and produced back for a few weeks or months. This cycle can be repeated several times. Often, the steam flood is preceded by cyclic injection. Steam injection has been used commercially for several decades. In fire flooding or in situ combustion process, air is injected and ignited inside the reservoir. A combustion front propagates through the reservoir pushing the oil out through production wells. A part of the oil is burnt to provide the energy to push the oil out. The variations of this process are wet combustion (where water is injected in the injection well after establishment of the combustion front) and reverse combustion (where the injection and production wells are switched after the establishment of the combustion front). The main attraction of this process is that it uses the most available and the cheapest fluid (air) as the injectant. The in situ combustion method has been field tested, but not commonly used commercially. Incremental production cost for steam injection and in situ combustion are estimated to be \$3–6 and \$5–10 per barrel of oil, respectively.[b]

Recovery Mechanisms

In steam injection, temperature of the oil is increased, which lowers the oil viscosity, thereby making it easier for oil to flow.[16] In fact, four distinct zones develop during steam flooding. The zone close to the injection well is the steam-saturated zone; oil saturation is reduced here to residual oil saturation (typically less than 0.2). The zone just ahead of the steam zone is the condensing zone; hot water at the boiling temperature is formed from condensation of steam. Ahead of this zone is the hot water zone, where the temperature decreases upstream from the boiling temperature to the reservoir temperature. Ahead of the hot water zone is the oil bank at its original reservoir temperature. Some amount of gravity override takes place because steam is lighter than water and oil. Steam distills lighter components from the oil, which move downstream and condense into oil as temperature falls enriching the downstream oil. This process also reduces the viscosity. The oil also swells in the heated zones, thus, reducing the amount of oil left behind. Cyclic steam stimulation increases oil recovery by reduction of viscosity, wellbore cleanup of asphaltic/paraffinic material, and pressure gradient because of the presence of injected steam.

In situ combustion recovers oil by reduction of viscosity, upgradation of the oil, reduction of residual oil, in situ steam flooding, in situ miscible flooding, thermal expansion, and wettability changes.[17] The oil is ignited with the injected air or oxygen. The combustion zone moves toward the production well as long as oxygen is supplied to it. Temperature increases to 600–1200°F, deposited coke is burnt by the oxygen, and hot gases with steam are formed. Downstream of the combustion zone is a vaporization zone, where water and lighter hydrocarbons from oil are vaporized,

[b]Taken from the website wysiwyg://256http://www.fe.doe.gov/oil_gas/res_efficiency/res_progareas.shtml

heavier hydrocarbons are thermally cracked, and coke is deposited. Steam, CO_2, and hydrocarbon gases move forward because of their lower viscosity, cool down by the existing oil/reservoir, and form a condensation zone ahead of the vaporization zone. The oil is enriched by the light hydrocarbon gases/CO_2 and its viscosity is lowered. The residual oil is reduced because the oil is enriched. Water saturation increases because of steam condensation. This water bank pushes the oil downstream. A part of the oil is burnt in the process and is never recovered.

The two main problems in these processes are bypassing and heat loss. Both in situ combustion and steam flooding are affected by gravity override because the injected fluid (air or steam) is lighter than the existing oil. The bypassing problem is more severe in the case of in situ combustion. Condensation has a stabilizing effect on the steam fronts. Steam foams have been developed to reduce bypassing for steam floods. Heat losses from the surface equipment, in the wellbore, to the surrounding formation and the water represent significant energy loss in steam floods. To reduce heat loss, the equipment and well bore should be insulated. By increasing the injection rates, the amount of heat loss as fraction of the total heat input can be reduced. This implies the patterns should be relatively small. Also the application of steam floods is restricted to shallow wells (<1000 m).

Screening Criteria

Steam flooding is applicable for viscous oil reservoirs. The oil gravity should be less than 25°API and the viscosity greater than 20 cp.[13] Oil composition is not critical, but having some light ends helps in steam distillation at the back of the displacement front. The reservoir should be thick (>20 ft) and the oil saturation should be high (>50% PV). Sand or sandstone is preferred with high porosity and high permeability (>200 md). The depth should be low (<4000 ft) to minimize the heat loss in the wells. The temperature is not that critical for steamflooding. For in situ combustion, the oil gravity should be between 10 and 40°API. Viscosity should be less than 1000 cp. Having some asphaltic components in the oil helps in coke deposition. The reservoir should be thicker than 10 ft and the oil saturation should be high (>50% PV). Sand or sandstone with high porosity and high permeability (>100 md) is preferred. The depth should be greater than 500 ft. The temperature should be higher than 150°F.

Field Experience

Steam flooding has been practiced in oil fields for many years. Between 1982 and 1992, oil production from steam flood increased from 288,396 to 454,009 b/d.[14] The number of projects remained almost flat at about 118. In situ combustion was much less popular. The oil production from in situ combustion decreased from 10,228 to 4,705 b/d. In Kern River field, California, cyclic steam injection, steam flood, and steam foam have been applied quite successfully.[18] This reservoir is relatively shallow (<1000 ft) and thick (70 ft). The porosity is high (~35%) and so is the permeability (~7600 md). The oil is heavy (13 API). The recovery was 6.8% with primary production, 15% with cyclic steam injection, 28.7% with steam flood, and additional 14% with subsequent steam foam injection. This test showed that steam flooding could be successful; gravity override is significant, but can be curtailed by foam injection. In the Midway-Sunset field, California, in situ combustion process has been tested.[19] This reservoir is an anticline with a dip of 20–45. It is about 130 ft thick at a depth of 2100–2700 ft. The oil is 14.5 API. The primary production is about 17% of OOIP. Ten years of air injection produced 24% OOIP. Gravity stabilization helped stabilize the in situ combustion process. Other technically successful pilots have been conducted elsewhere.

CHEMICAL METHODS

Chemical methods of EOR are usually carried out by using water or brine as the carrier fluid. The exception is foam flooding, which also involves an immiscible gas as the driving fluid. Although various chemical methods can be used by themselves, studies have shown synergism in their combined application.

Polymer Flooding

The idea behind this method is to reduce the driving fluid mobility relative to the oil using high molecular weight polymers.[20] Bypassed oil is reduced, thereby increasing production. From the early studies in the 1960s, it was evident that compared to water flooding, the addition of certain high molecular weight polymers in the driving fluid (water or brine) at relatively low concentrations (in the hundreds of ppm only) reduces the occurrence of fingering or channeling in both areal and vertical sweeps. Essentially, when the polymer solution enters the high permeability zones, the mobility decreases.[21–23] This allows the flow to occur within the low permeability zones.

Materials that are popularly used in polymer flooding are based on ionic polyacrylamides (PAM) and xanthan.[20] Ionic PAM is obtained either by free-radical polymerization of acrylamide monomer with subsequent hydrolysis or by free-radical copolymerization

of acrylamide and acrylic acid monomers followed by neutralization of the acrylic acid segments with sodium hydroxide. The degree of hydrolysis or fraction of ionizable groups ranges from 15% to 35%. Weight average molecular weights are in the order of 10^7 Daltons, and polydispersity indices are in the 2–3 range. In solution, these polymers attain the conformation of isolated chains in a dilute concentration, overlapping chains in the semidilute regime, and entangled network in concentrated regime. Xanthan, a biopolymer, is produced by fermentation of the bacterium *Xanthamonas campestris*. Weight-average molecular weights are in the $4–5 \times 10^6$ Dalton range, and they are monodisperse with polydispersity indices between 1.3 and 1.5. In water or brine solution, xanthan attains a double-stranded conformation stabilized by hydrogen bonds.

Flow characteristics within cores are both shear and elongational because of the presence of converging and diverging zones in the rock matrix. Polymer solutions, under these conditions, will exhibit both shear thinning and shear thickening behavior. Below a certain critical shear rate, the behavior is purely shear thinning. However, above the critical shear rate, shear thickening becomes dominant because of elongational effects. This is borne by the fact that elongational viscosities have been found to be as high as 10^4 times zero-shear viscosities.

Retention of the polymer within the rock matrix can occur with varying effects. There are three known retention mechanisms in the absence of polymer degradation: adsorption, mechanical entrapment, and hydrodynamic retention.[20] Thermodynamically, adsorption involves the removal of water molecules and small ions from the rock surface, and replaced by the polymer. This will occur if the Gibbs free energy change, ΔG, is negative. As ΔG depends on the enthalpy change ΔH, the temperature T, and entropy change ΔS, based on the following equation

$$\Delta G = \Delta H - T\Delta S \quad (1)$$

a decrease in the entropy must be offset by an increase in enthalpy to prevent adsorption. The positive entropy change occurs because of the removal of water molecules and small ions from the surface; adsorption of polymer chains results in only a slight loss in chain conformation. For a positive enthalpy change, anionic polymer species are needed if the rock surface is also anionic. This is the case with ionic PAM in most sandstone formations. In terms of adsorption rate, lower molecular weight polymer species are favored to reach the rock surface. Eventually, higher molecular weight species reach the surface and tend to adsorb more than their lower molecular weight counterparts. Usually, adsorption is delayed by minutes to weeks because of the time it takes for polymer species to reach the solid surface.

Mechanical entrapment occurs when larger polymer molecules cannot pass through smaller pore throats. On the other hand, hydrodynamic retention occurs when the polymer concentration increases at pore entrances, thereby reducing the polymer translational diffusion rate. In severe circumstances when the polymer solution contains microgels, hydrodynamic retention can result in cake formation leading to polymer plugging.

Polymer degradation within the rock matrix can occur by chemical-, mechanical-, and biological-based mechanisms. Their detriment is viscosity reduction. For ionic PAM and xanthan polymers, chemical degradation can occur through free radical and hydrolytic attack. Ionic PAM is usually prone to free radical-based chain scission degradation because of its relatively high molecular weight. Free radicals are formed from reducing agents, traces of transition metal catalysts, and oxygen. Usually, hydroperoxides are formed, which can also cause propagation reactions. Hydrolytic attack occurs in the acrylamide segments of ionic PAM at high and low pH values, especially at relatively high temperatures. Even at neutral pH at relatively high brine concentrations, ionic PAM precipitates because of the exchange of sodium ions on the polymer with calcium and magnesium ions in the brine.

Mechanical degradation is based on the elongational flow of the polymer solution. It occurs in ionic PAM because of its relatively high molecular weight, while xanthan seems to be stable to mechanical degradation.

Bacterial-based degradation of polymers occurs during storage or in cooler regions of the reservoir. Usually, biocides are used, but they readily adsorb on rock surfaces.

Based on overall performance, as well as problems encountered, incremental production cost of polymer flooding is cited to be between \$5 and \$10 per barrel of oil.[c]

Alkaline Flooding

As the presence of multivalent salts normally results in flocculation of the polymers used in chemical-assisted EOR, the introduction of a monovalent alkaline solution has been employed. As a separate downstream slug, alkaline solutions are normally used as sacrificial materials to obtain synergistic effects with surfactant and polymer flooding methods. Alkaline materials that

Table 1 Trends for material and external variables that promote Type III surfactant behavior

Material and external variables	Trends that promote Type III behavior
Oil	Decrease in molecular weight Decrease in branching (aromaticity)
Brine	Increase in salinity Increase in divalent/monovalent ratio Decrease in pH (for carboxylated surfactants)
Amphiphiles	Increase in molecular weight (or branching) of surfactant-hydrophobic part Decrease in polarity of surfactant-hydrophilic part Increase in long-chain alcohol concentration Decrease in short-chain alcohol concentration
External variables	Decrease in temperature (for anionic surfactants) Increase in temperature (for nonionic surfactants) Decrease in pressure

(From Ref.[27].)

are commonly used include.[24] sodium hydroxide, potassium hydroxide, sodium orthosilicate, sodium metasilicate, sodium carbonate, and potassium carbonate.

At the outset, it was noted that alkaline agents lower the interfacial tension (IFT) within the reservoir.[25] The accepted IFT-lowering mechanism is the neutralization of carboxylic acid-containing compounds (asphaltenes and resins) in the oil to form surface-active agents.[26] Mobility control can be affected by the design of a combination of monovalent and divalent cations resulting from the action of the alkaline agent solution. Surfactants produced from monovalent alkaline cations tend to be oil-in-water (O/W) types, while divalent alkaline cations result in water-in-oil (W/O) surfactants. The optimum is somewhere in between, which forms a bicontinuous micellar structure. This condition is difficult to uniformly attain across the reservoir because of consumption of monovalent cation alkaline material through ion exchange with hard brine, formation of divalent cations from the rock surfaces at high pH, and precipitation followed by coalescence of divalent-based surfactants produced from the oil. Such control difficulties make alkaline flooding design site specific at best, and it is better to effect mobility control by some other means, such as the use of a surfactant slug. Eventually, alkaline agents have been found to be more conveniently used as a preflush or as a leading slug before the surfactant slug.

Surfactant Flooding

This method is also known as micellar flooding, microemulsion flooding, or low tension water flooding.[27] The primary effect of the use of surfactants is the lowering of the interfacial tension between the driving fluid and the oil. More formally the capillary number, N_c, is defined as

$$N_c = \frac{\mu V}{\sigma} \tag{2}$$

where V is the interstitial fluid velocity, μ is the fluid viscosity, and σ the interfacial tension, must be increased by three or four orders of magnitude from a critical $N_c = 10^{-6}$. Amphiphilic surfactant molecules partition themselves at the oil–water interface to achieve this effect; their hydrophilic heads locate themselves in the water side, while their hydrophobic tails locate themselves in the oil side of the interface. Surfactants used in EOR normally have anionic hydrophilic heads, which tend to have lower adsorption on reservoir rock. Also, anionic surfactants are normally available in large quantities at a lower cost when compared to nonionic and cationic surfactants. Chemically, anionic surfactants commonly used in micellar EOR are sodium alkylsulfates or sodium alkylarylsulfonates. One drawback of anionic surfactants is their salt sensitivity, especially to multivalent cation salts. In hard brines, ion exchange between the sodium counterion in anionic surfactants and calcium (or magnesium and iron) in the brine causes the surfactant to coagulate. Thus, nonionic surfactants and anionic surfactants with ethoxy and propoxy groups have been studied extensively for EOR applications because of their higher salt tolerance when compared to anionic surfactants.

From a morphological standpoint, surfactants are oil-in-water (O/W) type, water-in-oil (W/O) type, or somewhere in-between.[27] O/W surfactants form micellar domains in water, within which contain oil particles; this is called the Windsor Type I structure. W/O surfactants form micellar domains in oil, within which contain water particles; this is called the Windsor Type II structure. The so-called Windsor Type III structure is bicontinuous in nature, and it is preferred

because of its relatively low interfacial tension and relatively high viscosity. Table 1 shows the various factors that promote Type III behavior.

There are two possible modes of injecting the surfactant slug.[28] One is a relatively high % PV slug (15–60% PV or more) with relatively low surfactant concentration. This mode of injection has been found to yield a more sustained production at lower oil proportion in the receiver wells. The other approach is the injection of low 3–20% PV slug at a relatively high surfactant concentration, which has been found to yield higher oil proportions at less sustained levels of production. Normally, the surfactant slug is followed by a polymer solution slug, which is in turn followed by a slug of water or brine. The use of an alkaline slug ahead of the surfactant has been found to be beneficial as a preflush,[29] which has the effect of reducing the adsorption of the surfactant onto the rock surfaces.

From an economic standpoint, a surfactant-based EOR has been found to involve an incremental production cost of $8–12 per barrel of oil.[d]

MICROBIAL METHODS

Microbial enhanced oil recovery (MEOR) typically involves the use of bacterial cells for in situ production of chemicals in an oil well. The method has been found to be appropriate in recovering more oil from stripper wells (producing less than 10 barrels per day);[30] thus, economic constraints result in restricted operating procedures. The organisms, nutrients, such as molasses, and air (for aerobic operation), are fed into the wellbore. Then, the well is closed for up to a few weeks to allow the cells to multiply and produce EOR chemicals, which can include gases, solvents, acids, biomass, and natural polymers.

Incremental production cost for MEOR was estimated to be $1–8 per barrel of oil.[d]

CONCLUSIONS

Enhanced oil recovery has been shown to be a viable approach toward the removal of additional oil from partially exploited fields. This is more evident as domestic production continues to gradually drop while demand keeps on increasing. Preference to specific methods depends on various factors, such as the nature of the field, economies of raw materials and utilities, and government codes and regulations.

Environmental Chemodynamics

Louis J. Thibodeaux
Louisiana State University, Baton Rouge, Louisiana, U.S.A.

INTRODUCTION

Environmental chemodynamics (EC) is a multiscience and engineering subject used by natural scientists and applied professionals for the conceptual understanding and quantitative tracking of anthropogenic and natural chemicals in their movements from the places of origin, along the various pathways of migration within and across media interfaces of the earth's geosystems (i.e., air, water, and soil) to points far and near where elements of the ecosystem are impacted. The participants in this multidisciplinary field include environmental chemists and engineers, geochemists, geologists, geophysicists, agricultural chemists, chemical engineers, environmental toxicologists and biologists, soil scientists, public health professionals, and other environmental scientists, practitioners, and specialists. One particular important application area in the field is the tracking of substances with hazardous and toxic properties targeting their contact with sensitive biological species including humans. The engineering design aspect of EC consists of defining pathways, quantifying chemical mobility, and using mathematical descriptions of key chemical, physical, and biological processes in forecasting their presence in space and time within air, water, and soil media primarily. This chemical presence is manifest as fluxes across media interfaces, and concentrations and residence times within the various media. The purpose of this entry is to define EC, describe the role it plays in chemical engineering and in environmental engineering science in general, and give examples of its application.

USER GROUPS

The chemical manufacturing process has an EC connection. Commencing with the extraction of raw materials from the earth to the delivery and use of the final products it is inevitable that hazardous substances will be formed. This is the first law (refer to Table 1 for the five natural laws of hazardous waste).[1,2] The use of ''green engineering'' and product substitution will substantially reduce the mass of hazardous materials produced but will not eliminate the problem entirely. The second law concerns recycle and reuse, but it can only be a partial solution, so the manufacturing engineer must have a basic understanding of the expected behavior of these chemical residues being discharged in the media adjoining the facility. Environmental chemodynamics provides a basis for obtaining a qualitative understanding of the relevant transport and transformation processes acting upon these substances as they enter the natural media (i.e., air, water, soil, and sediments). In addition, models are available in various levels of complexity, from vignette models to supercomputer versions, for use by the engineer to quantitatively track these residues in a real-time sense as they are released and move away from the plant-site. An example is the accidental spill of a quantity of chemical onsite. Regulatory reporting requirements increasingly demand an assessment of the mass fractions evaporated to air entering surface waters, percolating to groundwater and retained on the soil solids. Environmental chemodynamics concepts and models make it possible to understand the chemical behavior patterns in this case and provide tools in the form of mathematical algorithms by which to quantify the respective mass distributions.

The treatment of waste streams generated within industrial and commercial manufacturing, by municipalities, agricultural operations, etc. also has an EC connection. Typically environmental (civil) engineers or the equivalent applied environmental science professionals need to assess the multimedia impacts of these waste streams during the design and operation of the waste treatment facilities. These facilities are designed primarily to produce dischargeable residues, which are compatible with earthen materials (natural law no. 3 in Table 1). Other uses of EC by this group are much the same as those of the manufacturing process engineer.

The combined efforts of the manufacturing engineers, the waste treatment engineers, and pollution control applied scientists not withstanding, residual leaks are inevitable (natural law no. 4 in Table 1). It is clear that quantities of hazardous substances will always enter the natural environment. The earth forces that result in volcanic chemical emissions and the hazardous substances formed by many plants and animals for example have been ever present. However, it is the impact of human activities that has been the most

persistent and constant generator, increasing the quantities of hazardous substance in the last 10,000 years. The impact of these activities has been and is being monitored by environmental chemists, geochemists, biologists, toxicologists, and other environmental professionals—both scientists and engineers. Observing and cataloging chemical concentration levels in media and biota compartments and measuring organism response is the main objective of these skilled professionals. This knowledge coupled with EC protocols that are concerned with quantifying the chemical kinetics of sources and sinks, movement routes, partitioning, transport, etc., can provide needed key information relevant to the forensic aspects of establishing the cause and effect of the impacts encountered during monitoring. In this regard, EC knowledge is applied in a qualitative way aimed at understanding and explaining pathways and routes. In a more quantitative way by using predictive models, EC offers independent evidence of cross-media transport, media concentration levels, and exposure times for organism uptakes. In addition to elucidating the exposure pathway scenario, the EC analysis also provides a theoretical basis and a means for designing systems barriers for eliminating or deflecting the exposure pathway. An example of this is the use of clean soils or other natural material to cap a contaminated aquatic sediment bed surface; the imposed barrier significantly (i.e., 99%) reduces the chemical flux to water.

The fifth and final natural law of hazardous waste in Table 1 acknowledges that "nature" sets the standards for what is acceptable as to the presence of small quantities of hazardous substances in the media. Nature in this instance means the biological forms that encounter and are impacted by these substances in air, water, soils, etc. Regulators have been using EC protocols as one of the many needed in assessing chemical exposure to humans and other key biological species. These efforts have culminated recently in the design of the first multimedia, multipathway and multireceptor risk assessment tools by the USEPA.[3] Monitoring the presence of and movement of small quantities in the media is a difficult task which is both time consuming and expensive. Environmental chemodynamics modeling provides an economical means of extending this hard to get data. The advantage EC models have over monitoring is their ability to make predictions in time and space that extend and enhance the laboratory and field measurements. Increasingly, more sophisticated EC models will need to be developed, tested, and used. Historical evidence abounds as to the impact the physical activities by humans have had on altering the earth's biological status.[4] The mass production of chemical devices with hazardous properties which commenced in earnest in the early twentieth century has the potential for massive negative impacts as well.

THE SOURCE TERM FOR HAZARDOUS SUBSTANCES

Flux is the unique EC contribution; it connects chemical sources of the adjoining media. Primary sources that place hazardous substances in the media are end-of-pipe entry that include "smoke-stack" emissions to air from factories and automobile exhaust pipes, liquid and solid slurry sewer pipe outfalls to receiving waterbodies, the placement of pesticides onto agricultural soils, and the spreading of solid waste onto the land, in addition to the numerous inadvertent spills onto the land and water or release to air. These primary sources are always the precursors of numerous secondary chemical sources. The formation of secondary sources occurs for example when waste quantities accumulate and remained in areas adjacent to or in close proximity to many of these primary source points of entry. An example is fall-out of particles from the stack emission plumes deposited on the nearby soils forming a contaminated surface layer. In water bodies near sewer out-falls, particle settling and nonaqueous liquid discharges have formed layers of contaminated sediments. An example for the land application of waste was noted previously. These are just a few examples of media locales that become secondary hazardous substance sources. A unique focus of EC is to formulate the mechanism of release so as to realistically quantify the chemical flux from the secondary sources to the adjoining media.

Chemical transport and transformation have been a part of environmental science and engineering for decades. Air pollutant plume dispersion modeling and surface water quality stream modeling are mature elements of EC, commonly termed chemical fate and

transport (CFaT) models. They were developed for the tracking of chemicals and particles into air and water from the primary emission sources. It became clear to these professionals that the primary emission sources were giving rise to secondary source terms. In recent decades, ground water pollution has extended CFaT modeling into the subterranean, where both primary and secondary source terms were often involved. It was also becoming apparent that many so-called waste management practices were also creating secondary waste sources. Waste water treatment operations that emitted volatile chemicals to the air and waste piles that leached soluble chemicals to surface or ground water are well-known examples.

These secondary source terms are a particularly tough technical challenge to the air, water, and subterranean CFaT modeling efforts. Early attempts treated these as constant or as time varying forcing functions for describing the input rates or fluxes into the adjoining media. In doing so, the problem of quantifying the chemical inputs from the adjoining phase was grossly simplified and the multimedia nature of the problem was side-stepped. For example, in air modeling of these secondary sources, a time-series of chemical fluxes was selected so as to match the model projected downwind concentrations with the measured ones. Although the technique is operationally effective and is still being used, it nonetheless often skirts the hard problem of understanding and realistically quantifying the secondary source emission process. The technical problem of modeling the secondary sources is typical of all multimedia CFaT models. Developments in the waste management field now focus on the notion that chemicals in the environment needed a multimedia approach. Attempting to model and manage chemicals on a single media basis is a very unrealistic approach in most instances.

The unique contribution of cross-media flux assessment brought about by the EC approach allows the full and proper scientific attention to the mechanistic processes that occur within the secondary source media. Adding the source term to the existing suite of single media CFaT models essentially closes the chemical loop, technically speaking. With the development of science-based concepts, realistic chemical process models have become available for describing the cross-media transfers. With this piece in place, the way was clear to begin developing truly multimedia environmental models. The fugacity approach to multimedia modeling using compartments is possibly the best known of this genre.[5]

ORIGINS OF EC

Currently, chemical engineering is the applied science field that may best address the needs of environmental chemodynamics. It contained several of the ''right stuff'' basic science components: they were mathematics, chemistry, and physics. The ''science'' of chemical engineering is that body of knowledge that provides for the integrating of these basic sciences into a mechanistic process for the understanding of and developing quantitative design tools for predicting, controlling, and manipulating chemical behavior for product manufacture. ''Classical'' process design for chemical manufacturing was a mature engineering activity in the 1960s. Beyond manufacturing, the chemical engineering science paradigm provides the theoretical and practical wherewithal for developing environmental chemodynamics processes. However, to be completely applicable to the new EC field, it was necessary to assimilate large doses of the biological sciences and geosciences (i.e., geology, geophysics, and geochemistry). The processing paradigm of chemical engineering could naturally assimilate these additional sciences; however, the certainty the classical approach enjoyed in specifying design and control was compromised. Classical chemical engineering manufacture requires strict process design and control over vessels. The waste produced and the manufactured products released pose a particular challenge when they enter the natural system; this chemical processing system was not designed by scientists or engineers and it is in practical terms not under their control. The addition of the biological and geoscience components so necessary to environmental chemodynamics introduced additional complexities in the original. The net result was an increased level of uncertainties to the ''designs'' required of the new field. These ''designs'' in the context of EC included forecasting of chemical concentrations in time and space and predicting the chemical fluxes and time-of-persistence in the media compartments. Although unsettling for the novice chemical engineer working in the EC area, high levels of uncertainties doing predictive ''designs'' in natural settings are a reality and must be accommodated in the geoscience field.

AN EC SYLLABUS

The EC subject matter was selected and developed for use as a technical elective course for the curriculum in chemical engineering. The course contents appear in Table 2. Although developed for seniors and first year graduate students, it has been widely accepted and adopted in university departments of civil and environmental engineering and environmental chemistry. In addition, it is used widely in the geosciences, agricultural chemistry, agronomy, and environmental science departments at the graduate level. It contains introductory material, two theoretical chapters, and four applied chapters. Only a working knowledge of

7.3	Chemical transport and fate within subterranean media

algebra is needed for the use and interpretation of the many vignette environmental mathematical models presented. Some knowledge of calculus and differential equations is convenient for understanding the development of selected models and for developing alternatives. Numerous worked examples illustrate the application of the EC models.

The EC contribution to the science of chemical behavior in the geospheres was in providing theory-based general concepts and a practical understanding for the means of quantifying chemical exchanges between adjoining media (i.e., air-to-water, water-to-sediment, and soil-to-air). The necessary thermodynamic and transport theories appear in chapters 2 and 3 (Table 2). A focus on the interface regions between phases allow for the closing of the chemical loop and connecting the adjoining phases, thus allowing the development of truly integrated multimedia environmental models. The importance of this element was noted above in discussing secondary sources of chemical emissions into the media. The cross-media material course topics, the heart of the subject, appear in chapters 4, 5, and 6 (Table 2). By focusing on mechanisms on either side of the interfaces in turn, algorithms for interphase chemical movement are developed. A qualitative understanding of processes in each phase near each interface is developed prior to offering qualitative descriptions and the final algorithms.

The first section (i.e., 1 in Table 2) serves as an introduction and defines the scope of the subject. As implied in the title, it is one of chemodynamics or the movement of chemicals. Chemical transport is the primary focus of the material. Critics have noted that production and degradation rates of chemical reactions are all but absent in the course syllabus. Environmental reaction is a very important but is also a very broad subject and its inclusion at even a basic technical level into EC would detract from the transport message. Two basic subjects are necessary for understanding transport. These are chemical equilibrium at interfaces and the fundamentals of transport phenomena. Highly condensed material on these two key subjects are presented in chapters 2 and 3. The last chapter, number 7, is on the fate and transport in water, air, and soil. These are the traditional subjects of environmental modeling which treat each of the three media separately and as isolated units from a multimedia perspective. Nevertheless, this approach is very appropriate for numerous EC applications. The section stresses the commonalities of fate and transport in the three media; however, the brief coverage offered on each belies the importance of these respective intraphase transport topics.

An example follows that is used to illustrate some of the details of the EC analysis process and its forecasting characteristics. The general reader may skip over this technical section without loss of continuity of the subject. It involves an important and very common EC problem and illustrates the effective use of the flux concept in connecting the interphase chemical movement in a multimedia context.

AN EC EXAMPLE

Methods of measuring and modeling volatile chemical emissions to air from a surface soil source are common and important EC ''design'' application. The examples

are many. Spills of organic and inorganic liquids and solids will continue to occur. The direct placement of pesticides on to surface soils and the creation of soil-like solid waste piles containing volatiles are necessary activities. The latter includes the disposal of dredging materials (DM) derived from remediation contaminated bed sediment of harbors, bayous, lakes, estuaries, etc. Large areas of soil-like drying mud flats are formed that become sources of volatiles. In the case of the planned dredging of the Indiana Harbor and Canal near Chicago, U.S.A., the DM disposal operation will involve a 68 ha confined disposal facility (CDF) to be operated for 30+ years. Prior to building, the CDF estimates of chemical fluxes to air including naphthalene are needed. This and other polycyclic aromatic hydrocarbons will contribute to degrading the local air quality in addition to creating a breathing air risk to nearby residents. In this case, the scale of the naphthalene emission problem is a local one. On the other hand, volatile mercury problem involves a similar emission process, but its impact is on a much larger scale. Its flux from naturally enriched surface soils plays a significant role in its global chemodynamics as an intrinsic component of regional and global Hg budgets.[6] Examples of other types of common air emission include accidental spills and direct application to soils. All have a common EC process base both in the technologies used for measuring their magnitudes and in the multimedia models used to forecast the emission through time. The following two sections contain brief EC designs for both.

Zhang et al.[6] observed that the emission flux of a gaseous substance has to be estimated using a combination of theoretical models and data collection approaches because it is not a physical quantity that can be measured directly. The three commonly used estimation methodologies include in-air micrometeorological methods, spatial mass balance methods, and enclosed (flux chamber) methods. The latter is the most flexible technology and useful for exchange process studies; of these the dynamic flux chamber (DFC) is widely used.[6,7] Its operation involves a box-type enclosure placed upon a soil area A (m^2) with flushing air continuously pulled (or pushed) through to capture and deliver the emitted gases or vapors to an appropriate adsorbent trap for eventual chemical identification and quantification. The results of a series of steady-state DFC experiments with a naturally enriched Hg soil appear in Fig. 1. Here it is observed that as the air flushing rate through the chamber, Q (m^3/hr), increases, so does the flux of total gaseous mercury (TGM), n (ng/m^2 hr), from the soil. Both the collected flux data and the theoretical model flux developed for the process demonstrate this increase with an asymptotic approach to a maximum flux, n_{mx}. The important

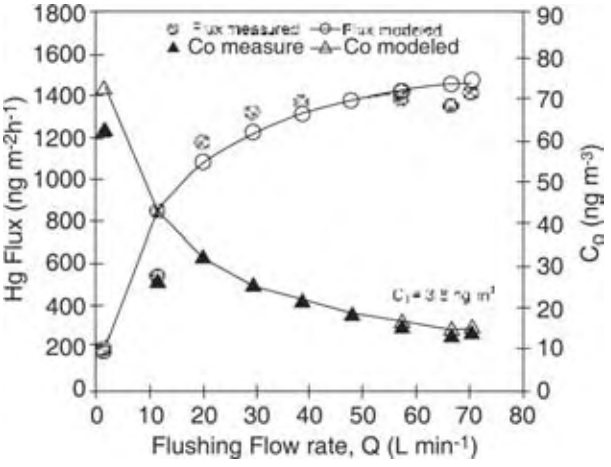

Fig. 1 Steady-state flux chamber measurements and model results of TGM moving from soil to air. (From Ref.[7].)

model equation is

$$n = \frac{n_{mx}}{1 + (\beta Sk_s + Ak_s)/Q} \quad (1)$$

where $\beta = 31$ is a consonant, $S(m^2)$ is the vertical chamber area, and k_s (m/hr) is the mass transfer coefficient of TGM in the soil surface layer. The decreasing data set shown in Fig. 1 is the outlet concentration of TGM from the chamber. Increasing the air flushing rate dilutes the constant the flux, resulting in decreasing outlet concentrations. Besides providing realistic estimates of the TGM flux to air from representative soil samples, such EC experiments establish the dominant processes that control the chemical-to-air releases. In this case, it is the soil source strength as total soil Hg concentration and the transport kinetic parameters on the soil-side and the air-side of the interface. With this information it is now possible to more confidently build field-scale EC models for use in estimating chemical emissions forecast now and in the future.

Volatile and semivolatile organic chemicals placed on surface soils have very similar chemical process behavior patterns as those shown above for Hg. Numerous laboratory and a few field flux measurements have been performed on this class of chemicals as documented in a recent review.[8] The review was performed to assess the quantity and quality of measured flux data and the availability of process-based emission models. The basic difference between the flux chamber model and the field-scale model is that the former involves a steady-state flux process and the latter is a transient one. The EC models needed for the large time-scale involved with most field applications must consider the so-called ''weathering'' effect which characterizes the depletion of the available-for-volatilization chemical mass in the

surface layers. Traditional chemical engineering modeling approaches to the drying of porous solids including a constant rate (i.e., flux) period and a falling rate period. As ''drying'' time increases, the effective position of the plane of origin of the volatile chemical recedes further into the soil column and thereby it encounters an increasingly larger diffusion pathway length to the air interface.

Decades of research by numerous individuals has uncovered numerous minute facts about this complex soil-side and air-side coupled chemical release process. While lab.-specific and controlled conditions allow sophisticated theoretical mathematical models to be developed that can match measured flux data very well, such elaborate protocols are of little practical use in most field applications. Vignette EC models that capture the theoretical essence of the significant processes and contain a minimum number of parameters that can be transparently adjusted for fine-tuning the model to the site data appears to be the most realistic approach. The following equation is a transient EC flux model that is simple but is theoretically consistent with the known major processes and capable of making quantitative predictions using a few key parameters:

$$n = (W_a H/K_d - C_a) \Big/ \left(\sqrt{\frac{\pi t}{D(\varepsilon_a + H/K_d \rho_b)}} + \frac{1}{k_g} \right) \quad (2)$$

In the equation W_a is the chemical loading onto the soil (mg/kg), H is Henry's constant, and K_d (m^3/kg) is the chemical soil-to-water partition coefficient. C_a is the concentration in the background air. The transport within the soil is dominated by air-filled pore spaces ε_a and is quantified by an effective diffusivity, D (m^2/hr). k_a (m/hr) is the air-side mass transfer coefficient. The independent variable is time t (hr): it represents the increasing time period that commences with the placement or spreading of the soil-like waste material on the land. The result allows time projection estimates of the chemical flux to air. At a certain time period, a shift occurs in the flux process; the vaporization process changes from being air-side resistance controlled, through the $1/k_g$ parameter, to being increasingly soil-side resistance controlled by the group under the square root symbol. In Fig. 2, measured flux data for dibenzofuran[9] and model results using Eq. (2) are shown. However, some challenges remain applying the model to a porous media that undergoes dramatic particle consolidation and volume changes as water is lost by evaporation and percolation.

Numerical values of chemical concentration and time-of-persistence in the media convey the information necessary for quantifying the related health risk.

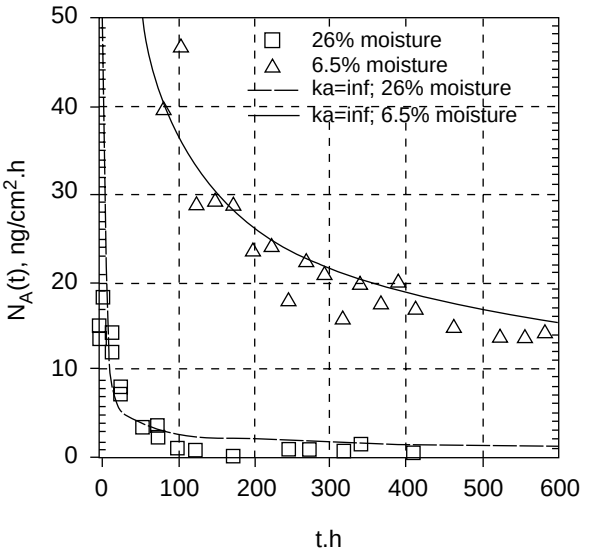

Fig. 2 Transient flux of dibenzofuran from soil to air in laboratory apparatus demonstrating the effect of soil moisture. (From Ref.[9].)

Flux is a somewhat abstract entity and does not relate this information directly. It quantifies the chemical movement rate across an interface plane into a receiving media such as the air boundary layer (BL) in the above example. Only when it is coupled with an air dispersion model does it produce concentrations in air. In the case of a large soil surface area source, a simple relationship exists between flux and concentration. For neutral air stability conditions in the atmospheric BL with steady-state wind speed v (m/sec), the concentration in air, c (mg/m^3), can be approximated by

$$c = \frac{c_a + 27n}{v} \quad (3)$$

where c_a is the concentration in the background air approaching the area source. According to Eq. (2), the flux decreases with increasing time as $n = k/t^{1/2}$

For a constant wind speed, Eq. (3) indicates that the concentration in air above the source decreases with time in a similar fashion.

From an air pathway exposure perspective, the time-of-persistence is also an important factor. In the case of a volatile chemical moving from a soil surface source a time-period, tp (sec), may be defined as the duration during which the concentration level in the air is at or above some predetermined safe level C^*. Using C^* and the simplified flux expression in Eq. (3), the time can be calculated:

$$\text{tp} = \left[\frac{27k}{v(C^* - C_a)} \right]^2 \quad (4)$$

where numerical values of k can be estimated from Eq. (2). This result indicates that for substances with small safe concentration numerical values, the time-of-persistence is very long. For those with high safe concentration levels, the tp can be very short. Taken together the Eqs. (3) and (4) are design algorithms which are useful for estimating the concentrations in air and the time-of-persistence needed for quantifying chemical exposures to biota located in the vicinity. This completes the presentation of EC flux concept in assessing chemical behavior and release as it applies to this important class of secondary emission sources.

CONCLUSIONS

A Brief History

Environmental chemodynamics was 35 years old in 2005. The widespread appearance of pesticide residues in soil, water, and air was the first instance in observing the multiphase spread of an anthropogenic substance. This was attributed to the development of analytical chemistry methods in determining minute amounts of pesticides in various media. Evidence of the widespread presence of chemicals was contained in an American Chemical Society (ACS) report on the cleaning of our environment.[10] 1,1,1-trichloro-2,2-bis(*p*-chlorophenyl)ethane (DDT) is an insecticide used in large quantities since 1942 and its residues attained worldwide distribution.[11] Global modeling of the primary reservoirs—the land surface, the troposphere, the mixed layer of the ocean, and the abyss—attempted to answer the question as to where does it go. This substance played a sentinel role in our appreciation of chemical hazards in the biosphere. A working conference of the National Academy of Sciences and National Academy of Engineering on principles and protocols for evaluating chemicals in the environment was convened in 1973. In the report,[12] which appeared two years later, the term ''chemodynamics'' was first defined. It was lengthened to environmental chemodynamics by Hague and Freed in 1975 upon publishing the proceedings of the 1974 ACS Conference containing papers on the behavior of chemicals in air, water, soil, and biota and included topics on their modeling in the environment, photochemical behavior, adsorption, leaching, and breakdown, vapor loss, interaction with biological macromolecular, and detoxification by biota.[13] These developments essentially launched the new environment field focused primarily on anthropogenic chemicals, but require support from nearly all the basic and applied science fields. Two textbooks[14,16] and a textbook chapter[15] on the subject appeared later in the decade of the 1970s. Fifteen years later numerous books have appeared. Most bear titles using the alternative descriptive phrases such as chemical or pollutant fate and transport in water, air, and soil, environmental chemical modeling, etc.[16–24]

The Future of EC, New Field or Just New Fashion?

The subject is an important concern to the profession of chemical engineering. The material was chosen and organized as a university level course with this targeted audience in mind. Groups that accepted, adopted, and used EC dwarfed the targeted audience whose primary mission remains chemical and materials manufacturing. The nontarget group consisted primarily of environmental scientists and engineers. The EC concept appeared at a key time-period in the growth of the environmental science and engineering movement. Measurable quantities of many hazardous chemicals were being found in all the natural media and existed in at elevated levels in many key biota. Laws regulating waste treatment, pollution control, and discharge limits were proposed, passed, and implemented.

The concern about chemicals in the environment began to move away from being a series of single media problems and approaches to being viewed as a multimedia one. The necessity of and growing reliance of mathematical models to track chemical movements and reactions in nature elevated the need to formulate science-based process algorithms. Surface water quality models and air dispersion models were in common use; later groundwater contaminant models appeared. Together these were generally termed CFaT models. Environmental chemodynamics provided the unifying concept as the means of connecting the single phase models. The fugacity-type models and a host of other multimedia, multiphase, and multicomponent risk assessment models were formulated and are continuing to develop in sophistification and are finding widespread applications.

Whether EC is a new subfield of environmental science/engineering field is irrelevant; the continuing use of the term, first offered by Freed and Hague, may be transitory as is fashion. However, it is unlikely that the subject will diminish in importance as long as humans continue to rely on chemical ''devices'' for enhancing their quality of life. A subfield by any other name that focuses on discovering and understanding the nuances of chemical mobility in nature plus providing quantitative designs on pathways, movement rates, etc. will not go out of fashion.

Environmental Law and Policy

Don C. Haddox

Teresa J. Cutright
Department of Civil Engineering, University of Akron, Akron, Ohio, U.S.A.

INTRODUCTION

The subject of environmental law and policy is immense, far too large to be adequately covered within the confines of a small entry. Any single aspect of environmental law could easily encompass an entire encyclopedia but still be found to be lacking in one or more areas. With that caveat, an overview of key environmental policies can be discussed, knowing that not all intricacies of any one program can be fully investigated or developed. Resource Conservation and Recovery Act (RCRA), Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), Safe Drinking Water Act (SDWA), Clean Air Act (CAA), Clean Water Act (CWA), Toxic Substances Control Act (TSCA), Superfund Amendments and Reauthorization Act (SARA), Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), National Environmental Policy Act (NEPA), Wild and Scenic Rivers Act, Endangered Species Act—the list can continue for pages before running out of federal acts that govern the use and protection of the environment. In many cases, individual states have, or are seeking, the authority to enforce the laws as they see fit; provided their implementation is at least as strict as that mandated by the federal statutes. This means that a state cannot implement a law that counters a provision of the federal act; however, it can utilize regulation that is more stringent than those measures called for by the federal law. Many states desire this level of autonomy to shape the environmental direction of their state. Difficulties can arise, from not only the complexity of the legal system, but also the unique obstacles associated with the interdisciplinary nature of the ''environment.'' Chemistry, biology, physics, engineering, health and safety, and long- or short-term sustainability along with the inherent uncertainty of many sciences complicate the ''fact'' vs. ''conjecture'' arguments necessary to provide for legal prosecution or defense.

Environmental law provides the user with an ''organized way of using all of the laws in our legal system to minimize, prevent, punish or remedy the consequences of actions which damage or threaten the environment, public health and safety.''[1] Implementation of the environmental law system entails much more than a compendium of information contained under the pretext ''Environmental Law'' found in a law library. In fact, it can and does involve using any law for the betterment of the environment and/or human health and safety. The practice of environmental law includes all of the following:

- Laws, both federal and state statutes and local ordinances.
- Regulations promulgated by federal, state, and local agencies.
- Court decisions interpreting these laws and regulations.
- The common law.
- The United States Constitution and state constitutions and treaties.[1]

For a bill to become an environmental law it follows the same legislative process as any other bill. That is, it is introduced in either the U.S. House of Representatives or the Senate, and then referred to congressional committees for consideration. A recommendation on whether the bill should pass is then provided. If the bill passes both the House of Representatives and the Senate it becomes an act. The act then becomes law if it is: 1) signed by the President of the United States or 2) not vetoed within 10 days. An additional complication with environmental bills, although not unique to the environmental field, is that the House and Senate generally pass different bills. This then generates the need to have a congressional congress of representatives from both sides to settle the disparity.[1] Resolution of the differences between the groups often results in complex and intricate wording of the bill to appease everyone.

The text of this entry will emphasize a summary of select acts that are generally regarded as important tools in the system of environmental regulation. The main body of each act will be summarized, along with key differences in enforcement authority between federal and state implementation if applicable. Finally, any recent additions or new interpretations along with

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120022526

current actions taken with regard to the act will be explored.

NATIONAL ENVIRONMENTAL POLICY ACT

The National Environmental Policy Act was passed in 1969 and signed into law on January 1, 1970, as public law 91-190 (now found in 42 U.S.C. §§ 4321-4370c). It was, and still remains, the first federal statute that required agencies to evaluate the impact of implementing major programs and alternatives in the early planning stages. This approach makes it the first, truly proactive environmental law.[2] There are two titles in NEPA. Title I contains the declaration of National Environmental Policy while Title II establishes the Council on Environmental Quality (CEQ).

Title I

The primary objectives of NEPA are to encourage the productive and enjoyable harmony between man and environment, promote preventative efforts that eliminate damage to the environment, advance the understanding of ecological systems and natural resources important to the Nation, and establish the CEQ. To achieve these goals, all federal agencies must file a formal Environmental Impact Statement (EIS) for any project or action that is expected to have a ''significant effect'' on the quality of the human environment. The specific requirements and timeline for completing an EIS is contained in Section 102(2)C of NEPA. In brief, a detailed assessment is required for: 1) environmental impact of the proposed action; 2) any adverse environmental effect that cannot be avoided if the action is implemented; 3) potential alternatives and the associated impacts; 4) the relationship between local short-term environmental uses and long-term productivity; and 5) irreversible allocation of natural resources should the proposal be implemented.[3] The assessment of natural resources served as the cornerstone to the future legislation regarding waste minimization.

Title II

The Council on Environmental Quality was established to oversee the completion of Title I. The council comprises three presidential appointees. The council also employs environmental lawyers and scientists to conduct thorough risk-based evaluations of the proposed activities so that the council recommendations provided are sound. Although the CEQ does not have any enforcement provisions, the council has been very influential in its advisory capacity. Currently, enforcement of NEPA has come through suits from private citizens filed under the Administrative Procedure Act. Part of the NEPA's success has been attributed to the successful filing of such suits. However, civil actions have also identified the key drawback with NEPA—the identification of ''significant impact.'' The use of the word significant can be open to interpretation as some of the effects are intangible and different for each person. For instance, some individuals view acid rain deposition on historical buildings as a significant adverse impact, whereas others simply view it as a nuisance.

RESOURCE CONSERVATION AND RECOVERY ACT

The RCRA, enacted in 1976, is found in 42 U.S.C. § 6901 et seq. and is also referred to as the Solid Waste Disposal Act (SWDA). Amended in 1984 by the Hazardous and Solid-Waste Amendments (HSWA), RCRA is designed to control the generation, transportation, storage, and disposal of hazardous materials from the ''cradle-to-grave.'' As of September 1999, approximately 40.7 million tons of hazardous waste is generated annually in the United States and governed by the RCRA.[4] The RCRA additionally provides the means to regulate underground storage tanks (USTs) and manage solid waste (including non-hazardous and/or medical waste); and a national research, development, and demonstration program for innovative or improved waste management and resource conservation.[5]

The RCRA is divided into 10 subtitles, lettered A–J, that assign different aspects of the program (Table 1). Of these 10, subtitles C, D, and I provide the skeleton for the most significant programs in RCRA.

Subtitle C establishes the hazardous-waste management system, which includes defining hazardous. According to RCRA, solid waste is determined to be hazardous because its quantity, concentration, or characteristics (referring to ignitability, corrosivity, reactivity, or toxicity) may:

1. Cause or significantly contribute to an increase in mortality or an increase in serious irreversible or incapacitating reversible illness.
2. Pose a substantial present or potential hazard to human health or the environment when improperly managed.[4]

Besides the obvious characteristics of a given contaminant establishing it as hazardous, a solid waste

Table 1 Subtitles of the RCRA

Subtitle A	Introduction and preamble
Subtitle B	Office of solid-waste; authorities of the Administrator
Subtitle C	Hazardous-waste management
Subtitle D	State or regional solid-waste plans
Subtitle E	Duties of the secretary of commerce in resource and recovery
Subtitle F	Federal responsibilities
Subtitle G	Miscellaneous provisions
Subtitle H	Research, development, demonstration, and information
Subtitle I	Regulation of UST
Subtitle J	Medical waste tracking act

Credit: U.S. Code Title 42, Chapter 82.

may also be listed as a hazardous waste because of its identification with a process or use that has been established by the Environmental Protection Agency (EPA). Three lists have been created: ''F'' for non-specific sources, ''K'' for waste from a specific source, and ''U'' for commercial chemical products. Full investigation and explanation of the listing process (and delisting) are beyond the scope of this entry and the reader is encouraged to seek further information on hazardous-waste identification from outside of this entry.

The other key aspects of Subtitle C outline the standards for generators and transporters of hazardous waste; permitting programs for treatment, storage, and disposal facilities (TSDFs); administration authorization to states; and provisions for enforcement.[6] Classification of TSDFs takes into account the types and amounts of hazardous material, as well as the length of time the material is stored at the facility, before identifying them as large or small generators. Small-quantity generators have 100–1000 kg of hazardous waste and/or <1 kg of acutely hazardous, for a maximum of 90 days. Storing more than 1000 kg of hazardous waste or more than 1 kg of acutely hazardous waste for longer than 180 days triggers a large-quantity TSDF label.[5,6]

The RCRA's Subtitle D establishes the guidelines for instituting solid-waste management programs including state and regional solid-waste plans. Management of sanitary landfills including federal requirements and specific criteria for approval of plans is included within this section. This includes the disposal of bulk, noncontainerized liquids, which is banned, and disposal of containerized liquids, which is on a case-by-case basis. Of interest within Subtitle D is the provision that EPA has no enforcement authority with respect to open dumps. The RCRA grants EPA the ability of enforcement only with respect to hazardous waste. All enforcement regarding nonhazardous materials is left to the discretion of the state.[4] The one control that RCRA imposes on states within Subtitle D is that a state may not impose a ban on importation of wastes for treatment, storage, or disposal; even practices that would significantly deter this from occurring are prohibited.[4] However, as EPA maintains very limited enforcement authority, the enforcement of this requirement may be difficult.

Subtitle I provides for the regulation of USTs that store regulated substances, where 10% or more of the regulated substance is below ground.[4] In 1992, it was estimated that there were over 2 million UST systems in existence and that as much as 20% of these systems were leaking.[7,8] The main objective of Subtitle I is the prevention of further environmental destruction because of leaking USTs. This is accomplished through the identification of existing tanks, which are then required to meet current standards of construction or be closed and/or removed. New tanks are held to strict standards during construction and installation, which includes government notification of any new installations. Minimum standards are established by federal law, but authority may be delegated to states that adopt laws at least as stringent as the federal standards.

COMPREHENSIVE ENVIRONMENTAL RESPONSE, COMPENSATION, AND LIABILITY ACT

The CERCLA, found in 42 U.S.C. § 9601 et seq., has five basic objectives:[9]

- Provide the enforcement agency the authority to impose cost and liabilities for principal responsible parties (PRPs) of the past and the future release of hazardous chemicals.
- Establish a fund for cleanup and prioritization of sites.
- Authorize EPA to initiate cleanup for emergency and remedial response.
- Establish a postliability fund in conjunction with the RCRA for site closures.
- Advance science in technology in all aspects of hazardous-waste management, treatment, and disposal.

The CERCLA's creation was a response to the growing concern over escalating dangers associated with inappropriately disposed hazardous waste. The most commonly cited incident being the Niagara Falls, New York's ''Love Canal,'' where then-president Jimmy Carter declared the former landfill a federal

emergency on August 7, 1978.[10] The CERCLA's 1980 enactment was the next legal step in an evolving scheme of environmental protection.

Passed on December 11, 1980, the CERCLA amends the SWDA and is commonly referred to as Superfund because of the funding objective designed into its overall principles. This trust fund was generated through the creation of a tax applied directly to the chemical and petroleum industries. In the first 5 yr $1.6 billion was collected to provide for cleanup of hazardous-waste sites, thereby meeting the second overall objective.[9]

The appropriation of the funds kept in the Superfund trust is governed by the Act itself. In addition to payment of EPA's cleanup and enforcement costs, certain monies can be recovered by private parties. This entitlement includes repayment for completion of an EPA-approved cleanup. Reimbursement claims may also be filed if a private party has completed a cleanup for which the facility owners refuse to pay, or if EPA has administratively required a cleanup that is considered capricious or for which they were not liable.[11] It is important to note that these reimbursements are not guaranteed entitlements and very rarely extend to those parties responsible for the negligent disposal practices that caused the hazardous condition. In fact, the vast majority of litigation under CERCLA is brought pursuant to cost recovery actions.[11] One noteworthy exception to the list of eligible reimbursements is the exclusion of federal facilities from having remediation costs financed through Superfund. These site numbers are significant with the majority of them being a direct result of Department of Energy or Department of Defense activities during World War II and stretching into the Cold War era.[11] Both departments have extensive long-term cleanup plans that must seek funding through alternative sources.

As of the end of the 2003 fiscal year, Superfund was officially bankrupt. Current legislation plans on using general fund appropriations (i.e., taxpayers) to revitalize the fund, requiring their contribution to be substantially over the $676 million previously collected. Other sources (called offsetting collections) that will be used include individual states, which pay a small portion of the cleanup, and other federal agencies paying for EPA services. In 2002, monies collected from offsetting collections and PRPs were $40 million and $130 million, respectively, while expenditures were $1.3–1.7 billion.[12] As a result, PRPs will be forced to bear the burden of cleanup. Sites that have no readily identifiable PRP to pay for the cost of remediation will be paid for from the $1.1 billion that the EPA has requested from the 2004 fiscal year general appropriations. In the interim, the EPA has requested a subcommittee to be established by the National Advisory Council for Environmental Policy and Technology to address how Superfund prioritized sites and future monetary issues.[12]

In the same way that RCRA governs new hazardous waste from the cradle to the grave, CERCLA creates a complementary Act that regulates waste generated and disposed of prior to the 1976 RCRA regulations. Hazardous wastes, for the benefit of CERCLA, are defined by other environmental acts (i.e., CWA, TSCA, RCRA, etc.) and can be expanded to include other materials as necessary by the enforcing agency. The sites identified as being the most problematic according to a hazardous ranking system are compiled on the National Priority List (NPL), which is maintained along with the current status of each site by the USEPA. Sites are placed on the NPL as a proposed listing. Once on the "final list," a remedial investigation/feasibility study (RI/FS) must be completed within 6 mo, followed by a proposed cleanup strategy. The USEPA then selects the appropriate treatment strategy and issues a Record of Decision (ROD) setting forth all the details of the proposed remedy. The ROD is then placed into the administrative record for a public response period. Ultimately, the ROD leads to a remedial design (RD) phase followed by a remedial action (RA) phase. Following satisfactory completion of all aspects of the ROD, a site may ultimately become "delisted," at which point it is removed from the NPL. At the end of the 2002 fiscal year, only 265 sites have been removed from the NPL. This leaves 1233 on the NPL, with 62 new proposed sites.[12]

The CERCLA is almost exclusively the domain of federal legislation via USEPA. State involvement is limited in most areas as an assistant in the provision of future maintenance of the site. A state may enter into an agreement with USEPA to take response actions and then seek finances from the Superfund to help defray the costs of the remedial action.[6] In an alternate scheme, where USEPA is the lead regulator, a state must agree with the selected remedy as set forth in the ROD before the RD/RA phases of the project may proceed. From the State's view the largest involvement also becomes a major stumbling block in some Superfund sites, the unwillingness or inability of a state to fund 10% of the required RA cost.[11] This figure includes all future maintenance of the site.

SUPERFUND AMENDMENTS AND AUTHORIZATION ACT

On October 17, 1986, the SARA was created to extend the reach of CERCLA. Found at 42 U.S.C. §11001 et seq., this amendment increased the Superfund trust to $8.5 billion, but more importantly added legislation stressing the importance of community involvement, knowledge, and well-being, while simultaneously increasing the emphasis on permanence in solutions to hazardous-waste sites. As a result, the most well-known

aspect of SARA is Title III, the Emergency Planning and Community Right to Know Act. The emergency planning provision requires a detailed plan (personnel training, evacuation procedures, hospital routes, etc.) in the event of an accident. The community right to know has two subtitles. Subtitle A requires facility owners and operators to provide information to the public. Subtitle B states the specific type of information required. For instance, material safety data sheets (MSDS) must be made available on request, emergency and hazardous chemical forms are submitted annually to the state, etc.

The RCRA's Overlap with CERCLA

As outlined above, RCRA is a preventative legislature regulating current/future hazardous-waste management. Conversely, CERCLA's goal is to rectify problems caused by the previous mismanagement of hazardous waste (i.e., it addresses past sins). There are three general areas in which RCRA and CERCLA statutes overlap: disposal of CERCLA-waste sites; reactions to imminent hazards; and corrective actions (CA) for releases from TSDFs.

Waste disposal from CERCLA sites must be managed in accordance with regulations outlined in subtitle C of RCRA. For instance, generator/regulator statutes would regulate wastes taken off-site for treatment. This would entail the proper labeling of all material as well as hazardous-waste manifests. In addition, any waste treated or stored on-site must be handled in accordance with TSDFs.

An imminent hazard is a clearly identifiable threat. Imminent hazards from either current or previously existing (whether still operational or abandoned) TSDFs are regulated by section 7003 of RCRA as well as section 106 of Superfund. Both statutes require the PRPs to take immediate action for cleanup. As Superfund is a comprehensive authority, it is the primary authority for imminent hazards. Duplication in RCRA is used to bolster government action for maintaining the statutes and enforcement of penalties.

Previously, unless a release from a TSDF posed an imminent threat, a ''remedy'' was not required. As of 1984, CA are required for all releases from TSDFs. Prior to this date, CERCLA was the only legislative body that provided the EPA authority for requiring CAs. Treatment, storage, and disposal facilities fall under RCRA subtitle C, which only mandated a remedial-site investigation. Often, action ceased after the site investigation because regulation at these sites was not really enforceable. Providing an overlap between the two legislative bodies required TSDFs to move from simply completing a remedial-site investigation to actually implementing CA.

CLEAN AIR REGULATIONS

Overview of Air Regulations

The legal definition of air pollution is ''the presence in the outdoor atmosphere of any one or more substances in quantities, which may or are harmful/injurious to human health or welfare, animal or plant life, or property, or interfere with the enjoyment of life, property or outdoor activity.''[13]

Based on this definition, the first documented case of air pollution occurred in 1272 when thousands of people died as a result of volcanic ash. During the early to mid-1900s, several air pollution episodes resulted in either unacceptable illness levels or death. For instance, in 1948 the mill town of Donora, PA, was subjected to a 4-day fog from the uncontrolled steel mill emissions reacting with other constituents in the atmosphere. The fog left 14,000 people (half the town) sick and 20 dead.

Events such as the Donora fog led to the establishment of air pollution regulations. Fig. 1 contains a timeline of the key federal air pollution regulations. As shown in Fig. 1, the clean air legislation, CAA, and Motor Vehicle Act were the first three key legislative documents for reducing the release of harmful compounds into the atmosphere. However, it was not until the Air Quality Act of 1967 that actual air quality standards were formulated. The standards were constructed in an effort to reduce emissions in the newly formed air quality control regions (AQCRs), i.e., the most heavily contaminated areas. Each state in an AQCR had to develop a State Implementation Plan (SIP) outlining how, and by when, they would achieve the necessary reductions. To generate the air quality standards and realistic SIPs, the contaminants were identified as either a primary or a secondary pollutant. A primary pollutant is defined as a compound that is directly emitted to the atmosphere as a contaminant (i.e., CO, SO_2, etc.). Conversely, a secondary pollutant is a contaminant that is formed in the lower atmosphere by a chemical reaction with other primary pollutants.

Clean Air Act Amendments 1970–1990

The establishment of ACQRs and SIPs started to move air pollution control in the right direction. However, the EPA still lacked the ''teeth'' needed to enforce the regulations. This was partly owing to the fact that when generating the SIPs, the states set their own air quality standards, therefore no one was using the same constraints. One of the key provisions of the CAA Amendments (CAAA) in 1970 was to establish National Ambient Air Quality Standards (NAAQS). Anything above the NAAQS was considered a pollutant.

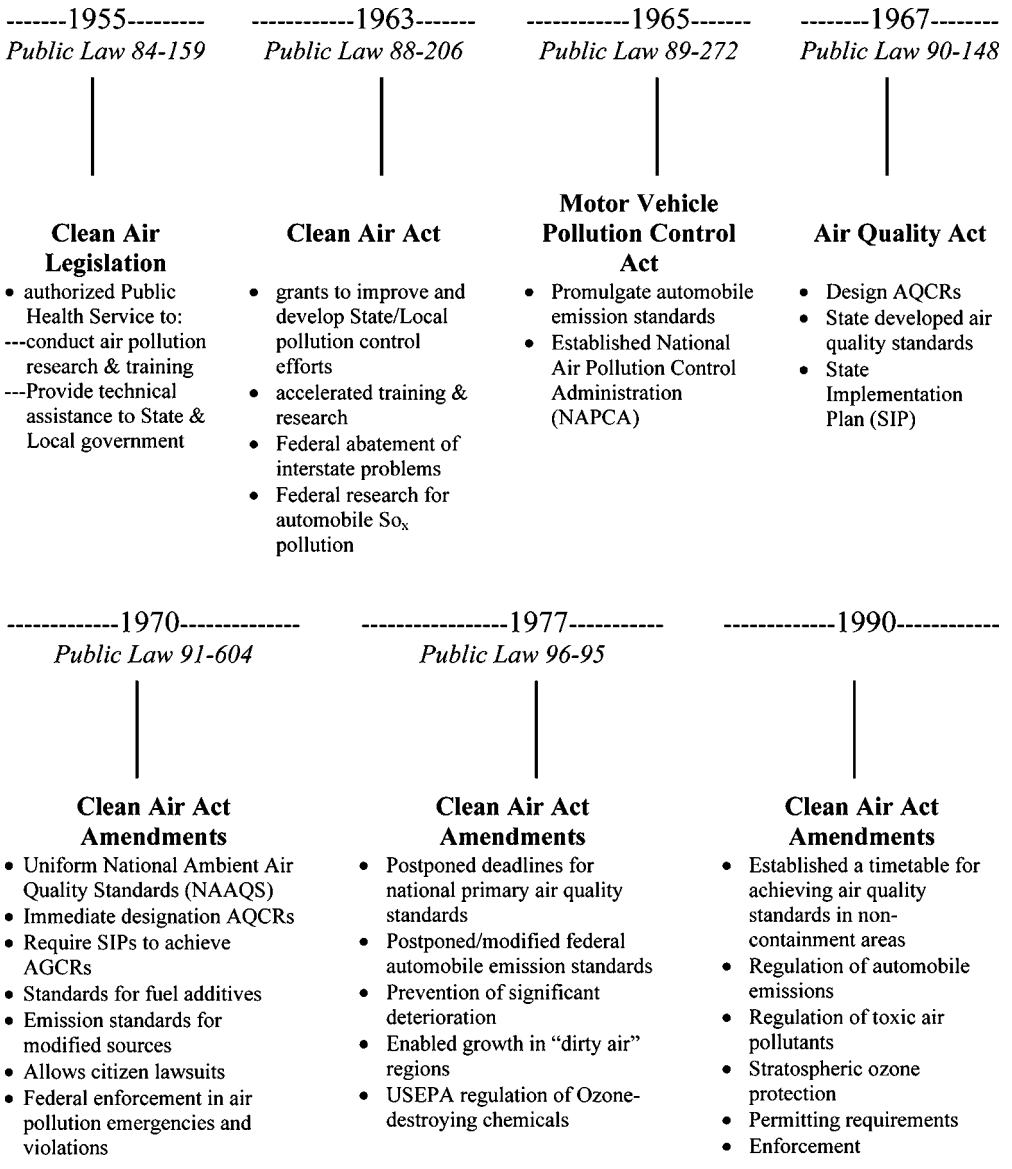

Fig. 1 Timeline of key federal air pollution regulations.

After the new standards were set, states had to resubmit SIPs. This time, the SIP was required to establish the approach for attaining the NAAQS within 3 yr. The NAAQS were more aggressive than previous legislation. In addition, uniform standards also stifled interstate competitions. Table 2 lists the NAAQS of key contaminants for the most commonly used sampling intervals. Refer to 42 USC § 7408(a)(1) for other sampling intervals. To provide more uniform enforcement of the new regulations, the National Air Pollution Control Administration was eliminated and all of the responsibilities transferred to the EPA.

The CAAA of 1977 realized that the aggressive approach of CAAA 1970 could not be achieved within an economically feasible manner. Therefore, deadlines were postponed. The key initiative of the amendment was the regulation of ozone destroying chemicals. This was the start of the phasing out of chlorofluorohydrocarbons. In 1990, amendments were passed that regulated at the federal level the control of minor point source emissions as well as nonpoint source emissions. Previous regulations only focused on boilers, incinerators, and flares. Major changes, such as regulation of hazardous and toxic air pollutants, and stratospheric ozone protection, were made to address global problems. Incorporation of such provisions was a major political achievement.

Emission Trading

Emission trading is based on the concept that the best way to improve overall air quality is to create a genuine economic incentive for industrial facilities to decrease emissions. To move away from the previous

Table 2 National ambient air quality standards

Pollutant	Primary standard ($\mu g/m^3$)	Secondary standard ($\mu g/m^3$)	Sampling time	Health and environmental effects when levels are exceeded
Carbon monoxide	10,000 (9 ppm)	NA	8 hr	Headaches, diminished alertness, heart damage, death, and smog
Nitrogen dioxide	100 (0.05 ppmv)	100 (0.05 ppmv)	1 yr	Lung damage, acid rain, and formation of ozone and secondary pollutants
Sulfur dioxide	365 (0.14 ppmv)	1300 (0.5 ppmv)	24 hr	Eye irritant, lung damage, kills aquatic life, acid rain, and formation of secondary pollutants
Nonmethane hydrocarbons	160 (0.24 ppmv)	160 (0.24 ppmv)	8 hr	Cancer, respiratory disorders, tissue damage, and dead vegetation
Ozone	157 (0.08 ppmv)	157 (0.08 ppmv)	8 hr	Eye irritant, lung damage, and respiratory problems
PM10	50 150	50 150	1 yr 24 hr	Eye irritant, lung damage, smog, crop damage, and discolored buildings
PM2.5	15 65	15 65	1 yr 24 hr	Eye irritant, lung damage, smog, crop damage, and discolored buildings
Lead (Pb)	1.5	1.5	3 mo	Brain damage, kidney damage, smog, and crop contamination

NA, not applicable, only primary standard.

command–control-type approach, the EPA developed several different emission-trading concepts. The three most commonly used approaches are the open market trading, offset trading, and allowance trading.

Open market trading encourages sources to voluntarily reduce emissions below the required standards. Other companies that are not in compliance can purchase the reductions to comply with regulatory limits and/or increase operational flexibility. Credits created under open market trading must meet strict criteria to ensure that the process yields continuous environmental improvement as well as meets the intent of air regulations.

Offset trading was developed under the New Source Review program to allow new or significantly modified sources of air polluters to be built in nonattainment areas without adversely affecting air quality. Previously, new sources could not be built in nonattainment areas regardless of the air pollution control devices used. With offset trading, contemporous emission rates are transferred between sources in the same area. New sources with the new advanced technology can achieve a greater reduction in emission rates than that required in the nonattainment area, thereby providing a permanent reduction in emissions.

Allowance trading is an annual, area-wide emission cap (i.e., budget) established over a defined area of air pollution sources. There is a specified time-dependent reduction schedule with allowances allocated to each party based on their historical emission rate. Each participating source has the option of meeting the annual compliance through a combination of emission control, use of assigned allowances, or purchase of allowances sold by other sources within the area. The purchase of another company's allowance makes allowance trading very similar to offset trading. The most well-known allowance trading has been with SO_2 for the reduction of acid rain.[14]

Success with the EPA's SO_2 trading has led to the proposal of global emission trading of CO_2. The key concepts for implementation are the level of emission per country and issuing of permits to each country and the associated industries. Although global trading is a good theory, too many obstacles remain. For instance, how will the quotas per country be determined? How will monitoring and emissions be enforced?

CLEAN WATER ACT AND OTHER WATER REGULATIONS

Prior to the CWA, the Treasury Department was the overseer for the United States Public Health Service (USPHS). From 1914 to 1962 the USPHS established comprehensive reviews of drinking water concerns and

established standards for over 28 compounds within each state. This was followed by the Water Quality Act of 1965, which required states to improve water quality, designate the intended use for interstate waterways, and adopt more uniform water quality standards.

In 1972, the Water Pollution Control Act, often referred to as the CWA, was passed. The primary provisions of the CWA are contained in 33 USC § 1251 et seq. The overall objective is to restore and maintain the chemical, physical, and biological integrity of the Nation's waters. Seven national goals were established to achieve this aim:

- Eliminate discharge of pollutants into navigable waters by 1985.
- Set interim goals of water quality to protect fish and wildlife and provide recreation by July 1, 1983.
- Prohibit discharge of toxic pollutants in concentrations, which may adversely affect the environment.
- Construct publicly owned treatment works (POTW) facilities with $5 billion/yr federal assistance.
- Establish waste treatment management plans with each state.
- Establish technology to eliminate discharge of pollutants.
- Develop and implement programs to control nonpoint sources.

Prior to 1972, water quality regulations were limited to point sources. A point source is a single source, such as a commercial facility or municipal wastewater treatment, that discharges effluent directly into a waterway. With the CWA, water quality was expanded to encompass nonpoint sources. Nonpoint sources often associated with waste from runoff (agricultural, mine tailings, etc.) are those contaminant sources whose origin cannot be identified.

National Pollutant Discharge Elimination System and Pretreatment Requirements

The National Pollutant Discharge Elimination System (NPDES) permits were based on effluent limitations in a staggered fashion to achieve the goals set forth in the 1983 CWA amendments. The permits are issued to individual wastewater treatment plants to reduce the number of pollutants released into nearby waterways. The permits contain standard conditions applicable to all POTWs, site-specific constraints, compliance monitoring, and reporting requirements.

The NPDES is a voluntary process that covers priority pollutants, conventional wastewater (BOD, TSS, fecal coliforms, etc.), and nonconventional pollutants (COD, ammonia, priority toxics, etc.). Once established, the monitoring plans revealed that several nonconventional constituents in industrial effluents either interfered with municipal treatment or passed through unaltered. Interference with treating conventional wastes could result in a loss of compliance of the regulated, conventional pollutants. Compounds passing through unaltered violate the intent of clean water statutes. This led to the need for industrial pretreatment to ensure that POTWs could handle the incoming waste streams. Industries requiring pretreatment prior to effluents being released for municipal treatment include pulp and paper, metal plating, electroplating, foundries, pharmaceuticals, petroleum refining, tanneries, etc. Pretreatment standards for each industry must be met before the facility can discharge to a POTW.

SAFE DRINKING WATER ACT

The SDWA (public law 93-523,) was passed on December 16, 1974, to expand the nation's goals to include drinking water. Within 6 mo of legislation, National Interim Primary Drinking Water Regulations (NIPDWRs) were enacted to ensure that serious efforts were being made. Every 2.5 yr the USEPA would review the current water quality and publish recommended maximum contaminant levels (MCLs) for potentially threatening chemicals, thereby generating new NIPDWRs. The continual review of NIPDWRs led to the establishment of national primary drinking water standards (Table 3).

In 1986, the most significant amendments were made to the SDWA. Some of the key provisions of this amendment include mandatory standards for 83 contaminants by June 1989, mandatory regulation of 25 contaminants on a triennial monitoring schedule, disinfection of all public community water supplies, and monitoring of contaminants that are not regulated. In 1996, the SWDA was amended to include National Secondary Drinking Water Standards (NSDWRs). The secondary standards are nonenforceable MCLs that deal with the aesthetics of the water (taste, color, odor, etc.), but whose exceedance would not cause a public health risk. While unenforceable, some states have adopted secondary MCLs that are higher or lower than those established in the NSDWRs as standards that are enforceable. Finally, there are MCL goals (MCLGs) that establish a nonenforceable, health-based goal at which no known or anticipated adverse effects on human health occur and that allow for an adequate margin of safety.[15] Maximum contaminant level goals are often used as a guide in establishing actual MCLs. As a result of the SDWA and its amendments, more than 240,000 publicly owned water systems have been established that serve over 300 million people.

Table 3 Primary and secondary drinking water standards for select contaminants

Primary standards		Secondary standards	
Inorganic	(mg/L)	*Inorganic*	(mg/L)
Antimony	0.006	Aluminum	0.05–0.2
Arsenic	0.05	Chloride	250
Barium	2.0	Copper	1.0
Berrylium	0.004	Fluoride	2.0
Cadmium	0.005	Iron	0.3
Chromium, total	0.10	Manganese	0.05
Copper	1.3	Silver	0.1
Cyanide	0.20	Zinc	5
Lead	0.015		
Mercury	0.002	*Others*	
Nickel	0.1	Color	15 units
Nitrate-N	10	Corrosivity	Noncorrosive
Nitrite-N	1.0	pH	6.5–8.5
Selenium	0.05	Foaming agents	0.5
Thallium	0.002	Odor	15 color units
Select VOCs		Sulfate	250 mg/L
Benzene	0.005	Total dissolved solids	500 mg/L
Carbon tetrachloride	0.005		
Dichloromethane	0.005		
Ethylbenzene	0.7		
Styrene	0.1		
Tetrachloroethylene	0.005		
Vinyl chloride	0.002		
Xylenes, total	10.0		
Select synthetics			
Alachlor	0.002		
Atrazine	0.003		
Benzo(a)pyrene	0.0002		
Chlordane	0.002		
Diethylhexyl phthalate	0.006		
Dinoseb	0.007		
Endrin	0.002		
Heptachlor	0.0004		
Lindane	0.0002		
Methoxychlor	0.04		
PCBs	0.0005		

TOXIC SUBSTANCE CONTROL ACT

The Toxic Substance Control Act (TSCA) was passed in 1976 and is contained in 15 USC § 2601 et seq. It regulates toxic substances, other than wastes, that are not adequately covered by other statutes. Promulgation of TSCA gave the EPA the authority to manage chemicals from production to final disposal. In fact, if a compound (e.g., carbon tetrachloride) is found to pose unreasonable risk to human health or the environment, the EPA can immediately remove it from commerce.[3] The TSCA's requiring a premanufacture notification (PMN) 90 days prior to manufacture has minimized the occurrence of immediate emergency removal of toxic chemicals. The PMN contains information on the physical/chemical properties, health and environmental effects, quantities, intended uses, and potential exposures. If the chemical cannot be processed, used, or disposed of without posing unreasonable risk, the EPA can ban its production. In situations where the PMN does not contain sufficient information to ascertain potential risks, additional testing can be ordered. The testing could be required from the manufacturer, processor, and/or distributor of the chemical in question.

In addition to the PMN, section 4 of TSCA requires the formation of a review committee. Each year the committee selects 50 compounds that are currently produced and/or processed to be retested. To ensure that the intent and guidelines of TSCA are being met, each industry must keep meticulous records on the quantities of chemicals imported, manufactured,

and used. Every 4 yr the list is submitted to TSCA for review. The quadrennial review led to four of the key provisions of TSCA: establishment of asbestos emergency response, ban of lead-base paints, restriction of hexavalent chromium in wastewater, and prohibition of the production of polychlorinated biphenyls (PCBs) past 1979.[6]

CONCLUSIONS

Environmental law is an ever-changing entity evolving because of a complex interaction between the protection of human health and the environment and the demands of an industrialized nation. It would be difficult, at best, to find an individual or company that would admit to a blatant disregard for environmental protection; however, the economic constraints that drive the day-to-day operations of a business will often govern a short-term decision. Corporations are, by and large, in business to make money. The easiest way to make money may be in direct conflict with what is in the best interest of the environment. An example of this was in the September 8, 2003, issue of C&E News, which reported the sale of PCB contaminated properties without requiring owners to clean the soil to threshold constraints. The institution of laws and regulations, like those found in this review, are the result of public outcry over decisions historically made with the protection of the environment as nothing more than an afterthought. The careful enactment of environmental laws places the burden of protection on those who have been historically responsible for the destruction of environmental resources, while still allowing for the careful growth of industry that promulgates a healthy economy.

For more in-depth coverage of any law highlighted during this review or not specifically noted, the reader is encouraged to seek the guidance of one of the many books devoted specifically to the law of interest. The texts used as reference for this review are all good sources of additional material. Additionally, the actual CFR, if applicable, may be retrieved with little difficulty. Volumes of material on each law can give the researcher a very detailed view in as broad or as limited a scope as desired and should be used whenever a more complete picture of a given law is necessary.

Epoxy Resins

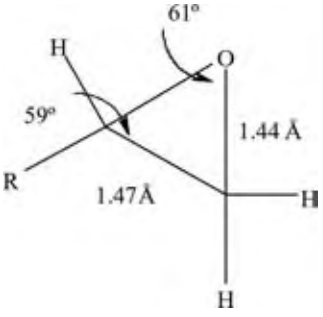
Ian Hamerton
University of Surrey, Surrey, U.K.

INTRODUCTION

Epoxy resins are a technologically important family of cross-linked, thermosetting polymers, which offer a good balance of thermal, mechanical, and electrical properties. The cured polymers are characterized by their good adhesion to a variety of substrates, hardness, chemical inertness (in the cured state), and thermal resistance. In this entry, the structure of the epoxy group, routes to commercial manufacture, physical properties of monomers and oligomers, and a variety of methods used in the characterization of these materials are addressed. Prior to cure, the monomers are typically formulated, and the range of modifiers available is discussed along with an indication of the property enhancements that may be achieved in this way. Polymerization may occur either in the absence or in the presence of curing agents, and the effect of the nature of these compounds on the cured properties is examined with particular attention to fracture toughness and flame retardancy. Finally, the technological importance of the materials is underlined with a discussion of the principal applications to which they are routinely put.

EPOXY RESINS

Epoxy resins have been in existence for over a century, with reports of the first synthetic work being carried out in 1891, although the first commercial products appeared only during the 1940s. These early materials, offering low-pressure molding resins, were based on the phthalic anhydride-cured diglycidyl ether of bisphenol A (DGEBA), which remains the mainstay of the epoxy industry. Epoxy resins are formed from monomers containing at least two epoxy (oxirane) groups.

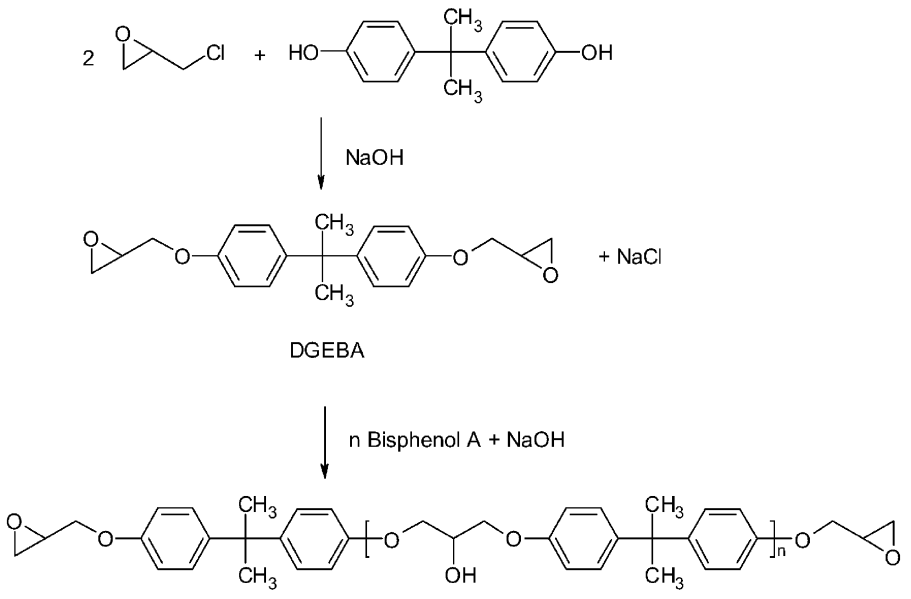


The three-membered ring is planar and may be bonded to a variety of substituents, R = $-CH_2OPh$, O-alkyl, CH_2-N-aryl, etc. The structure confers considerable ring strain, as the internal bond angles of the ring deviate substantially from the ''ideal'' angle of 109° for a tetrahedral sp^3-hybridized carbon. This makes the geometry similar to that of cyclopropane, but the marked electronegativity of the oxygen accounts for the inequality in the internal ring bond angles and lengths. The second, arguably more important, consequence of this geometry is the effect on the chemical reactivity of the functional group, with particular ramifications for the cure chemistry. In contrast with ''conventional'' noncyclic ethers (i.e., R-O-R′, Ph-O-Ph, or Ph-O-R), in which the ether bridge resists attack by alkalis, ammonia, or amines, the epoxy ring is susceptible to both nucleophilic attack (on one of the ring carbons) and electrophilic attack (on the ring oxygen), and mixtures of epoxy monomers and aliphatic amines will follow a nucleophilic mechanism at room temperature.

Commercial Manufacture of Epoxy Resins

The first commercial epoxy resins were structurally and chemically very similar and followed patent applications by Pierre Castan for denture bases (the technology was later licensed to CIBA, Switzerland)[1] and Sylvan Greenlee for damage tolerant surface coatings (Devoe and Raynolds, U.S.A.).[2] Whilst a number of synthetic routes to manufacture epoxy monomers exist,[3] two commercial paths prevail, depending on the desired structure (e.g., glycidyl ether or ''ene oxide'' monomer) and proposed application. Most commercial epoxies are produced via the dehydrohalogenation of halohydrins (in practice, this is usually epichlorohydrin) in the presence of a stoichiometric amount of a strong base catalyst (e.g., NaOH) to form a glycidyl ether (shown for the most common precursor, bisphenol A, in Scheme 1. The stoichiometry and reaction time can be controlled very carefully to produce the monomer shown, DGEBA ($n = 0$), a particular grade of epoxy, which can be used in electrical applications where high purity is necessary. More commonly, excess bisphenol A is added and the reaction is allowed to proceed to yield oligomeric polyethers, of varying chain length with $0.2 \leq n \leq 12$, containing hydroxyl groups along the backbone. Epoxies of this

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007755



Scheme 1 Commercial preparation of the diglycidyl ether of bisphenol A, DGEBA, and higher oligomers.

general type (and those formed from glycidyl amines) feature heavily like the resin matrix in advanced composite applications, adhesives, and coatings. However, examination of the reaction scheme reveals that the use of stoichiometric quantities of alkali produces significant quantities of halide ions, particularly chloride, associated with this route (arising from incomplete epichlorohydrin utilization), even after rigorous washing. Commercial oligomers may contain anything up to 1% chloride. In many electrical applications, the presence of even low (parts per million) quantities of chloride is simply not acceptable as it alters the electrical conductivity of the cured resin (normally a good insulator) and accelerates component corrosion in use. Furthermore, the presence of chlorine may also impart a colored taint to the resin and also reduce its reactivity (active chlorine blocks the reaction of less basic catalysts such as commonly used tertiary amines).

In some microelectronic or higher performance structural applications (e.g., satellites in which reduced levels of UV absorption are desirable, to withstand the harsh space environment), an alternate preparative procedure is employed involving epoxidation via Prileschaiev's reaction, e.g., using peracetic acid.[4] Two commercial structures depicting the resulting diepoxides are shown in Fig. 1 and the lack of strong UV-absorbing groups (chromophores) is immediately apparent. The other important characteristic, particularly in microelectronic applications, is the lack of hydrolyzable chloride ions and inorganic salts (ash). The latter is a direct result of the synthetic route employed, as the starting materials (typically buta-1,3-diene or acrolein, which acts as a dienophile) undergo a Diels–Alder reaction to yield adducts, containing cyclohexene moieties.

Physical Properties of Epoxy Resins

The monomeric form of DGEBA (shown in Scheme 1, where $n = 0$) may exist as a waxy crystalline solid (m.p. 43°C) even in some mixtures with other species of higher molecular weight, but it is unusual. The increasing chain length of the oligomer tends to yield viscous amber liquids at lower molecular weights or brittle solids as n increases (see Table 1 for representative melting temperatures). Epoxy resins are most likely to form glassy, amorphous solids, although liquid crystalline thermoset epoxies, containing highly rigid structural

motifs are known to form nematic phases.[5,6] Polymerization of these monomers, e.g., diglycidyl ether of 4,4′-dihydroxy-α-methylstilbene, using 4,4-*bis*(aminophenyl) methane (DDM), as a curing agent preserves the anisotropic order in the thermoset network, leading to high cross-linked organization of mesogens, which is claimed to have improvements in modulus, reductions in the coefficient of thermal expansion, and increased fracture toughness.

Characterization of Epoxy Monomers and Polymers

Many analytical techniques may be applied to the characterization of uncured epoxy resins, from simple chemical analysis to more sophisticated forms of spectroscopy. In the uncured form, the solubility of monomeric and oligomeric species renders them amenable to analysis. Common analytical measurements made on uncured epoxy monomers include determination of the epoxide content (achieved by the production of halohydrin from the cleavage of the epoxy rings using haloacids), hydroxyl content (using near infrared spectroscopy or assay with lithium aluminum hydride to yield hydrogen determined volumetrically or using gas liquid chromatography), and chlorine content. The latter may take the form of organically bound chlorine, either hydrolyzable (resulting from incomplete epichlorohydrin) or inactive (resulting from the reaction of epichlorohydrin with a secondary alcohol or phenol). The total chlorine content is commonly determined by oxidizing the material using a Parr bomb and quantifying the chloride content as silver chloride. Hydrolyzable (saponifiable) chlorine may be determined by treatment with excess caustic soda, followed by back titration with standard hydrochloric acid.

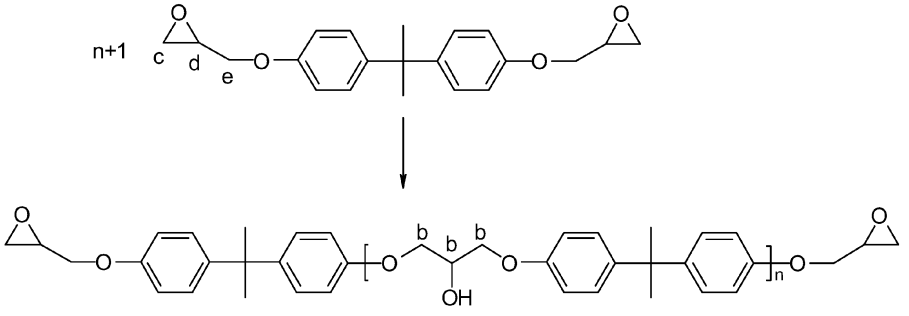
Conventional (spectroscopic) analysis techniques are also readily applied to determine structural details (e.g., the epoxy ring and the repeat unit) and can also be applied to determine the degree of polymerization, particularly where the poor solubility of the oligomer may hamper solution-based techniques. Mertzel and Kœnig[7] presented a thorough spectral characterization of EPON 828 (a commercial grade of DGEBA).

Thus, infrared spectroscopy reveals that the characteristic epoxy ring breathing vibrations are located at ca. 863 and 915 cm^{-1}, and these are useful for kinetic analysis and quantification, with an overtone band evident at 4535 cm^{-1}, whilst ^{1}H NMR spectroscopy reveals that the methylene and methyne ring protons of the oxirane ring resonate at ca. 2.67, 2.87, and 3.34 ppm. ^{13}C NMR is not only useful for yielding structural information (e.g., the glycidyl methylene at ca. 65 ppm, the methyne ring proton at ca. 50 ppm, and the methylene ring proton at ca. 45 ppm), but also epoxy equivalent weight (EEW). The latter is achieved by calculating the ratio between the integrals of the chemical shifts for the terminal ether carbons (C_c, C_d, and C_e; Scheme 2 and the bridge carbons (C_b).[8] The agreement between ^{13}C NMR and chemical analysis in this study was quite reasonable, although where discrepancies arose (e.g., 171 g/epoxide cf 193 g/epoxide or 971 g/epoxy cf 1086 g/epoxy), the spectroscopic analysis consistently gave a lower value of EEW.

Formulation of Epoxy Resins

Epoxy resins are amenable to modification in many ways and commercial epoxy formulations often contain a number of materials whose presence serves to modify the properties and characteristics of both uncured and cured epoxy. These additives fall into the following general categories:

i. Reactive and nonreactive diluents (to reduce viscosity and aid general processability, such as wetting characteristics and allow the incorporation of other fillers). Reactive diluents are often monoepoxides.
ii. Fillers (see Table 2 for a selected list).
iii. Plasticizers may be long-chain, nonreactive molecules, e.g., poly(vinyl chloride) or 2-hydroxyethylmethacrylate, entrapped within the epoxy network, whilst ''flexibilizers'' react with the epoxy group during cure. Both are employed to improve properties such as strain tolerance, impact strength, low temperature crack resistance, and adhesive properties such as lap shear,



Scheme 2 Polymerization of the DGEBA monomer to the corresponding epoxy polymer, showing the terminal ether carbons (C_c, C_d, and C_e) and the bridge carbons (C_b).

Table 2 Selected fillers and potential property modifications

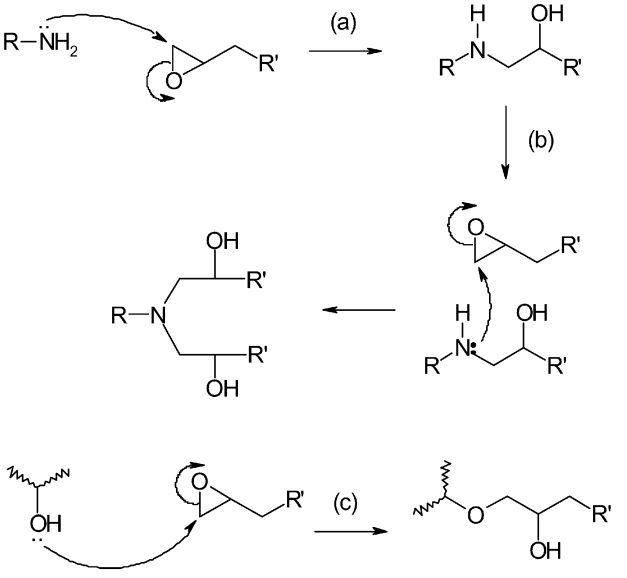
Filler	Resin property modification
Alumina	Abrasion resistance, dimensional stability, electrical resistivity, thermal conductivity, toughness
Aluminum	Impact resistance, machinability, mechanical properties, thermal conductivity
Aluminum silicate	Chemical resistance, dimensional stability, extender, pigmentation
Aluminum trioxide	Flame retardancy
Beryllium oxide	Thermal conductivity
Calcium carbonate	Dimensional stability, extender, machinability, mechanical properties, pigmentation
Calcium sulfate	Dimensional stability, extender
Carbon black	Electrical conductivity, pigmentation, reinforcement, thermal conductivity, thermal resistance
Copper	Electrical conductivity, thermal conductivity, thermal resistance
Glass microballoons	Density reduction
Mica	Chemical resistance, dielectric properties, electrical conductivity, lubricity, moisture resistance, toughness
Sand	Abrasion, thermal conductivity
Silver	Electrical conductivity, thermal conductivity
Titanium dioxide	Dielectric properties, extender, pigmentation
Zirconium silicate	Arc resistance

(From Shaw, S.J. Additives and modifiers for epoxy resins. In *Chemistry and Technology of Epoxy Resins*; Ellis, B., Ed.; Blackie Academic and Professional: Glasgow, 1993.)

and particularly peel strength, but they may also reduce chemical and solvent resistance.

Curing Agents for Epoxy Resins

Epoxy resins undergo cure to yield three-dimensional networks from a liquid or thermoplastic monomer or oligomer and the resulting product is a hard, insoluble, and infusible product. Epoxy monomers with higher functionality (e.g., trifunctional monomers, such as triglycidyl isocyanate or the tetrafunctional *N*,*N*,*N*′,*N*′-tetraglycidyldiaminomethane, TGDDM) are often more reactive than difunctional analogs. During the cure, the epoxy and curative (e.g., curing agent, accelerator, and a variety of additives, discussed later) undergo conversion to a solid via gelation and perhaps vitrification (which occurs as the glass transition temperature, T_g, approaches the cure temperature). The cure reaction proceeds via two general routes: homopolymerization to yield a polyether structure following initiation by a catalytic curing agent; copolymerization or polyaddition involving a multifunctional curing agent to produce a more highly cross-linked network (shown in Scheme 3 for polyamines). These



Scheme 3 General mechanism for amine cure of epoxy resins involving (a) primary and (b) secondary amines; (c) hydroxyl catalyzed polyetherification reaction. This is shown for one functional group; R and R′ denote the other half of an aryl or alkyl backbone.

step-growth mechanisms do not generate volatile condensates and consequently the production of void-free moldings or artifacts can be achieved relatively easily without the need for applied pressure. The characteristic structure and consequent reactivity of the epoxy ring ensure that epoxy resins are extremely versatile and may undergo cure with a wide variety of commercial curing agents (see Fig. 2 for typical structures).

Epoxy Resin Cure

The versatility of the epoxy group has already been highlighted: reaction may occur with a number of different curatives via different reaction mechanisms with associated kinetic expressions. Furthermore, the topic is a complex one and falls outside the scope of this entry, but some general observations may be made. In the initial stages of cure, when the cure temperature may greatly exceed the glass transition temperature of the uncured epoxy mixture, the reaction mixture comprises low molecular weight species (e.g., monomers, dimers, trimers, etc.). As cure proceeds, the epoxy initially undergoes chain extension, before further branching takes place to yield large, highly branched molecules; during these early stages, the reaction is under chemical control. With further branching, the reaction mixture experiences a rapid increase in viscosity and a critical point is reached when gelation occurs: the formation of an incipient three-dimensional network. If the cure temperature is too low, then vitrification may occur before gelation occurs; further reaction is inhibited as the glass transition temperature of the curing mixture reaches the cure temperature and molecular mobility is limited. Thus as cure proceeds, the increasing viscosity ensures that the kinetics of the reaction mixture become increasingly subject to diffusion control in determining the rate and extent of reaction. Prior to gelation, the reaction mixture contains a significant proportion of soluble material (the "sol"); after this point, the weight fraction of sol decreases dramatically (essentially approaching zero) as the gel fraction grows. Furthermore, the incipient network undergoes further growth as the cross-link density increases to tie polymer chains together, and it is often in these later stages of reaction that the development of the thermomechanical properties, necessary for application of the epoxy resins, occurs. The relationship between cure, C, temperature, T, and elastic property, P, may be depicted using a method proposed by Gillham and coworkers (Fig. 3).

In general, the cure may be monitored using a variety of techniques:

i. Direct assay of the concentration of functional groups.
ii. Thermal analysis.
iii. Rheological changes during cure.

During the early stages of reaction, solution-based analysis techniques (e.g., "wet" chemical tests, such as titrimetry or chromatography: HPLC or GPC) may be used to determine the extent of network growth. However, when the cure reaches the gel stage, the reduction in solubility renders such methods ineffective, necessitating the use of more exotic, nonsolution-based

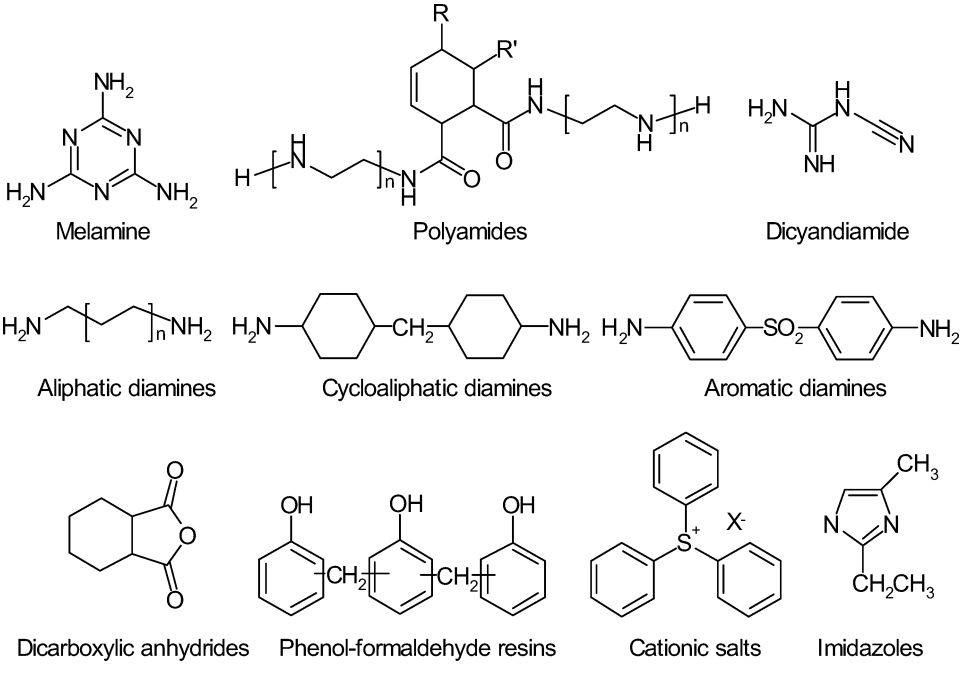


Fig. 2 Structures of selected catalysts and curing agents commonly used for the cure of epoxy resins.

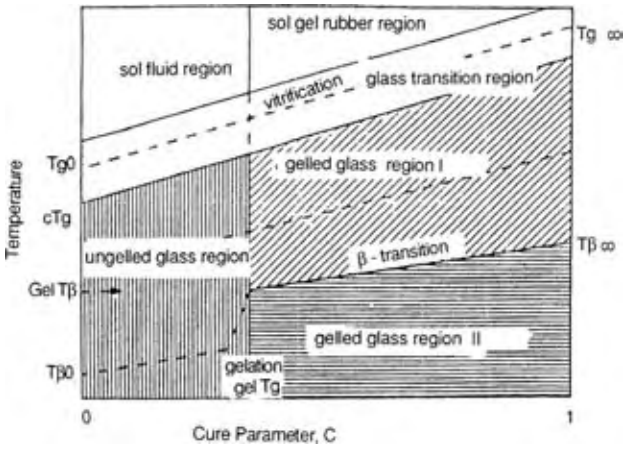

Fig. 3 The CTP diagram, a modified version of the T_gTP proposed by Wang and Gillham.[9] $C = (T_g - T_{g0})/(T_{g\infty} - T_{g0})$, where T_{g0} is the initial glass transition temperature of the uncured resin; $T_{g\infty,}$ is the glass transition temperature of the fully cured resin; T_g, is the glass transition temperature of the partially cured resin. (From Ref.[3].)

techniques, such as cross-polarization-magic angle spinning nuclear magnetic resonance (CP-MAS NMR) spectroscopy to obtain structural information.

Cured Epoxy Resin Properties

Undoubtedly, DGEBA remains the most widely researched and commercially most important epoxy resin, because of the impressive combination of its relatively low melt viscosity, physical strength after curing, and its relatively low production cost. However, the presence of glycidyl ether groups in the polymer not only imparts molecular flexibility and improves processability (by reducing the melt viscosity of the uncured resin), but they also decrease the heat resistance of the cured epoxy resin. This, coupled with relatively poor thermomechanical properties ($T_g < 120°C$), renders the polymer unacceptable for high performance applications (unless special aromatic curing agents are formulated into the final polymer). Where high performance is required, the tetrafunctional, predominantly aromatic TGDDM offers a good balance of properties (e.g., good long-term high-temperature properties, high mechanical strength retention, very low cure shrinkage, fine chemical resistance, etc.) at relatively low cost. The aerospace industry makes widespread use of TGDDM in mixtures containing the curing agent diaminodiphenylsulphone (DDS), for advanced structural composites and structural adhesives, etc. because of their high strength : weight ratio and relative ease of cure, although it is common to use a small quantity of a boron trifluoride ethanolamine complex as an accelerator. The ease of processing is also very attractive: the TGDDM (e.g., XU MY 722) may be heated to 140°C and DDS may be stirred in slowly and quite easily at this temperature to yield a clear, homogeneous blend before being degassed at 0.1 MPa for 15–30 min. The storage life of the degassed melt is exceptionally good and may be refrigerated in this state for several months. This is a key issue, because the production of complex composite components using lay up procedures may take many days to achieve, during which advancement in the prepreg is undesirable. Cure proceeds at 177°C via a combination of primary amine-epoxide, secondary amine-epoxide, and epoxide-hydroxyl reactions; whilst, according to infrared spectroscopy, ether formation occurs to a significant degree in the later stages. Table 3 displays a selection of cured resin properties for mixtures containing near stoichiometric quantities of DDS, from which the effects of both mixture composition and curing schedule may be appreciated.

STRATEGIES FOR TOUGHENING EPOXY RESINS

Conventional polyfunctional epoxy monomers, in common with most high performance thermoset polymers for load bearing applications, can be classed as brittle in fracture (i.e., typically offering G_{IC} values of $300\,J/m^2$ or less). The inevitable combination of high aromatic content (i.e., comprising rigid rings) and high cross-link density following cure not only leads to the desired elevation in glass transition temperature, stiffness, and chemical resistance in the polymer, but also to deleterious effects on its fracture toughness. The latter reflects the reduction in the molecular mobility of the matrix and its ability to yield under stress, and thus absorb energy. Consequently, for some 20 years or more, much research effort has been directed toward the development of different approaches to increase the toughness of epoxy resins. It is now generally accepted that the principal microdeformation process taking place in loaded, cross-linked epoxy resins is localized by shear yielding in areas of high stress concentration. Several general approaches have been examined in detail for improving this most important performance parameter and is discussed individually.

Mineral Filler Modification

The incorporation of glass microballoons has already been mentioned in the context of density reduction.

TGDDM: *N,N,N′,N′*-tetraglycidyl-4,4′-diaminophenylmethane; DDS: diaminodiphenylsulfone; phr: parts per hundred of resin; A: 80°C (2 hr), 100°C (1 hr), 150°C (4 hr), 200°C (7 hr); B: 180°C (2 hr), 210°C (2 hr).
(Adapted from Table 8.4 in: Lin, S.-C.; Pearce, E.M. High-performance epoxy resins, Chapter 8. In *High-Performance Thermosets, Chemistry, Properties, Applications*; Hanser: New York, 1998, p. 259.)

However, it has been known for some 20 years that significant enhancements in the modulus and toughness of epoxy resins can be made through the introduction of small glass spheres (microspheres) or silica. The results are impressive: the addition of ca. 40 vol.% of glass beads can lead to a doubling in Young's modulus and an increase in the fracture toughness (K_{IC}) of some 400% with no reduction in tensile strength.[10,11]

Rubber (Elastomer) Modification

The use of rubbers (particularly epoxy-terminated butadiene nitrile, ETBN, rubber or carboxy-terminated butadiene acrylonitrile, CTBN, rubber) to toughen thermoset polymers is perhaps the most widely explored method and has been applied with some measure of success in epoxy resins. Phase separation of the second rubbery phase occurs during cure and its incorporation in the epoxy matrix can significantly enhance the fracture toughness of the thermoset. Although the rubber has a low shear modulus, its bulk modulus is comparable to the value measured for the epoxy, ensuring that the rubber inclusions introduced during modification can play a full role in bearing a significant load within the polymer. Several mechanisms have been proposed to account for the observed increase in fracture toughness for rubber modified epoxy resins: shear yielding, void growth, and rubber bridging, although the contribution that each phenomenon makes to the mechanism is the subject of both research and debate. Huang and Kinloch concluded that at lower temperatures shear yielding represents the principal energy-absorbing mechanism (and that rubber bridging made an appreciable contribution at subzero temperatures), whilst at elevated temperatures shear yielding and void growth become equally important.[12] The incorporation of a dispersed rubber phase, with each particle acting as a stress concentration, offers numerous sites at which plastic deformation can occur and, where stress concentration occurs at the tip of a crack, the rubber particles undergo failure and cavitation. The latter leads to the production of voids within the polymer matrix and these grow in response to further loading, thus dissipating energy.

Apart from the nature of the actual rubber employed, the degree of toughness enhancement is influenced by a variety of factors, including the volume

fraction of elastomer incorporated, the molecular weight of the resin (Fig. 4), the size and size distribution of the rubber particles, and the magnitude of the interfacial bonding. In general, for CTBN-toughened epoxies, beneficial enhancements in fracture toughness are found for rubber loadings up to ca. 18–20 wt.%, whilst toughened epoxies typically contain many particles in the size range 1–5 μm, which contain both rubber and resin with smaller phase-separated particles (<0.2 μm). It is clear from a review of the literature in this area that there is some disagreement as to whether submicron or larger particles are more efficient toughness enhancers. Contradictory results have been reported, although the difference in particle size may lead to differences in the mechanism through which toughness is enhanced. Thus, larger particles may be acting as bridging particles, whereas smaller particles may be undergoing cavitation within the crack tip zone.[13]

Core-Shell Rubber Modification

A variant of rubber toughening involves the use of preformed core-shell rubbers comprising a highly cross-linked polybutadiene core with a grafted shell of a vinylic polymer. In this case, the particles are small, typically ca. 0.1 μm, and thus have little effect on the observed viscosity of the epoxy. One of the principal advantages of this over simple rubber toughening is the ability to produce predetermined controllable morphology in the cured polymer.[14]

Thermoplastic Modification

The incorporation of engineering thermoplastics, such as poly(arylene ether sulfone)s, polysulfone, poly(phenylene oxide), or poly(ether imide) is a more recent innovation[15,16] and has also been shown to yield significant improvements in the toughness of cured epoxy resins.[17,18] Importantly, however, unlike their rubber modified analogs, the introduction of engineering thermoplastics into epoxy resins does not result in a reduction in modulus, high-temperature properties, or creep resistance. Whilst original attempts to toughen epoxy resins in this manner yielded only modest improvements in fracture toughness, it has been shown that enhancements close to those obtained for CTBN can be achieved.[17] Bucknall and Patridge[19] have demonstrated this for a number of epoxies, and is shown in Fig. 5 that the incorporation of PEI serves to increase the toughness of the cured epoxy markedly, although the T_g of the PEI phase is always lower than that of the neat thermoplastic because of plasticization of PEI by low molecular weight species.

The approach taken by Sefton et al.[18] for the synthesis of novel thermoplastics designed to undergo phase separation from the thermoset epoxy matrix is complementary to the method employed by Bucknall and Patridge,[19] in which the nature of the thermoset is varied to achieve a similar result.

Several basic morphologies are observed in thermoplastic-modified epoxies and, indeed, other thermosets. Homogeneous [Fig. 6(A), in which no phase separation is observed] and particulate [Fig. 6(B), in which the modifier phase separates to produce small domains] morphologies occur at low concentrations of modifier. In these cases, the thermoplastic modifier is encapsulated within a thermoset matrix, whereas in the phase-inverted morphology, [Fig. 6(C)] the minor thermoplastic component is the continuous phase surrounding large, discontinuous domains of the major

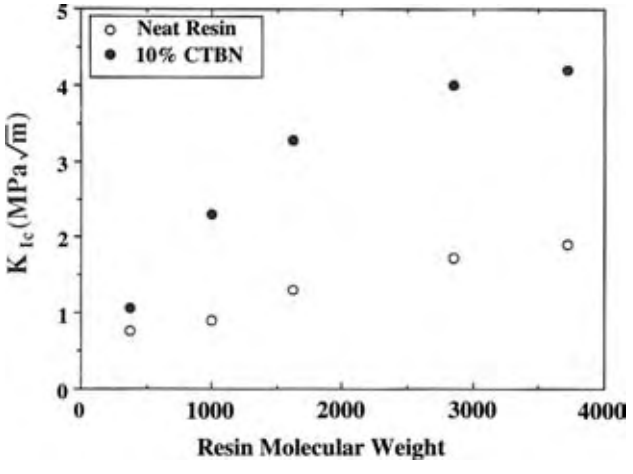

Fig. 4 Plot of fracture toughness vs. resin molecular weight for neat and CTBN-modified DGEBA-DDS.[13] (From Ref.[3].)

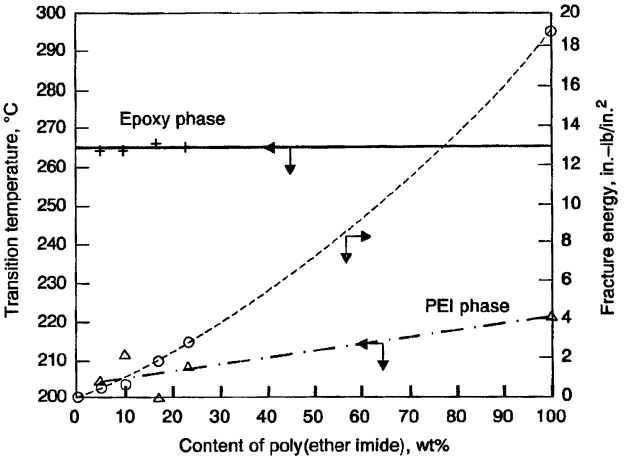

Fig. 5 Fracture energy and glass transition temperature of poly(ether imide) PEI, *N,N,N′,N′*-tetra-glycidyl-4,4′-diaminodiphenylmethane, and diaminodiphenylsulphone. (From Ref.[20].)

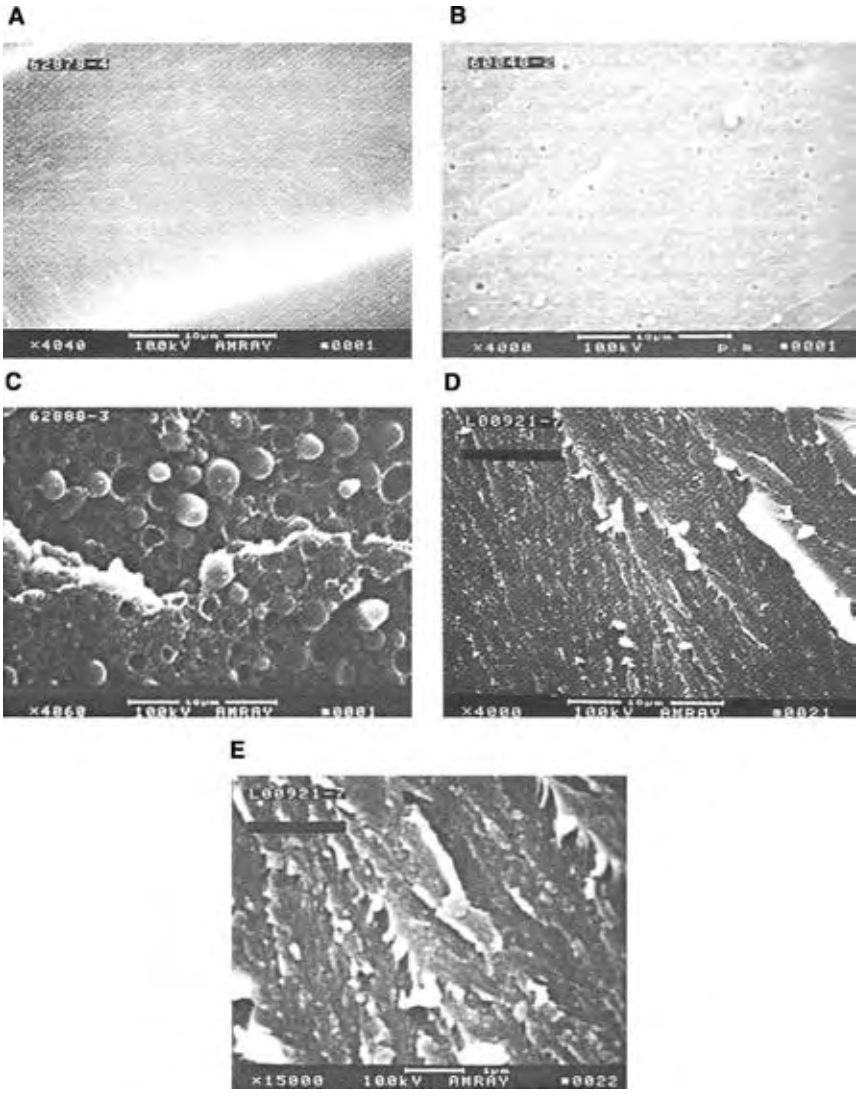

Fig. 6. Scanning electron micrographs of various morphologies produced with tailor-made thermoplastics toughened epoxy resins: (A) homogeneous, (B) particulate, (C) phase inverted, (D) and (E) cocontinuous. (From Hamerton, I., Ed.; *Chemistry and Technology of Cyanate Ester Resins*; Blackie Academic and Professional: Glasgow, 1994.)

thermoset component. A final morphology, designated ''cocontinuous'' [Figs. 6(D) and 6(E)], occurs in semi-interpenetrating networks and results in both phases remaining continuous in three dimensions. Practically, the larger phase-inverted morphologies may be observed using scanning electron microscopy (SEM; see Fig. 6), whereas the smaller scale of the cocontinuous morphologies, in which the phase sizes reflect the higher degree of compatibility between thermoset and thermoplastic, requires the use of transmission electron microscopy (TEM; see Fig. 7).

Flame Retardant Epoxy Resins

The demand for flame retardant (FR) epoxies is extremely high owing to their widespread use in adhesives, coatings, advanced composites, and the electronics industry. Currently, extensive use is made of bromine to impart flame retardancy and a typical laminating resin for printed wiring boards is an FR4 epoxy resin. This comprises DGEBA advanced with tetrabromobisphenol A (Fig. 8) and a cross-linking agent package based on a styrene–maleic anhydride copolymer and an optionally brominated bisphenol A and/or an optionally brominated DGEBA. In 2004, the typical price for a brominated epoxy (in liquid, solid, and solid solution forms) was around 220 €/tonne.

However, both the European Community (EC) and the United States (U.S.) Government have expressed concern about the use of FRs, particularly those containing halogens, because of the toxicity and perceived adverse environmental impacts of these compounds. Thus, the EC has proposed to restrict the use of brominated diphenyl oxide FRs because highly toxic and potentially carcinogenic brominated furans and dioxins may form during combustion.[21] The World Health Organization and the U.S. Environmental Protection Agency have also recommended exposure limit and risk assessment of dioxins and similar compounds.

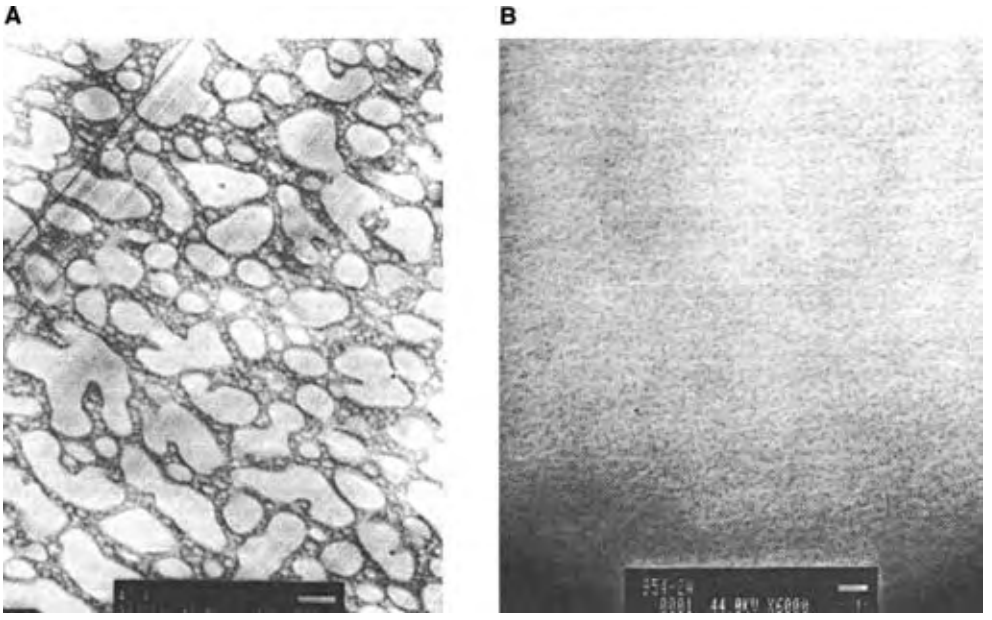

Fig. 7 Transmission electron micrographs of morphologies produced with tailor-made thermoplastics toughened epoxy resin (Fiberite 954-2A): (A) phase inverted and (B) cocontinuous. (From Hamerton, I., Ed.; *Chemistry and Technology of Cyanate Ester Resins*; Blackie Academic and Professional: Glasgow, 1994.)

Consequently, nonhalogenated FRs are being examined as alternatives to existing compounds, and an extensive literature already exists in this area.[22] For epoxy resins, the most effective route to improving the flame retardancy is the reactive approach, wherein inherently, FR groups are incorporated into the polymer backbone or side chain. Organophosphorus groups, such as dialkyl or diaryl phosphates (Scheme 4), are readily introduced via reaction with the epoxide group.

In this way, a range of polymerizable diepoxides or organophosphorus-containing curing agents based on phosphine oxide, phosphate, or 9,10-dihydro-9-oxa-10-phosphaphenanthrene-10-oxide (DOPO) have been prepared and evaluated (Fig. 9).

The incorporation of DOPO derivatives in DGEBA has been found to increase not only flame retardancy but also thermal stability. The DOPO-based diamine shown in Fig. 9, having a reactivity toward DGEBA intermediate between DDS and DDM, has also proved to be an effective FR. It displays a char yield (in a DEGBA/DOPO-amine) polymer of 32% at 700°C under nitrogen, compared with 13–15% for a phosphorus-free epoxy. Tricyclophosphazenes are already known to impart flame retardancy,[23] and whilst polyepoxides containing the tricyclophosphazene structure have been synthesized, the preparative route is perhaps less cost effective than that of the corresponding polyamine (Fig. 9, top left). Incorporation of the tricyclophosphazene moiety might be achieved more readily through coreaction with a conventional commercial epoxy monomer. Silicon, which shares many aspects of its chemistry with carbon, is another element that has been examined widely as a potential FR. Research has shown that the addition of relatively small amounts of silicon can improve the flame retardancy of polymers significantly, both through char formation in the condensed phase and the trapping of active radicals in the vapor phase. Incorporation can be achieved via epoxy- or amino-functionalized linear silanes or oligosiloxanes (see Fig. 10).[24] The latter can be polymerized in their own right (with or without curing agents), but also blended and copolymerized with conventional epoxy monomers. Incidentally, synergistic effects may be obtained by combining phosphorus- and silicon-containing epoxies or curing

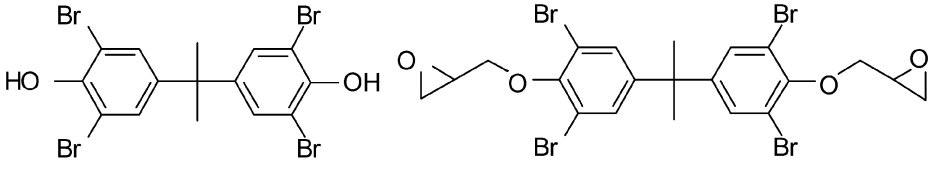

Fig. 8 Tetrabromobisphenol A (left) and brominated DGEBA (right).

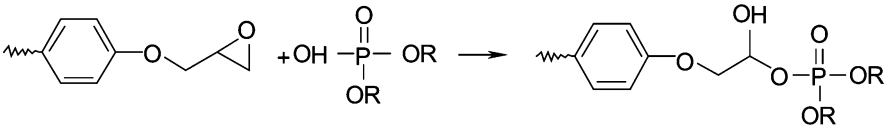

Scheme 4 Dialkyl (or diaryl) phosphate modified epoxy resin, where R is methyl, ethyl, butyl, or phenyl. (Redrawn from Ref.[22].)

agents: a polymer containing 4.8% P and 12.7% Si achieves a limiting oxygen index (LOI) of 41 (where a value of at least 26 is required for a material to be qualified as self-extinguishing).

Polyhedral oligomeric silsesquioxane (POSS) reagents are becoming an increasingly important route to the preparation of nano-reinforced polymers (or ''nanocomposites''). POSS molecules are cube-shaped hybrid inorganic–organic structures comprising silicon atoms at the vertices, sandwiching oxygen atoms. Each of the silicon atoms may be functionalized, using a wide variety of chemical transformations, so that mono-, di-, or poly-functionalized POSS reagents may be prepared in high yield and purity.[25] In some cases, highly functionalized POSS-epoxides may present problems because of high crystallinity (making liquid incorporation difficult) or high cross-link density (in which high degrees of conversion may be difficult to achieve, for example, conversions of 78–90% have been reported for such materials)[26] and mono-substituted epoxy-POSS reagents may offer the best route for producing nanocomposites bearing pendant POSS structures.

TECHNOLOGICAL APPLICATIONS FOR EPOXY RESINS

A wide range of commercial epoxy monomers are available and cured epoxy resins find application in areas as diverse as protective coatings, electrical applications, reinforced resins (composites), bonding and adhesives, flooring, and tooling and casting. Whilst a full discussion is beyond the scope of this entry, several of the principal applications are addressed.

Surface Coatings

Along with dental adhesives, the development of applied epoxy resins for protective or decorative purposes was one of the principal reasons for the original development of epoxy resins in the U.S.A. Some 50 years

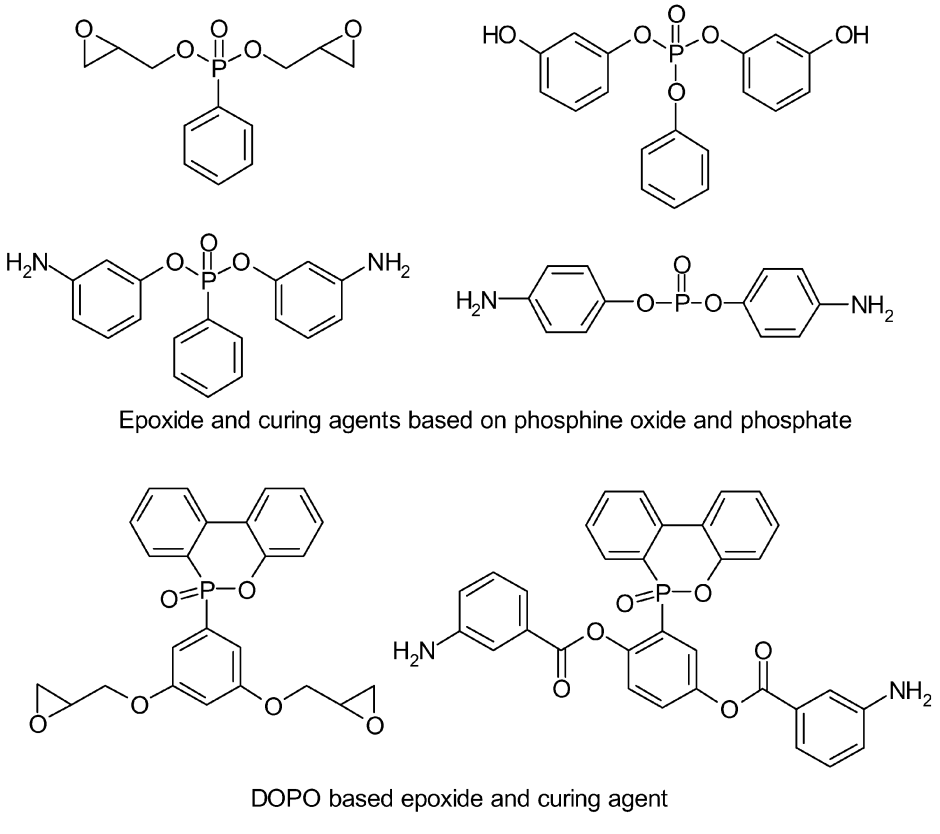

Fig. 9 Selected phosphine oxide-, phosphate-, and DOPO-based epoxides and curing agents. (Redrawn from Ref.[22].)

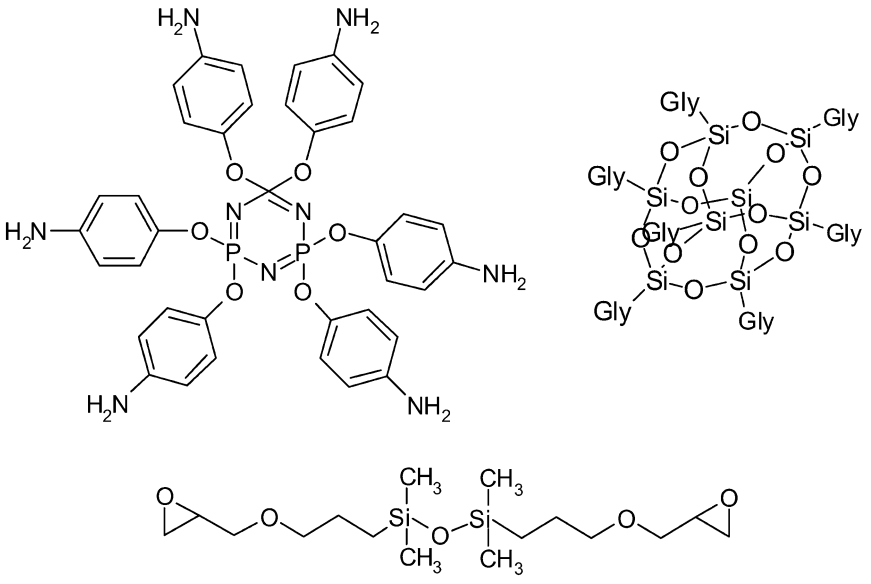

Fig. 10 Selected tricyclophosphazene (top left), POSS- (top right), and silane-based (bottom) epoxides and curing agents.

later, during the early 1990s, around half of the epoxy resins in Western Europe and the U.S.A. was used in protective coatings (often in the construction industry), which was by far the largest single category (Table 4). This is an unusually high figure for a family of polymers that is generally more expensive than their market rivals for coatings or laminates (e.g., phenolic resins). Consequently, it is of paramount importance that for an epoxy to be used to supplant a phenolic, it should have markedly superior properties to offset the cost.

Electrical Properties of Epoxy Resins

Epoxy resins are finding increasing use in many applications associated with the electronics industry (e.g., encapsulation, potting, thin film coating, embedding or packing of electronic circuits, etc.). This is partly attributable to their versatility discussed previously (i.e., ease of processing, a wide choice of curing agents, etc.).

Table 4 Uses of epoxy broken down by market sector

	1967 (%)	1990 (%)	1991 (%)
Protective coatings	55	49	51
Electronic applications		14	13
Reinforced resins	20	7.5	8
Bonding and adhesives	5	7.2	7.25
Flooring		6.5	6.25
Tooling and casting	10	7.5	7.25
Other	10	8.3	7.25
Total	100	100	100

(Adapted from Modern Plastics International (**1992**, Jan): 48.)

Cured epoxy resins have a combination of electrical properties that make them attractive in electrical and electronic applications:

- Dielectric permittivity of ca. 3–6 at ambient temperature and low frequencies.
- Dissipation factor, $\tan\delta$, of 10^{-3} to 10^{-2} for 60–1000 Hz.
- Dielectric strength ca. 120–180 kV/mm.
- Volume resistivity of 10^{19}–$10^{12}\,\Omega$/m.
- Good adhesion to metals and silicon.
- Low permeability or absorption of water (typically 0.1–0.25% for certain epoxies or epoxy formulations).
- Low viscosity prior to cure.
- Low stress resistance.
- Low heat of reaction.

Although some competitor resins (e.g., polyimides and cyanate esters) are replacing epoxy resins in some more demanding applications, in which the superior glass transition temperatures or lower dielectric permittivity/low dielectric loss are preferred, brominated epoxies are still widely used.

Epoxy-Based Composite Materials

Epoxy resins have found application in carbon fiber reinforced composites for some 30 years or more and the benefits are well documented (Table 5). The traditional limitations are also summarized simply in the same table.

Epoxy resins are by far the most widely used polymer matrices for advanced structural composites and, if carbon, glass, and aramid fiber reinforced epoxies

Table 5 General characteristics of epoxy-based carbon fiber reinforced plastics (CFRPs)

Benefits conferred by epoxy-based CFRPs	Traditional limitations epoxy-based CFRPs
Weight saving over aluminum alloys (high specific stiffness and strength)	Susceptibility to operational impact damage
Tailored directional mechanical properties	Restricted environmental stability in terms of temperature and moisture absorbency
Reduced component count over metallic equivalents	Excessive localized damage through lightning strikes
Modified radar response compared with metallics	Uncertainties on repair techniques
Resistance to corrosion in saline environments	Cost compared with metallics
Excellent fatigue resistance	Labor-intensive and time-consuming manufacture process
Dimensional stability	

are considered together, they accounted for over 90% of the aircraft market alone in 1990.[27] Table 6, shows the wide diversity of applications to which epoxy-based advanced composite materials have been put in to use.

In Table 7, typical key laminate properties for thermoset and thermoplastic composites are given. It is immediately apparent that suitable toughening (discussed previously) can achieve superior compression after impact and comparable edge delamination strength to composites prepared from a thermoplastic matrix.

The fabrication of components from advanced composite materials also requires suitable tooling to shape and conform the prepreg during lay-up and epoxy have a role to play in this operation as well. Whilst less durable than conventional tooling constructed from steel or aluminum, tooling prepared from carbon fiber reinforced epoxy resins offers lightweight and, most importantly, a good match with the

Table 6 Selected applications for epoxy-based advanced structural composites

Aircraft	
Structural	CF/epoxy suitable in less thermally critical areas
Interior components	Cargo liners – monolithic laminate of aluminum, E or S-2 glass, of Kevlar with epoxy, polyester or phenolic
Space	
Launch systems	CF/epoxy composite motor cases
Communication Satellites	Antennae and large bus (housing) structures
Spacecraft	CF/epoxy metering truss (Hubble space telescope)
Space shuttle	CF/epoxy payload bay doors
Sports/leisure	
Golf	Medium or high modulus CF/epoxy club shafts
Tennis racquets	Modified epoxy/CF, boron, Aramid, and Spectra head/frame
Bicycles	CF/epoxy frame and spokeless/disk wheels
Skis	CF/epoxy skis and poles—high stiffness and compressive strength
Fishing rods	Lightweight CF/glass/epoxy hybrid rods
Archery	CF/thermoset bow (prepreg or pultruded) and pultruded CF arrow (resist bending and shattering)
Marine/naval vessels	CF/epoxy submarine hulls
Construction	Filament wound epoxy pipes
Tooling	CF/epoxy composite—fine CTE match with prepreg
Automotive	Composite drive shaft - CF/epoxy/CF stiffened aluminum shaft, passenger car floors, epoxy/GFRP springs
Racing cars	Oriented CF/epoxy composite chassis—improved energy absorption
Transportation	Epoxy/glass faced aramid honeycomb for monorail
Masts, antennae, radomes	Improved strength and dielectric properties over GFRP
Musical instruments	Epoxy/CF sound boards as facings for violins and guitars—more reliable than wood, retains tuning, improved sound projection

Table 7 Typical laminate properties on intermediate modulus carbon fiber at a fiber volume of ca. 60%

linear coefficients of thermal expansion for both carbon fiber prepreg (2.5–3.6 ppm/°C) and carbon fiber wet lay-up (5.5 ppm/°C). This contrasts sharply with, e.g., mild steel (11.0 ppm/°C) or aluminum (23.0 ppm/°C), the expansion behavior of which varies widely from the prepreg undergoing cure.

Epoxy Resin Adhesives

Originally produced during the two decades following the Second World War, epoxy resin adhesives have grown in popularity such that they are now used widely in many commercial and domestic settings. Over the years, epoxy resins have gained a large measure of popularity as adhesives for a combination of favorable characteristics:

- Excellent adhesion to a variety of substrates including most metallic alloys.
- Short- and longterm operation up to ca. 150°C.
- Highly versatile and able to achieve a wide range of processing, cure, and properties characteristics.
- No volatiles evolved during cure—no requirement for high pressure bonding operations.
- Good wetting properties on well prepared surfaces.
- Relatively low cure shrinkage.

DGEBA is the most commonly used epoxy in adhesive formulations. Although they may range from very simple, low molecular weight, primarily aliphatic resins to more complex, multifunctional, primarily aromatic materials. A wide choice of curing agents is available, in common with other applications. Schmidt and Bell[28] published a very thorough discussion of the adhesion of epoxy resins to metal surfaces. Initial adhesion strength values achieved by epoxy adhesives and coatings are principally because of the inherent epoxy chemistry: ring opening leads to the generation of aliphatic hydroxyl and ether groups in the cured polymer. This high polarity offers sites for the formation of strong hydrogen bonds between epoxy molecules and metal oxides (with typical bond energies of 5–10 kcal/mol).

CONCLUSIONS

Epoxy resins undergo cure to yield three-dimensional networks from a liquid or thermoplastic monomer or oligomer, and the resulting product is a hard, insoluble, and infusible product. Cured epoxy resins offer a good balance of thermal, mechanical, and electrical properties, as well as good adhesion to a variety of substrates, hardness, chemical inertness (in the cured state), and thermal resistance. Additionally, epoxies may be modified easily with a range of additives to improve fracture toughness and flame resistance. Commercial epoxy resins find application in many technological applications, often as market leaders: protective coatings, electrical applications, reinforced resins (composites), bonding and adhesives, flooring, and tooling and casting.

Ethylbenzene

Guy B. Woodle
UOP LLC, Des Plaines, Illinois, U.S.A.

INTRODUCTION

Ethylbenzene (EB) is a single-ring alkylaromatic compound that is used almost exclusively as an intermediate in the production of styrene monomer. On a commercial scale, essentially all EB is produced by alkylating benzene with ethylene. As of April 2004 approximately 30% of the worldwide EB production is carried out by liquid phase alkylation using a homogenous aluminum chloride catalyst in a process that was first commercialized in the 1930s.[1] Ethylbenzene was first produced commercially using a zeolite catalyst in a vapor phase reactor in 1980, which was a significant improvement over the aluminum chloride process. However, it was the development and commercialization of liquid phase and mixed liquid–vapor phase technologies in the 1990s that allowed for efficient production of high-purity EB. In 2003 the annual world EB production capacity was around 28.6 million metric tons, and EB production capacity is forecast to grow at an annual rate of just under 5% from 2004 to 2014.[2]

PHYSICAL AND CHEMICAL PROPERTIES

Ethylbenzene is a colorless aromatic liquid. It is only slightly soluble in water, but infinitely soluble in alcohol and ether. Additional properties are listed in Table 1. Ethylbenzene is chemically reactive with the most important reaction being its dehydrogenation to form styrene. Styrene is used to produce polystyrene, which is used in the manufacture of many commonly used products such as toys, household and kitchen appliances, plastic drinking cups, housings for computers and electronics, foam packaging, and insulation. In addition to polystyrene, styrene is used to produce acrylonitrile–butadiene–styrene polymer (ABS), styrene–acrylonitrile polymer (SAN), and styrene–butadiene synthetic rubber (SBR).

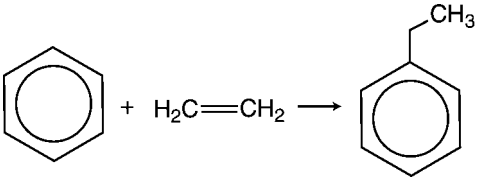
Ethylbenzene can also be oxidized to form ethylbenzene hydroperoxide, an intermediate in a process to produce propylene oxide.

REACTION KINETICS AND THERMODYNAMICS

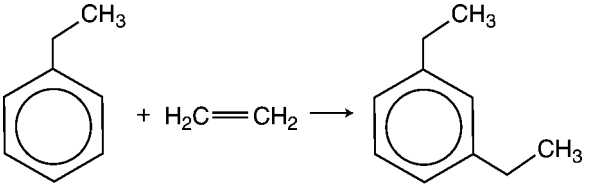
Commercially produced EB is based on alkylating benzene with ethylene.

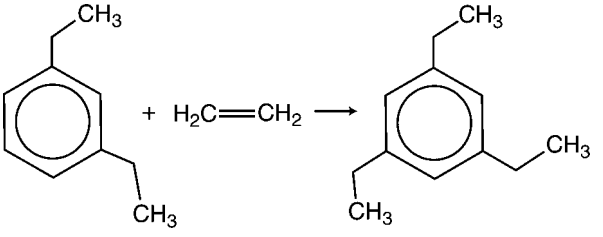
Benzene Alkylation with Ethylene

In the production of EB, alkylation is the reaction of ethylene with benzene according to the equation:



Successive alkylation reactions occur to a limited extent resulting in the formation of diethylbenzene and other higher ethylated benzenes, commonly called polyethylbenzene (PEB).





Kinetic reaction rate constants increase with the number of ethyl groups alkylated on the benzene ring. For example, the relative rate constant for alkylation of EB is roughly twice that for the alkylation of benzene. Reaction rate constants continue to increase with each successive alkylation reaction until a limitation is reached, such as steric hindrance. The formation of penta-EB and hexa-EB proceeds very slowly for this and other reasons so that only trace quantities are formed.

Alkylation reactions are exothermic. The initial alkylation of ethylene to benzene and each successive alkylation reaction generate roughly the same amount of heat (Table 2).

In addition to alkylation reactions, transalkylation reactions play a significant role in EB production.

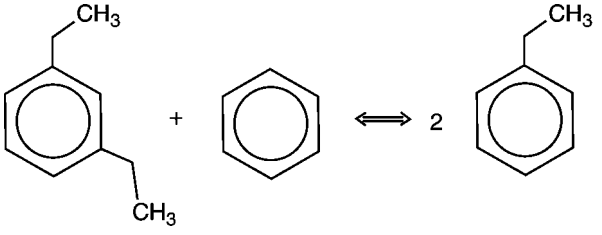
Commercially it is found to be economically attractive to transalkylate all the PEB formed as a result of successive alkylation reactions with benzene in a separate transalkylation reactor to produce additional EB.



Transalkylation reaction rates are relatively slow and conversion is generally limited by equilibrium. For transalkylation reaction, the heat of reaction is essentially zero, which leads to a reactor that operates nearly isothermally.

The occurrence of both alkylation and transalkylation reactions results in a reaction chemistry that is affected by equilibrium. The equilibrium has been studied and is illustrated in Fig. 1. The horizontal axis is the ratio of ethyl groups to benzene rings and is often referred to as the ethyl-to-phenyl ratio. In the case of an alkylation reaction, the ethyl-to-phenyl ratio is the moles of ethylene to moles of benzene. Similarly, for a transalkylation reaction, the ethyl-to-phenyl ratio is equivalent to the moles of ethyl groups contributed by PEB to the moles of phenyl groups contributed by PEB plus benzene. At ethyl-to-phenyl ratios above about 0.6, the equilibrium EB concentration is relatively constant at about 48 wt% whereas the PEB concentration continues to increase as the ratio approaches 1.0. Most commercial reactors operate with ethyl-to-phenyl ratios less than 0.6. The equilibrium composition varies only slightly across the temperature range of commercial interest.

Ethylene + DEB → tri-ethylbenzene (TEB)	−25.9
Ethylene + TEB → tetra-ethylbenzene	−25.5

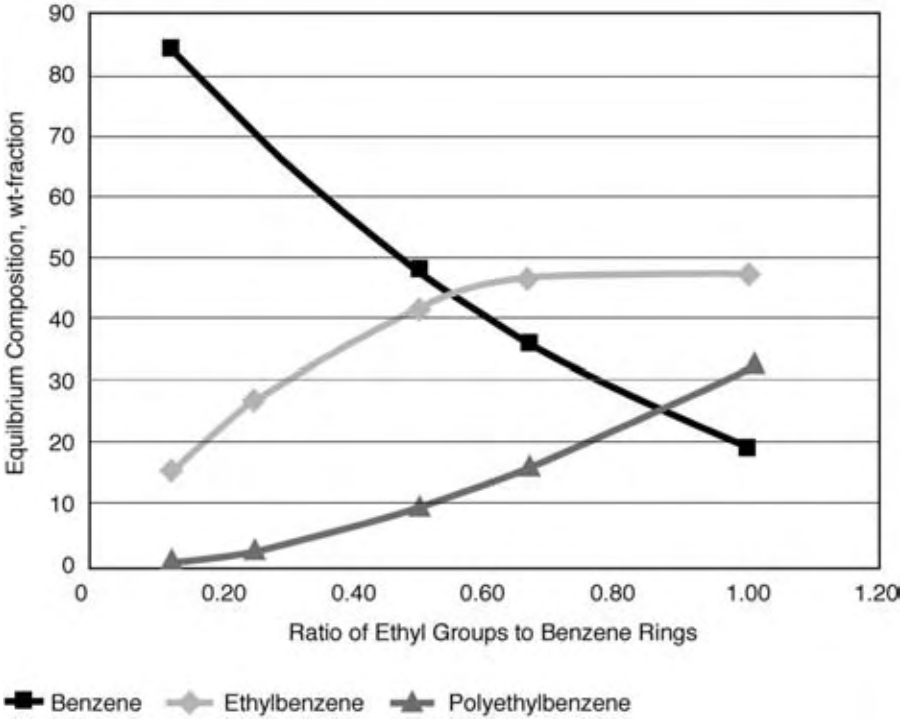

Fig. 1 Ethylbenzene equilibrium composition.

Other reactions, such as oligomerization, cracking, and isomerization, can also occur resulting in the formation of compounds such as cumene, butylbenzene, xylene, diphenylethane, and other high-boiling compounds. The formation of these by-products is impacted by the alkylation reaction conditions, in particular whether the reactions occur in the vapor phase or the liquid phase. For example, EB isomerization to xylene typically only occurs under vapor phase reaction conditions where reaction temperatures are relatively high. Isomerization does not occur to a great extent in the liquid phase because of the lower operating temperatures. The formation of by-products is also affected by the type of catalyst.

Acid catalysts are used to promote the alkylation of ethylene to benzene. Acid catalysts suitable for benzene alkylation include protonic acids (i.e., H_2SO_4, HF, and H_3PO_4), Friedel–Crafts catalysts (i.e., $AlCl_3$ and BF_3), and more recently, solid acid catalysts. Solid acid catalysts used for the commercial manufacture of EB are typically zeolitic molecular sieves and materials such as ZSM-5, faujasite, MCM-22, and zeolite beta.[3] Zeolites' physical and chemical properties can be modified to optimize the activity, selectivity, and stability of the catalysts. This flexibility of zeolites has made them the preferred catalyst of choice.

Many zeolites occur naturally as minerals. Some of these are natrolite, chabazite, sodalite, faujasite, and mordenite. Several of these naturally occurring zeolites can be produced synthetically, which makes them suitable for commercial application. In particular, faujasite-type structures zeolite X and Y have been broadly used in the petrochemical and chemical industries. A large number of new zeolite materials have been discovered and developed that cannot be found in nature. These specialty synthetic materials include MCM-22 and zeolite beta. The use of these synthetic zeolites has enabled the production of EB to become the highly efficient process it is today.[4]

Because the liquid phase process is predominantly used for new EB plants, the critical operating and design parameters for liquid phase benzene alkylation are discussed below.

Alkylation Benzene-to-Ethylene Ratio

The benzene-to-ethylene molar ratio (B/E) for the alkylation reaction section is the most important parameter for design and operation of an EB plant. A high B/E is beneficial from an equilibrium and catalyst selectivity standpoint, but the large molar excess of benzene relative to ethylene requires substantial energy to recover and recycle. The first liquid phase plants were designed and operated with B/E equal to 6 or greater. Over time, as improved catalysts were developed, the B/E has steadily decreased. In 2004, units are typically designed with B/E in the range of approximately 3.0–3.5. This substantial decrease in B/E has resulted in significantly lower capital costs, because nearly three-fourths of a plant's equipment cost is associated with recovery and recycle of

the excess benzene used in the reactors. Generally, a commercial plant is operated at or very close to the design B/E and is not frequently adjusted. With further improvements in the near future, commercial units will operate at even lower B/E ratios with B/E ratios possibly approaching 1.5 being made possible.

Alkylation Reaction Temperature

For liquid phase alkylation, the reaction temperature is normally in the range of 170–270°C to achieve an acceptable reaction rate using typical commercial catalysts. Excessive temperatures can increase by-product formation, so reactor design temperatures are often set with this in mind. Temperature also affects the reactor operating pressure and hence the equipment cost. Varying temperature within a relatively small range has little impact on the alkylation reaction overall, so generally, a commercial scale plant is maintained at a constant temperature near the design value throughout its operation cycle.

Reactor design plays a significant role in temperature control. Multiple ethylene injection points and heat removal stages are incorporated into the reactor section design to allow reaction temperature to be maintained in the desired range. A common design for reactor sections contains four ethylene injections with one heat removal stage. Another design option uses six ethylene injections with two heat removal stages. Other configurations have been used commercially.

Alkylation Reaction Pressure

Reaction pressure is sufficiently high so as to prevent any components from vaporizing in the alkylation reactor section. Alkylation reactors are typically operated at about 35–40 bar to maintain the reactor catalyst outlet streams in the liquid phase even at the maximum operating temperature. The ethylene injected into the reactor dissolves into the liquid hydrocarbon mixture such that the alkylation catalyst beds are always in the liquid phase. Reaction pressure is not normally varied during operation.

Transalkylation Benzene-to-Polyethylbenzene Ratio

To obtain an economically viable PEB conversion in the transalkylation reactor, a molar excess of benzene relative to PEB is needed. A high benzene-to-PEB ratio (Bz/PEB) results in high-equilibrium PEB conversion, but at the expense of increased capital cost and operating cost associated with the recovery and recycle of the excess benzene. As the Bz/PEB is decreased, these capital and operating costs decrease, but the PEB conversion level declines and formation of heavy by-products increases.

Similar to the B/E in the alkylation reactor section, the first liquid phase plants were designed and operated with Bz/PEB close to 10 or higher. Over time, transalkylation catalyst system stability has been improved and the Bz/PEB has steadily decreased and in 2004 plants are typically designed with Bz/PEB in the range of 2.0–4.0. Generally, a commercial plant is operated at or very close to its design Bz/PEB and the operating Bz/PEB is not frequently adjusted.

Transalkylation Reaction Temperature

The reaction temperature is the key variable for controlling the operation and performance of the transalkylation reactor. Transalkylation reactors are designed to operate across a relatively wide temperature range. During initial operation when catalyst activity is high, relatively low reaction temperatures are sufficient to obtain the desired conversion of polyalkylated compounds. As the catalyst ages and loses activity, the temperature is increased to maintain PEB conversion at or near the desired level. Liquid phase transalkylation reactors typically operate between 170°C and 270°C.

Catalyst Poisons

Because of the acidic nature of the zeolite catalysts used in the production of EB, a number of materials can interact with the zeolite and negatively impact its performance. These compounds are referred to as catalyst poisons and mostly impact the catalyst activity, although selectivity can also be affected.

Any basic or alkaline material can react with a zeolite to effectively neutralize the acidic active sites, which generally results in irreversible loss of catalyst activity. Basic compounds found in the ethylene or benzene feedstocks can include amines, amides, nitriles, and trace metal cations such as sodium and potassium. Of particular concern are nitrogen-containing organic compounds typically present in the benzene feed.

There are different types of nitrogen compounds that have been identified as benzene feed contaminants. The most common ones are *N*-formyl morpholine (NFM), *N*-methyl pyrolidone (NMP), morpholine, monoethanol amine (MEA), diethanol amine (DEA), and acrylonitrile (ACN). Both NFM and NMP are common aromatic extraction solvents that are used to

purify benzene. They are used commonly in Europe and less frequently in the rest of the world. Morpholine is a decomposition product of NFM and has also been identified in various benzene feeds. Corrosion inhibitors, including MEA and DEA and other similar compounds, are used in benzene recovery columns and can be found in the feed to an EB plant. Transoceanic shipment containers sometimes alternate loads between benzene and ACN, which can lead to nitrile contamination. In addition to these most common compounds, other basic nitrogen compounds can be present in the feed depending on its origin, processing, and handling.

Feed Treatment to Remove Catalyst Poisons

Even trace quantities of catalyst poisons can lead to significant catalyst deactivation and have a large impact on commercial production. There are varieties of adsorbent materials that are capable of removing basic nitrogen compounds from the feed streams. The type of nitrogen species in the feed is an issue that affects the choice of material as well as the guard bed design. Additionally, it is necessary to consider both the equilibrium capacity of these materials and their mass transfer properties when selecting a guard bed material and design.

The most common guard bed materials are acidified resin, clay, and zeolite. The choice of optimum guard bed material is generally a function of several variables, including nitrogen adsorption capacity, mass transfer properties, disposal methods, regenerability, and cost. These variables also influence the design of the guard bed.

COMMERCIAL PRODUCTION

Liquid Phase Aluminum Chloride Catalyst Process

The primary means of producing EB from the 1930s to about 1980 was the liquid phase aluminum chloride catalyst process. Although the aluminum chloride catalyst process is still in use at many plants, its share of worldwide EB production is diminishing as all new plants use a solid acid catalyst.

A flow diagram of a typical aluminum chloride catalyzed EB plant, based on the widely used Monsanto/Lummus technology, is shown in Fig. 2. The Monsanto/Lummus technology is used in the majority of aluminum chloride catalyst plants because it significantly reduces aluminum chloride catalyst consumption by operating at higher reaction temperatures than competing processes.

In the latest version of aluminum chloride plant designs, the alkylation reactions occur in a homogenous liquid phase at 160–180°C. The conditions of the alkylation reactor prohibit the recycle of PEB to the reactor. As a result, these plants have a separate transalkylation reaction zone. The recycle PEB stream is mixed with the alkylation reactor effluent and fed to the transalkylation reaction zone. The aluminum chloride present in the alkylation reactor effluent catalyzes the transalkylation reactions.

The effluent stream from the alkylation–transalkylation reaction section is cooled, washed, and neutralized to remove and recover the $AlCl_3$ catalyst. The washed hydrocarbon stream contains unconverted benzene, EB, PEB, and other minor reaction byproducts. It is separated into product and recycle

streams by fractionation in a series of three distillation columns. The first column recovers unconverted benzene in the overhead stream, which is dried in a drying column before being recycled to the alkylation reactor section. The second column separates the product EB as the overhead stream. The last column recovers PEB from the high-boiling, heavy by-product tar components. The PEB is recycled to the transalkylation reaction section.

The handling and disposal of the aluminum chloride catalyst and waste has become increasingly more costly and complicated because of environmental considerations. Equipment and piping corrosion and fouling along with the related environmental issues led to the development of EB processes based on solid acid, heterogenous catalysts. These are the main reasons why new plants are not based on the Friedel–Craft-type catalysts. Major equipment pieces needed to be replaced on a regular schedule because of corrosion. This resulted in extensive turnarounds, poor plant onstream efficiency, and thus, are primary contributors to the high operating costs associated with the aluminum chloride process.

Vapor Phase Zeolite Catalyst Process

The first commercial plant based on the Mobil/Badger vapor phase technology was commissioned in 1980.[5] From 1980 until the early 1990s, use of the vapor phase process gained in popularity because it offered several advantages over the aluminum chloride process. A major benefit of the vapor phase process was the use of a zeolite catalyst that eliminated the issues associated with corrosion and waste disposal of aluminum chloride.

The alkylation of benzene is performed in a vapor phase, fixed-bed reactor using a ZSM-5 based catalyst. ZSM-5 is an aluminosilicate zeolite with a high silica and low aluminum content. ZSM-5, a highly porous material, is considered a medium-pore zeolite with two types of pores, both formed by 10-membered oxygen rings. The first type of pore is straight and elliptical in cross section and the second type of pore is circular in cross section and intersects the straight pores at right angles in a zigzag pattern. Therefore, throughout its crystalline structure, ZSM-5 has an intersecting two-dimensional pore structure.

The original vapor phase design accomplished the alkylation and transalkylation reactions in a single reactor. Subsequent designs performed the transalkylation reactions in a vapor phase, secondary reactor that was separate from the alkylation reactor. Fig. 3 shows a flow diagram for the latest publicly disclosed version of the process, sometimes referred to as the third-generation EB process. The alkylation and transalkylation reaction section consists of a fired reactor feed heater, a multibed alkylation reactor, a transalkylation reactor, and various heat exchange equipment. Both the alkylation and the transalkylation reactors are vapor phase, operating at temperatures in the range of 370–420°C and pressure in the range of 0.69–2.76 MPa.

The third-generation process is capable of achieving an EB yield greater than 99%. However, the high-temperature vapor phase operation of the reactors is not trouble free. The significant extent of the isomerization reactions and the catalyst deactivation by deposition of carbonaceous material are the most important problems associated with the high temperature. Any xylene formed because of isomerization cannot be separated and therefore ends up contaminating the EB product. While the xylene impurity is not a significant problem in the vapor phase EB plant, it is not desired because it results in higher operating cost in the downstream styrene plant. Catalyst deactivation occurs at a rate that requires periodic catalyst regeneration. The length of time between regeneration can vary from as little as 2 mo to slightly more than 1 yr depending on the specific plant design and operating conditions. Because the reactors must be taken off-line for regeneration, the onstream efficiency can be low, resulting in high operating costs for a vapor phase plant. Additional equipment may be required for the regeneration procedure, depending on the specific plant design, which adds capital cost to the plant.

The Mobil/Badger vapor phase process includes four distillation columns. The first major separation is in a benzene recovery column where unconverted benzene is recovered as an overhead product for recycle to the alkylation and transalkylation reactors. The bottom stream is fed to an EB recovery column where EB product is separated from cumene, the PEB, and other heavy components. The cumene, PEB, and other heavy by-products are further separated in the PEB recovery column. The heavy residue is typically used as fuel in the reactor feed heater. The PEB fraction is recovered in the overhead stream and recycled to the transalkylation reactor where it reacts to form additional EB. A fourth column is used as a stabilizer column to vent any light components and to remove water from the system.

Liquid Phase Zeolite Catalyst Processes

EB*One*™ process offered by Lummus/UOP

One of the shortcomings of the vapor phase zeolitic EB process is the occurrence of side reactions that can lead to high levels of contaminants in the EB product.

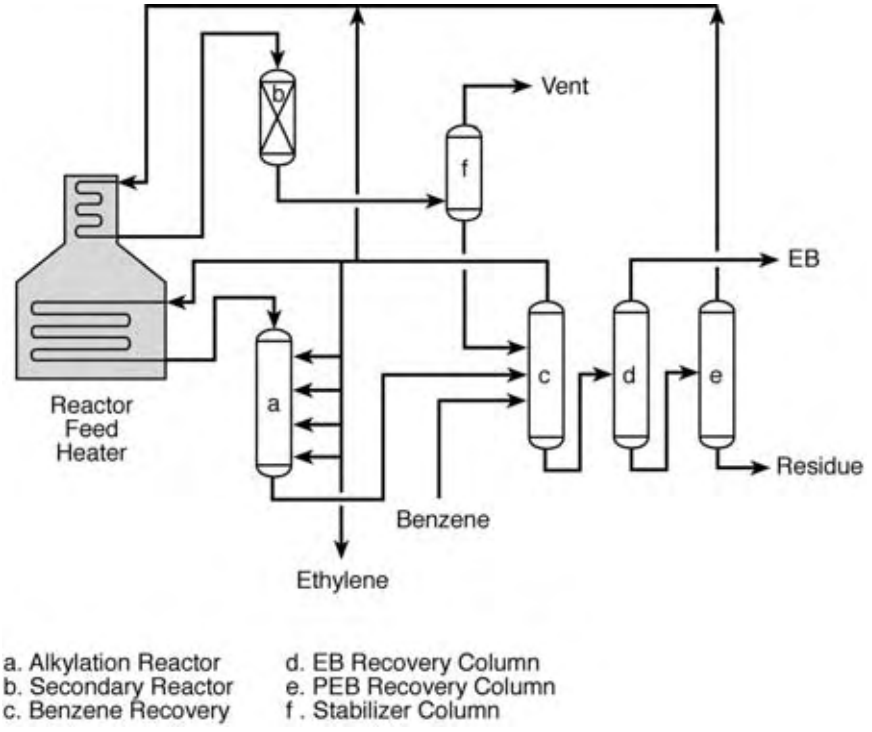

Fig. 3 Mobil/Badger vapor phase EB process.

The commercialization of liquid phase processes, which operate at substantially lower temperatures, decreased the side reactions dramatically, resulting in ultra-high-purity EB product. This improvement alleviated problems previously encountered in the downstream styrene plant. The first liquid phase commercial plant based on the Lummus/UOP process was commissioned in 1990. Since then, more than 25 projects have been licensed with more than 17 plants in commercial operation as of 2004. The liquid phase plants typically achieve high onstream efficiency, often greater than 99%, which results in low turnaround and maintenance costs. This technology is now licensed by UOP LLC and ABB Lummus Global.

The first liquid phase plants used a zeolite Y based catalyst for both the alkylation and the transalkylation reactions. A significant improvement in the process occurred in the mid-1990s when EBZ-500^{TM} catalyst was developed and put into commercial operation.[6] EBZ-500 catalyst is based on zeolite beta, which has unique characteristics that make it highly suitable for benzene alkylation. Zeolite beta has a tetragonal crystal structure with straight 12-membered ring channels with crossed 10-membered ring channels. This crystal arrangement gives zeolite beta a unique three-dimensional structure that results in high catalyst activity, an important feature in the relatively low-temperature liquid phase process. Furthermore, benzene alkylation in the liquid phase is typically limited by diffusion, so zeolite beta with its relatively large pore dimensions is well suited for the application.

A typical EB*One* plant flow diagram is shown in Fig. 4. The alkylation reactor is maintained in the liquid phase and uses multiple catalyst beds and ethylene injections to improve the reaction selectivity. Dividing the ethylene into multiple feed streams keeps the alkylation catalyst deactivation rate very low. In some plants using EBZ-500 catalyst, operating lengths of more than 8 yr have been obtained without catalyst regeneration. The ethylene conversion is essentially 100% in the alkylation reactors, and the reactors operate nearly adiabatically. The exothermic heat of reaction is recovered and used within the process to heat internal process streams or to generate steam.

In the few instances when EBZ-500 catalyst has been regenerated, it has been restored to essentially the same activity and selectivity as fresh catalyst. The regeneration is a mild carbon burn procedure that is relatively inexpensive. If required, in situ regeneration equipment can be incorporated into the design. This is not common and is usually considered only for locations were ex situ regeneration facilities are not readily accessible.

The transalkylation reactor is also maintained in the liquid phase but uses EBZ-100^{TM} catalyst, which is made using zeolite Y. Transalkylation reaction is nearly thermo-neutral, so it operates essentially isothermally. The reactor temperature is generally adjusted to provide the desired level of PEB conversion. While a high temperature results in high PEB conversion that closely approaches equilibrium composition, these conditions can result in undesired side reactions.

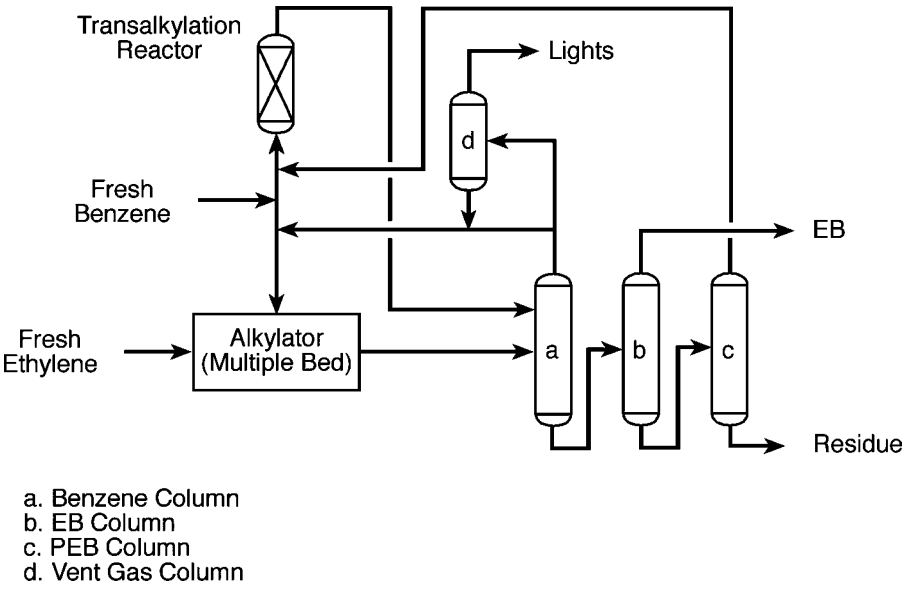

Fig. 4 Lummus/UOP's EB*One*™ process.

Deactivation of EBZ-100 catalyst is rare, usually only occurring because of unusual upsets or operation of the transalkylation reactor. Plants have operated for approximately 10 yr without regenerating the transalkylation catalyst. If EBZ-100 catalyst requires regeneration, an inexpensive, mild carbon burn procedure is used.

The alkylation and transalkylation reactor effluent streams are sent to the distillation section, which consists primarily of three fractionation columns. The first column is the benzene column. It separates unconverted benzene into the overhead stream for recycle to the reactors. The benzene column bottom stream is the feed to the EB column. The EB column recovers the EB product in an overhead stream at purities as high as 99.98 wt%. The bottom stream of the EB column feeds a relatively small PEB column where PEB is fractionated overhead and recycled to the transalkylation reactor. The bottom stream of the PEB column, referred to as flux oil, is generally used as fuel in an integrated styrene complex.

Ethylbenzene yields greater than 99.5% can be achieved by the Lummus/UOP technology.

EBMax™ process offered by Mobil/Badger

The EBMax process offered by Mobil/Badger is a liquid phase alkylation reaction using a catalyst based

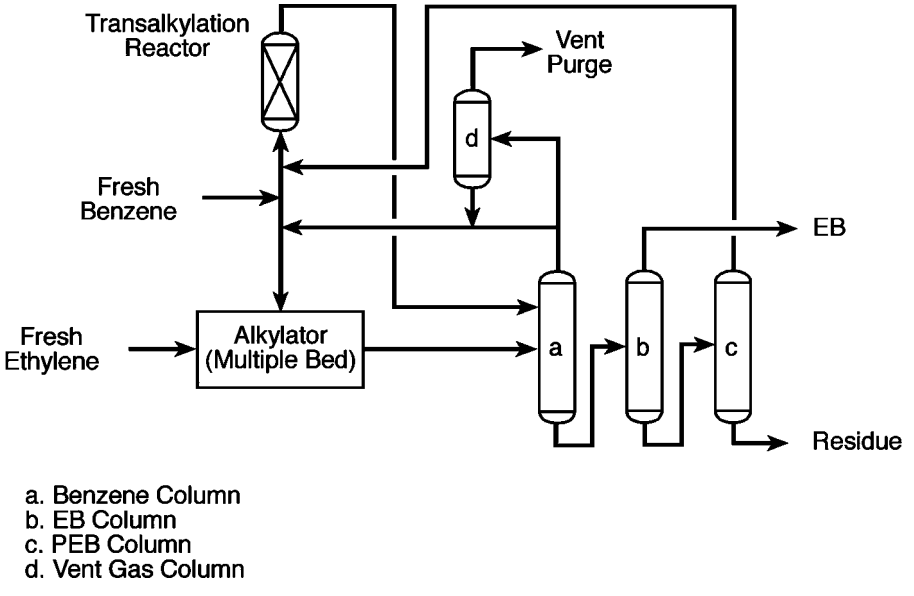

Fig. 5 Mobil/Badger's EBMax™ process.

on MCM-22. A commercial plant based on the EBMax technology was commissioned in 1995 at Chiba Styrene Monomer Company.[7]

MCM-22 is classified as a medium-pore zeolite consisting of two independent, nonintersecting, 10-membered ring channels. One of the channels contains "super cages'' that have a diameter defined by 12-membered rings. The MCM-22 crystal surface is covered with 12-membered ring pockets with each pocket being half of a "super cage.'' It is within these surface pockets that the alkylation reactions are thought to occur.

A typical EBMax plant flow diagram is shown in Fig. 5. The alkylation reactor is maintained in the liquid phase and uses multiple catalyst beds and ethylene injections. The ethylene conversion is essentially 100% in the alkylation reactors, and the reactors operate nearly adiabatically. The exothermic heat of reaction is recovered and used to generate steam, heat reactor feed streams, or as heat duty in the distillation columns.

The transalkylation reactor in an EBMax plant can be either vapor phase or liquid phase. More recently, the transalkylation reactor has been designed as liquid phase because of its improved energy efficiency. The transalkylation reaction is conducted in the liquid phase using Mobil TRANS-4^{TM} catalyst.

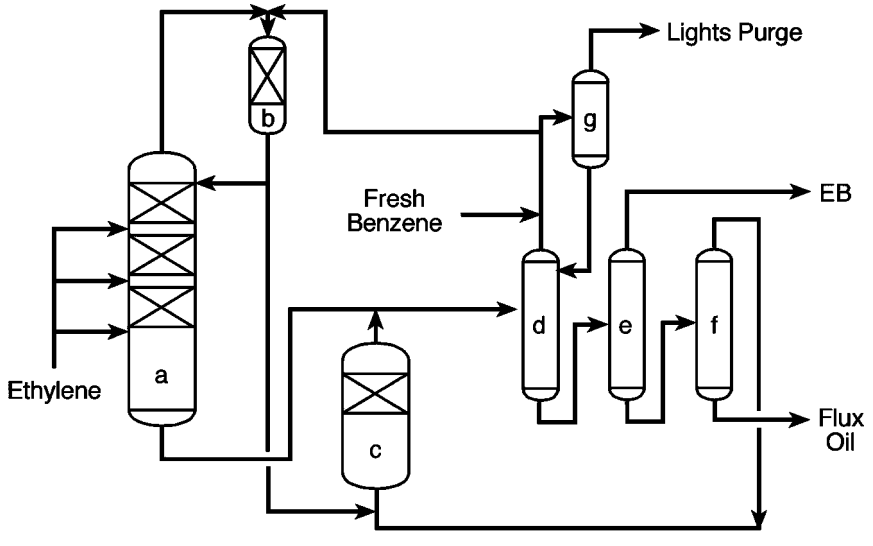
The alkylation and transalkylation reactor effluent streams are sent to the distillation section, which consists primarily of three fractionation columns. The first column is a benzene column and it separates unconverted benzene into the overhead stream for recycle to the reactors. The benzene column bottom stream feeds the EB column. The EB column recovers the EB product in the overhead stream, and the bottom stream of the EB column feeds the PEB column where PEB is fractionated overhead and recycled to the transalkylation reactor. The bottom stream of the PEB column is removed as a residue stream and is generally used as fuel in an integrated styrene complex.

Mixed Liquid–Vapor Phase Zeolite Catalyst Process

The CDTECH EB^{TM} process is based on a mixed liquid–vapor phase alkylation reactor section. The design of a commercial plant is similar to the liquid phase technologies except for the design of the alkylation reactor, which combines catalytic reaction with distillation into a single operation.[8]

Theoretically, catalytic distillation can overcome limitations in a typical two-step process consisting of reaction followed by distillation or separation. Often, a two-step process is limited by chemical equilibrium, heat transfer, mass transfer, or some combination of these. Catalytic distillation can overcome many of these constraints by simultaneously separating products from reactants, maintaining nearly isothermal operation and lowering the external ratio of reaction diluents.

The CDTECH alkylation reactor consists of two main sections—a catalytic distillation section and a standard distillation section—as shown in Fig. 6. Benzene is fed to the top of the alkylation reactor and ethylene is fed as a vapor below the catalytic distillation section, creating a countercurrent flow of



a. Alkylator

e. EB Column
f. PEB Column
g. Lights Column

Fig. 6 CDTECH EB^{TM} process.

the alkylation reactants through the catalytic distillation section. Throughout the catalytic distillation section, a vapor–liquid equilibrium is established with ethylene largely concentrated in the vapor phase. The ethylene that dissolves into the liquid phase rapidly alkylates benzene on the catalyst active sites to produce EB. The rapid reaction of ethylene in the liquid phase creates a driving force for additional ethylene to dissolve into the liquid phase where the alkylation reaction occurs on the catalyst active sites. The exothermic heat of reaction creates the vaporization necessary to effect the distillation. The alkylation reaction products, mainly EB, diethylbenzene, and smaller amounts of other by-products, are continuously fractionated and removed from the catalytic distillation section. In the lower section of the alkylation reactor, standard distillation occurs and the reactor bottom stream contains primarily EB, PEB, and other high-boiling by-products.

The catalytic distillation section uses a zeolite catalyst that is packaged into specially engineered bales. The catalyst bales function similarly as typical column structured packing and are designed to optimize both the distillation and the chemical reaction processes that occur in this portion of the alkylator.[9]

The alkylator typically does not achieve 100% conversion of the ethylene, so the overhead stream from the alkylation reactor contains some unconverted ethylene and benzene. This overhead stream is fed to a finishing reactor were the unconverted ethylene is fully reacted. The finishing reactor is a fixed-bed reactor that operates in the liquid phase.

One particular advantage of the CDTECH process is the ability of the alkylation reactor to accept a dilute ethylene feed. Because the alkylator operates in a mixed vapor–liquid phase, it is capable of utilizing dilute ethylene feeds, for example, offgas from a fluid catalytic cracking plant or dilute ethylene from a steam cracker plant. In general, ethylene feed streams containing significant amounts of hydrogen, methane, or ethane do require some pretreatment and cannot be used directly in the straight liquid phase technologies.

ECONOMICS

Although there are several different commercial technologies in use; the economic information described below relates only to the liquid phase technology. The cost of EB production consists of three main components: raw materials, utilities, and the fixed cost associated with the plant. The cost of utilities includes fuel, electricity, steam, cooling water, catalyst, and chemical costs required to operate the plant. Ethylbenzene plants typically have a small net negative utilities cost because the credit value of steam generated usually exceeds the cost of other utilities used throughout the plant.

The major cost components for EB production using the liquid phase process are listed in Table 3. The major cost of production is the cost of ethylene and benzene raw materials, which accounts for more than 95% of the total cost of production because of the extremely high product yield of the commercial processes. As seen in Table 3, more than 95% of the total cost of production comes from the raw material costs of the ethylene and benzene feedstocks. The remaining cost, less than 5%, comes from fixed and utilities costs. The utilities costs are zero or slightly negative because all heat input and the heat of the alkylation reaction is recovered as low-pressure steam, which is valuable for a downstream styrene plant. The efficiency of this liquid phase process delivers extremely high commercial yields. The benzene cost is the largest cost component, so the economics of EB production is highly dependent on benzene price.

Table 3 Typical economics for an EB liquid phase process[a]

	Unit	Quantity Unit/MT	Price $/Unit	Cost $/MT[b]
Product				
Ethylbenzene	MT	1.0000	530	530.0
Raw materials				
Ethylene	MT	0.2653	629	166.9
Benzene	MT	0.7387	453	334.6
By-product credits				
Flux Oil	MT	0.0030	125	(0.4)
Net feedstock cost				501.1
Utilities cost				(0.6)
Fixed cost				12
Total cost of production				512.5

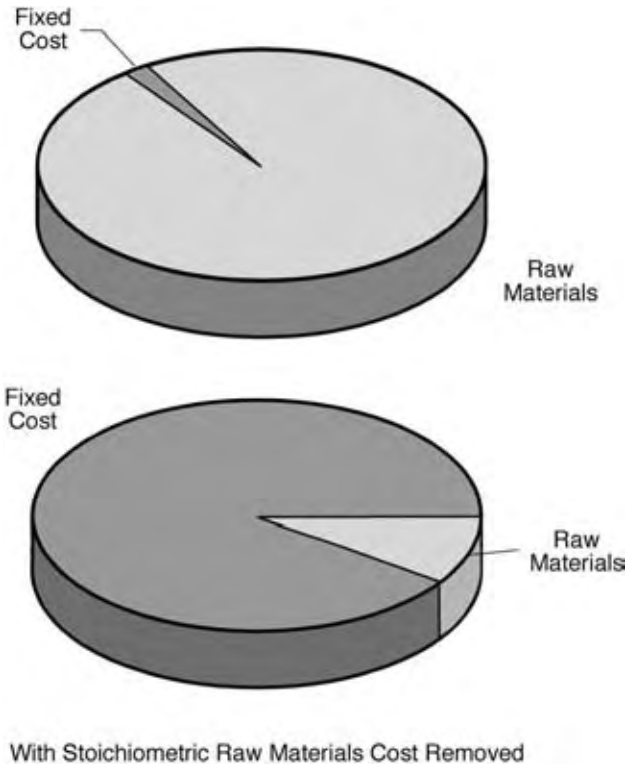

Fig. 7 Distribution of EB cost components.

The raw material cost has two components—one dictated by the stoichiometry and one caused by yield losses occurring as a result of the process technology. If the unalterable stoichiometric raw material consumption is removed from the cost of production, the resultant distribution of cost components appears very different, as illustrated in Fig. 7. From this perspective, the raw material cost is only about 10% of the incremental cost of production and the fixed costs become dominant. Recent catalyst and process design improvements have reduced the variable costs of EB production, while ever-increasing plant complexity and more stringent environmental regulations have greatly increased the fixed costs. Other recent trends, such as globalization of the EB–styrene market, have also resulted in higher fixed costs.

The result of the shift in focus from variable costs to fixed costs is that plants are being designed for larger capacities. For example, in 2003, typical new EB plants in the Asia Pacific Region produced an average of 368 KMTA EB per year, nearly double the capacity of typical plants started up just 5 yr earlier.

CONCLUSIONS

Since its first commercial production in the 1930s, EB, mainly through its role as an intermediate in the production of polystyrene, has become an important feedstock for products that are used in everyday life. Most people come in contact with numerous products produced from styrene throughout the course of a normal day. Because of its close link with styrene production, the demand for EB is expected to continue growing at a rate comparable to the demand growth rate of styrene, which is nearly equal to the gross domestic product (GDP) growth rate.

The chemical processing technologies that have been developed are sophisticated and produce EB to meet that demand at the lowest possible cost. Research and development aimed at discovering further improvements in existing technologies and identifying new technologies for EB production remains an area of great focus with strong potential for application in the marketplace.

Fermentation Processes

Kimberly Ogden
Department of Chemical and Environmental Engineering, University of Arizona, Tucson, Arizona, U.S.A.

INTRODUCTION

Fermentation technology started with wine and brewing industries. Throughout the centuries, methodology continuously improved and the technology was transferred to the pharmaceutical industry for the production of antibiotics in the 1930s. Throughout the 1980s and 1990s there was a huge increase in the number of products manufactured from live cells. The two major scientific discoveries that contributed to the industrial expansion were recombinant DNA techniques and hybridoma cell technology. Molecular biologists discovered how to isolate, purify, modify, and reinsert DNA from one species to another and produce significant amounts of a protein product in the host cell. Hybridoma cells are a cross between a cancer cell and a mammalian cell that allows the cell line to reproduce longer and produce mammalian enzymes and antibodies.

CELL TYPES—CHOOSING A HOST/VECTOR SYSTEM

All fermentation or bioprocesses start with the selection of the cell type. The choice is dependent on the product synthesized, the amount of product needed, the purity of the required product, and of course the cost. A biopharmaceutical such as an antibiotic, antibody, or protein that is directly injected into a human requires a highly pure product, whereas food products require intermediate purity, while commodity products such as ethanol produced for alternative fuel usage do not require as stringent sterile methodology. The advantages and disadvantages of the major classes or cell types are summarized in Table 1.

Bacterial cells have been studied for many decades and are well understood. The most common strain used for early recombinant DNA work was *Escherichia coli*. It is still used frequently today for laboratory studies. The common gram-positive strain is *Bacillus subitilis*. Other bacterial cells are studied to determine their potential to destroy environmental pollutants or to synthesize specialty chemicals. Bacteria are not extremely complex, which is advantageous from a DNA manipulation standpoint, but a challenge in terms of the organism's ability to synthesize a human protein product. At the other end of the spectrum are mammalian cells. These cells make proteins, antibodies, and antigens that are very similar to humans, but the cells grow slowly, require expensive media, and are typically mortal.

In addition to bacteria and mammalian cells, yeast, plant cells, and insect cells have been studied for synthesis of bioproducts. The yeast strain, *Saccharomyces cerevisiae*, is used in the food industry and the genetics are reasonably well understood; however, it tends to express only low levels of a foreign protein and hyperglycosylates the product. Plants themselves offer the advantage of diversity. As many as 25% of today's pharmaceuticals (primarily nonprotein products) are extracted from plants. Plant cell cultures do allow for more control than using an intact plant; however, genetic knowledge is less than what is known for bacterial and animal cells, and product expression levels are low. Only a few plant cell systems are used commercially in Japan and Germany. The most well-known product made in plant cell culture is the anticancer agent, paclitaxel or Taxol. The insect cell–baculovirus system is used primarily as a research tool and for small-scale studies (100 L). The advantages of this system are that it does allow for high expression of foreign protein and offers potential safety advantages because viruses that affect insect cells do not affect humans. However, the insect system does not quite mimic the mammalian cell system, in that the protein product may have slight structural modifications, which are useful when making vaccines but not necessarily so for complex products.

A technology that has made great strides in the past decade is the use of transgenic animals and plants for production of proteins. The living animal or plant becomes the ''bioreactor.'' The use of transgenic animals is less developed than that of plants. Animals have the advantage of performing complex posttranslational processing steps that cannot be done in animal cell culture. New genetic information is inserted into the embryo of the animal and the nontoxic protein is expressed by the mature animal—typically in the milk. The primary concern is safety. Besides the possibility of having a negative health effect on the animal, there is fear regarding the mutation of animal viruses that jump species and become a serious health issue

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120018064

Table 1 Comparison of cell host–vector systems for product synthesis

Cell type	Advantages	Disadvantages
Escherichia coli	High growth rate Wide range of host backgrounds Wide range of vectors and promoters High expression levels and cell densities Low-cost media	Formation of inclusion bodies Misfolded protein products No ability to glycosylate Proteolytic activity Usually low levels of product excretion No posttranslational processing Must ensure removal of endotoxins during purification
Bacillus subitilis	Second best studied bacteria Gram positive—no outer membrane—excretes proteins	Problem excreting some foreign proteins Makes large amounts and varieties of proteases (degrades proteins rapidly) More difficult to manipulate genetically owing to limited vectors and promoters Instability of plasmids more problematic than *E. coli*
Other bacteria	Typically studied or used to produce one product of interest. One example is *Zymmonas mobilis* for producing ethanol from glucose	Genetics less understood than *E. coli*
Yeast Most common—*Saccharomyces cerevisiae*	Food and beverage industry Larger than bacteria, harvested easier Grow only 25% slower than bacteria to high cell densities Glycosylation of proteins (add sugars) Secrete proteins Easier for regulatory approval	Difficulty with high protein expression Difficulty with good excretion Range of genetic systems is limited Inefficient if extensive posttranslational processing is needed
Fungi	Better secretion than yeast Natural producer of antibiotics	Filamentous growth difficulty for large-scale cultivation (but problem has been addressed) Normally produce low levels of desired protein (except for penicillin studied in detail) Inefficient if complex posttranslational modification needed
Plant cells	Used to make pharmaceuticals currently derived from plants (25% of all pharmaceuticals currently extracted from plants) Food flavors, fragrances, insecticides dyes Taxol™—anticancer drug	Slow growth Plant genetics poorly understood Products are often not proteins and chemically complex Expensive to culture so need high-value products like Taxol
Mammalian and hybridoma cells	Availability of host and vector systems Excretion of product Ability to produce authentic proteins (correct folding, glycosylation, and posttranslational processing) Low proteolytic activity	Slow growth Expensive, complex media Low protein expression levels Shear sensitive cells Vectors are derived from virus and there is fear of reversion to pathogenic form Must ensure removal of nucleic acids from hybridoma lines Most strains are mortal so dead cells must be removed
Transgenic plants Most common—corn	Easy separation of product Environment friendly Dow, Monsanto, Sigma–Aldrich, Prodigen, Epicyte Pharmaceutical developing products No virus transmission	Movement from plant to plant even though contained Fear of getting into food chain
Transgenic animals	Complex posttranslational processing not done by cell culture Sheep, goats, and pigs	Development in its infancy Regulation issues Transfer of disease/virus

for humans. The fear is real because some viruses that still lack effective treatment are believed to have originated in animals, such as AIDS and SARS. Screening of animals for virus is an extremely expensive undertaking and may limit the cost-effectiveness of their use for production.

Transgenic plant technology holds great promise. Several crops including corn, tobacco, potato, and soybean have been studied for the production of antibodies and proteins. The product, especially antibodies, concentrates in the corn kernels, and is easily separated. The systems are safe in terms of virus transmission, because plant viruses do not survive in animals. The one concern is the ability to keep the plants isolated from other crops. The pharm plant products, as they are called, cannot be allowed into the food chain. So currently, these plants are not grown in any food producing areas.

Optimization of recombinant protein production is a continuing objective of industrial and academic research. Engineering and science work together to reach this objective. For instance, a common problem is genetic instability (segregational, structural, host cell gene mutation, and/or growth rate dominated), because the overproduction of foreign proteins is always detrimental to cell growth and survival. Cells have been genetically manipulated to alleviate this problem by inserting antibiotic resistance genes into the plasmids and supplying antibiotics to the medium. Research continues to find the ''ideal'' host–vector system that rapidly grows and expresses high levels of foreign protein that are excreted while minimizing production of impurities. The ideal system also does not produce proteases and folds and glycosylates the protein product as required.

The disadvantages shown in Table 1 continue to be areas for research and development, and progress is made everyday toward overcoming these challenges. One example of the amount of research and development in the area of strain development is the number of patents found using Scifinder. In the last 20 yr, approximately 340 bacterial strain patents, 150 yeast strain patents, 1300 plant cell patents, 4300 hybridoma cell patents, and 2700 transgenic plant patents have been issued internationally. The number of journal articles published is phenomenal.

GROWTH KINETICS

Cells growth is described as an autocatalytic reaction. All growth requires an initial seed or inoculum of cells. As the cells are given nutrients, they metabolize this food to make more cells. The nutrient requirements vary considerably with cell type, but all cells undergo the growth phases shown in Fig. 1—stationary, exponential, deceleration, stationary, and death phases. During lag phase, the cells are adjusting to their environment. No cell division occurs but the cells may increase in size as they ''turn on'' metabolic processes to begin cell division. The length of this phase varies significantly from minutes to hours to days depending on both the cell type and the environment. The shortest lag phase is achieved by transferring rapidly dividing cells into the same environment from which they came.

The exponential growth phase is the time when the cells divide at a relatively constant rate. Products that are growth associated, which include many proteins and antibodies, are synthesized during this growth phase. As the cells begin to run out of a particular nutrient or if they become inhibited by too much product, their growth rate decreases and this is the deceleration phase. Cells tend to ''turn off'' some enzymatic processes associated with cell division and ''turn on'' different enzymes associated with cell maintenance. After this, the cells enter the stationary phase. This phase is defined as the phase where there is no net increase or decrease in cell mass. However, the cells may be slowly dividing and dying. Secondary metabolites such as antibiotics are produced. Some products such as ethanol may be produced during both exponential and stationary growth, but at different rates. The final phase is death phase, when the cells die. This phase is very prevalent in mammalian cell cultures that are ''mortal,'' whereas bacterial cells may remain in stationary phase for weeks with very little death.

A variety of cell measurement techniques are commonly used to monitor growth. These include:

- Direct counting using a microscope and hemacytometer
- Counting by diluting and plating the cells on solid medium
- Particle counters
- Dry cell weight

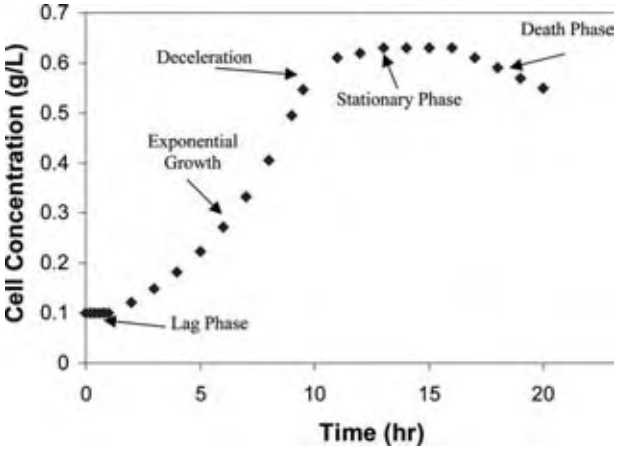

Fig. 1 Growth phases for a cell culture.

- Cell volume by centrifugation
- Turbidity or optical density—560–600 nm
- Measurement of product formed or amount of substrate consumed
- Measurement of cellular protein or DNA

This list includes both direct and indirect methods. The latter requires performing calibration curves to relate the indirect measurement to cell number. Indirect measurements are typically less time-consuming and allow for quick results; however, the danger is that something other than cells is being measured. For example, when optical density is being measured, other particles or color from nutrient components also absorb light and may affect results. Also, some indirect measurements do not differentiate between alive and dead cells. Thus, calibration curves must repeatedly be performed. Often consumption of the limiting nutrient is monitored or the amount of a product formed. Combining cell measurements and chemical measurements is the most accurate.

Various models ranging from unstructured, nonsegregated to structured, segregated are used to describe cell growth. The most common kinetic expression is the Monod equation:

$$\mu = \frac{\mu_{max} S}{K_s + S} \quad (1)$$

where μ is the specific growth rate, μ_{max} is the maximum specific growth rate, K_s is the saturation constant, and S is the substrate. This growth expression is inserted into batch, continuous, biofilm, scaffold, or immobilized reactor equations to predict the rate of utilization of substrate, cell concentration, and growth-associated product concentration. The semiempirical expression assumes that a single chemical species, S, is limiting, while changes in other nutrient concentrations have no effect; and that a single enzyme system with Michaelis–Menten kinetics is responsible for the uptake of S. Although this premise is seldom true, the Monod equation is used routinely to describe bioreactor behavior of everything from well-defined recombinant bacterial or mammalian systems to wastewater treatment systems. Growth rates are affected by temperature, pH, and media composition.

Chemically structured models provide a more general approach with greater predictive power by relating cell growth and product production not to just one substrate, but to nitrogen, carbon, and oxygen uptake, and also include expressions that relate important kinetic interactions among cellular subcomponents such as RNA, DNA, lipids, and proteins.[1] These more sophisticated models predict growth rates better, and thus reactor behavior, but consist of between 4 and 40 equations. Segregated models typically differentiate between productive and nonproductive cells within one reactor system.[2,3] The very complex models are not typically used by industry but are used in research laboratories. There are future challenges for modeling efforts.[4]

REACTOR TYPES

Fermentation processes are run in batch, fed-batch, continuous, or immobilized systems (Fig. 2). The choice of reactor is extremely important and determines the amount of product synthesized, the number of impurities, the yield, stability, and reliability. Some of the factors that must be considered when choosing the reactor system include production temperature, type of cells, genetic instability, growth associated product vs. secondary metabolite, and the amount of product needed (e.g., small quantities of a high-value medicine vs. large quantities of ethanol for fuel). Each type of reactor is discussed here and the advantages and disadvantages are given in Table 2.

A batch system (Fig. 2) is one in which all of the nutrients needed to grow a cell culture are added to a

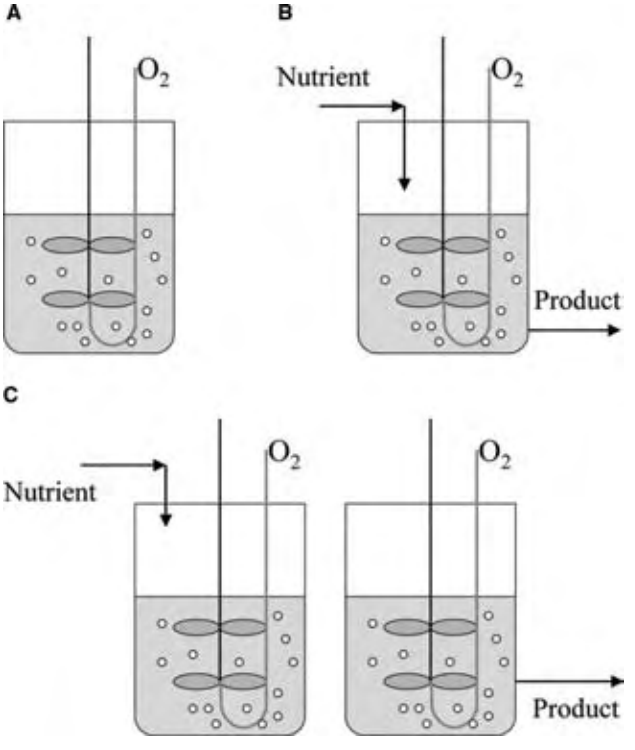

Fig. 2 Reactor types used for fermentation processes: (A) batch reactor, (B) continuous reactor or chemostat, and (C) fed-batch reactors with either a feed stream or a product withdrawal stream.

Table 2 Comparison of reactor systems for product synthesis

Reactor type	Advantages	Disadvantages
Batch	Less generations, thus less genetic instability Easier to keep sterile Flexibility in number of products produced Allows for production of secondary metabolites Used for high-value products	Can have large variability from batch to batch. Lower productivity than continuous
Fed-batch	Allows for intermittent removal of inhibitory product Allows for addition of inducers Allows for low feed rate for production of secondary metabolites Used for high-value products	Lower productivity than continuous Maintenance of sterility more difficult than batch
Continuous (CSTR or chemostat)	High productivity of growth-associated products Used for waste treatment, ethanol production, and other large-volume products Powerful experimental tool	Maintenance of sterility Difficult to produce secondary metabolites Genetic instability limits productivity High power consumption
Immobilized (batch or continuous)	High cell concentrations Cell reuse and eliminates processes of cell recovery and cell recycle Eliminates cell washout at high dilution rates Combination of high cell concentrations and high cell flow rates leads to high volumetric productivities May provide favorable microenvironmental conditions (cell–cell contact, nutrient-product gradients, pH gradients) resulting in better performance Can provide genetic stability—plasmid maintenance Can provide protection against shear damage (mammalian cells) Less moving parts	Product should be excreted by cells for continuous operation Diffusion limitation of nutrients Control of microenvironments is a challenge Gas evolution and cell growth can disrupt cell matrix Cells may be killed during immobilization Limited to low-viscosity systems Excessive foaming
Continuous with recycle	Operating at dilution rates greater than the maximum specific growth rate Increased productivity	Maintenance of sterility High energy costs
Two continuous reactors in series	Separate production and growth operations	Maintenance of sterility

large well-mixed reactor typically having temperature, pH, and other controllers attached to it. A few cells or an innoculum is added to the vessel and then after the culture has reached stationary or death phase, the cells are harvested and the product is purified and packaged for sale. Batch reactors are very common in industry. These reactors are flexible, can be used for multiple products in a given plant, and are used for both growth associated and nongrowth associated products, and genetic stability is more easily controlled.

Continuous reactors (Fig. 2) have both a continuous feed of nutrients and withdrawal of cells and product. The ideal continuous reactor is a stirred tank (CSTR) where the system is perfectly mixed and pH, temperature, and dissolved oxygen are controlled. When cells are grown continuously in a CSTR the reactor is known as a chemostat, a reactor with a constant chemical environment in which typically one nutrient is limiting while others are supplied in excess. The flow into the reactor is equal to the flow out of the reactor, and thus the volume remains constant. The term dilution rate is used to describe chemostat behavior. It is the flow rate into the reactor divided by the reactor working or liquid volume. The maximum flow rate of nutrients is limited by the growth rate of the cells. The cells have to be retained in the reactor long enough to divide, otherwise a state termed ''washout'' occurs. In other words, the dilution rate has to

be less than the growth rate of the cells to maintain a productive reactor.

A fed-batch reactor (Fig. 2) is one in which either nutrients only are fed to the reactor or products only are withdrawn. The feed rate or withdrawal rate may be discontinuous as well. One common example of a fed batch reactor is when cells are grown batch-wise until the late exponential phase, then a small amount of feed is added to the reactor continuously to provide just enough nutrients to allow for the production of secondary metabolites. These secondary products are then removed at given time intervals and purified. Other examples of fed-batch reactors include the discontinuous removal of an inhibitory end product such as ethanol from a fermentor, or the timed addition of an inducer to ''turn on'' production of a growth associated product after a cell culture has entered midexponential growth.

Immobilized systems (Fig. 3) are the ones in which the cells are confined to a space and are either chemically or physically adhered to a surface such as activated carbon or entrapped within a matrix.[5,6] Cells bind to a surface by: 1) electrostatic forces, when the surface is charged like ion-exchange resin; 2) covalent bonding, when a coupling agent like gluteraldehyde or metal oxides are used to treat the surface prior to cell attachment; 3) hydrogen bonding; and/or 4) van der Waals forces. Hydrogen bonding and van der Waals attachment form weaker bonds and thus large amounts of desorbed cells often result. When cells are entrapped, a variety of matrices are used including, but not limited to, gelatin, agar, Ca-alginate, Al-alginate, k-carrageenan, chitosan polyphosphate, polystyrene, cellulose triacetate, and collagen.

The major advantage of immobilized systems is that the cells are maintained in the reactor vessel and thus higher cell concentrations can be achieved compared to a chemostat reactor. The reactor system can be operated at dilution rates greater than the maximum specific growth rate of the culture. These reactors can also be used in batch mode if the product is not excreted by the cells.

In addition to gel-type matrices and activated carbon, which typically result in spherical support systems, immobilized systems sometimes consist of a membrane surface for cell adhesion and cells are immobilized on long fibers of tubes (Fig. 3). The reactor then resembles a shell and tube heat exchanger. The membranes are made of materials such as nylon, polystyrene, cellulose acetate, or ethyl cellulose. These membranes are semipermeable membranes. Cells are immobilized on the shell side; growth nutrients are pumped in and diffuse through the membrane while metabolic products diffuse back across the membrane, and are removed from the reactor system.

The major disadvantage of immobilized systems is diffusion limitations. As the immobilized cells grow, it becomes more difficult to transport nutrients to them within the cell matrix and for products to diffuse out of the matrix. Many times the cells contained in the inner part of the immobilized support die because of these transport limitations.

Reactors with a recycle stream have been used in the chemical industry for years to increase productivity in continuous operations and avoid wasting feedstocks. For bioreactors, recycle reactors are the most effective if the biomass is concentrated and recycled while the liquid stream is removed. The system shown in Fig. 4 contains an inclined settler that allows for sedimentation, concentration, and recycle of the cells while the product is removed from the top of the settler.[7] A continuous filter or centrifuge can also be used to concentrate the cells. Recycle reactors, like immobilized systems, allow systems to be operated at dilution rates greater than the maximum specific growth rate because of the increased cell mass. The disadvantages are the same as for chemostat reactor; the most severe being the sterility issues and increased energy costs especially if centrifuges or filters are used for cell concentration.

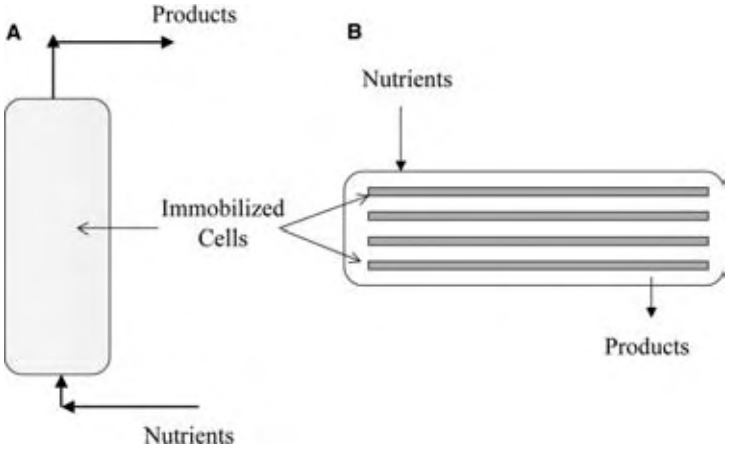

Fig. 3 Immobilized reactor systems: (A) packed bed and (B) hollow fiber reactor.

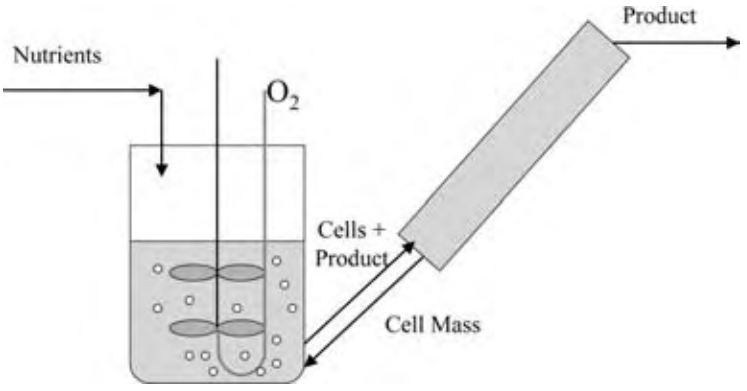

Fig. 4 Bioreactor with inclined settler to recycle concentrated biomass to the reactor.

Another type of reactor strategy that has been investigated in detail is the use of two continuous reactors in series. The advantage of this type of system is that it allows for increased productivity compared to a batch system or one CSTR. It also allows for the separation of growth and product synthesis. For example, the first reactor is run to maximize cell growth and consume the majority of the substrate, then the dilution rate in the second reactor is adjusted to allow for production of non-growth-related products or secondary metabolites.[8] The second reactor may have an additional fresh feed stream (Fig. 5) to aid in controlling the dilution rate and supply any required additional nutrients. Finally, if recombinant products are produced, the first reactor is again used for growth, and the inducer to turn on product synthesis is added to the second reactor to maximize production while minimizing the amount and, thus, cost of the inducer.

SCALE-UP

Effective scale-up is essential for successful bioprocessing. While it is desirable to keep as many operating parameters constant as possible during scale-up, the number of constant parameters realizable is limited by the degrees of freedom in designing the large-scale operation. Scale-up of aerobic fermentors is often carried out on the basis of a constant O_2 transfer coefficient, kLa, to ensure the same O_2 supply rate to support normal growth and metabolism of the desired high cell concentration populations. Propeller design, stirrer geometry, and agitation rate as functions of temperature and pressure are typically varied.[9] The challenge is greater when shear-sensitive cultures are used. In this case, pneumatically agitated airlift systems, stirred tank geometries, and hybrid bioreactor configurations combining the actions of an internal airlift draft-tube and axial-flow propeller have been studied.[10] The overall goal is to examine all aspects of bioreactor design while improving productivity and maintaining product quality. The majority of the work in this area was published in the 1980s and early 1990s.[11]

More recently, an economic study was done.[12] This study showed that multiple bioreactor approach to scale-up increases the return on investment (ROI) of the entire plant when compared to one large bioreactor to make high-value products. The increase in ROI results from the smaller size of the downstream units compared to the base case, because downstream processing accounts for about 80% of the total cost for high-value products like tissue plasmid activator.

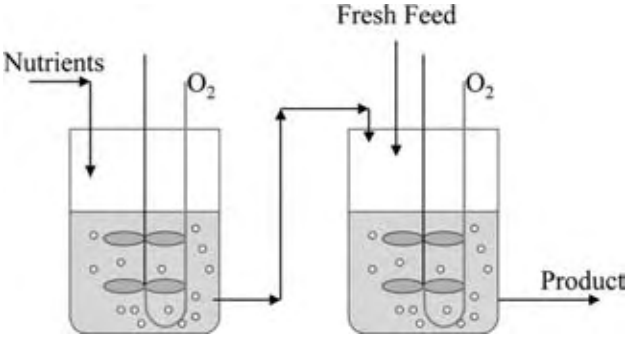

Fig. 5 Two continuous reactors in series. Typically, the first one is used for cell mass production and the second reactor is used for product synthesis.

CONTROL AND MONITORING

The measurement of analyte concentration is a critical part of successful bioreactor monitoring. Although strategies exist for measuring the majority of relevant analytes, industrial online bioreactor control is carried out primarily by measurement and control of temperature, pH, dO_2, CO_2, and, in some cases, cell density. This is because the available technology cannot be easily and inexpensively adapted to measure the analyte in an aseptic manner and measurement is not often achieved in real time so that online control is challenging. Biosensors for a variety of applications for

detecting contaminants in soil and water, and biowarfare agents are being studied extensively, but the current literature (2000 or later) does not contain too many articles or patents on bioreactor control. One book published in 1990 discusses on-line measurement and parameter estimation in bioreactors.[13] Recently, a research group is investigating the use of near-infrared (NIR) spectra in the 700–1800 nm region to obtain fermentation data on biomass, glucose, lactic acid, and acetic acid. Batch, repeated batch, and continuous fermentations were monitored and automatically controlled by interfacing the NIR to the bioreactor control unit.[14]

The long range goal continues to be to relate the metabolic activities of cell cultures to bioreactor control. Early studies focused on measuring the respiration quotient and rate of ammonia addition for pH control and combining these measurements with elemental and microscopic balances to predict behavior of batch, fed-batch, and continuous yeast cultures.[15] Cybernetic models continue to be studied with the goal of using these models to control bioreactors.[16]

CONCLUSIONS

There are many articles and textbooks available for further information about fermentation processes and bioreactor engineering.[17–19] The technology continues to be an area of study to improve production of pharmaceuticals, specialty chemicals, antibodies, and food products. Choosing the correct cell type and reactor strategy is of utmost importance. This choice also effects the downstream processing or separation sequence used to purify the product; thus, a systems approach to fermentation is extremely valuable.

Current and future areas of bioreactor research and development are the growth of tissues in biofilm or scaffold reactors for regeneration of tissues. Great strides continue to be made. For example, it is now possible for a patient's cells to be shipped to a company, cultured in a scaffold bioreactor, and subsequently reimplanted. Regenerative and rejuvenating therapies may become common in the near future. Human genes, proteins, antibodies, and cells are used in combination to replace, repair, and restore tissue that is damaged by disease, injury, or old age. Tissue cell reactors for these purposes require precise control compared to those used for the production of food or pharmaceutical products, but the principles of operation build upon the knowledge learned from the existing whole-cell bioreactors. A more controversial area of research is the use of stem cells for medicinal purposes. The ethical issues surrounding this type of work may slow down its development but these areas will be an important part of the next few decades of research.

Another area is the production of chemical intermediates from renewable feedstocks. Cargill–Dow and Dupont are just two of the companies beginning to market biobased polymers and plastics to replace petroleum based polymers. Again, the fermentation fundamentals originally developed for food manufacturing continue to apply to a wide variety of products.

INTRODUCTION

Fermentation and separation processes are vital unit operations in the production of biological products using microbial and mammalian cells in the pharmaceutical, food, and chemical industries. Although primary metabolites leading to such industrial chemicals as alcohols and acids often reach yields close to their theoretical maximum, the fermentation of secondary metabolites such as antibiotics and enzymes yields significantly lower values. In recent years, while microbiologists have focused their research on new strain developments, biochemical engineers have devoted their research to the advancement of fermentation and separation technologies to address productivity and environmental or regulatory issues.

BACKGROUND

Industrial fermentation processes are either aerobic, where aeration is a must for the growth and production of the microorganisms, or anaerobic, where aeration is irrelevant to the process. For example, in the presence of the *Acetobacter* species acetic acid is produced by the oxidation of ethanol at a concentration of up to 15% (wt/vol) (g/100 ml). Full aeration is required; interruption of the air supply for only 30 sec can kill acetic-acid-producing bacteria. On the other hand, lactic acid is the end product of dextrose glycolysis using species of the genus *Lactobacillus*, especially *L. delbrueckii.* The specific rate of lactic acid synthesis is strongly dependent on the media pH but independent of aeration. In this case, adjustment of media normality is essential. Localized low-pH zones seriously hinder the bacterial growth and consequently the yield. Fast dispersion and dissolution of the pH adjusters [alkali—$Ca(OH)_2$] in the glucose media are critical factors for successful production of lactic acid. Because the design of lactic acid (anaerobic) fermenters is akin to that of typical large-scale stirred tank reactors, this entry will be limited to the design of aerobic fermenters only.

Biochemical engineers are often challenged when scaling up fermentations demonstrated by microbiologists on a laboratory scale. Those skilled in the art have realized the difficulty and ambiguity involved in scaling up multiphase mixing systems from a biochemist's 1 L flask to a cubic-meter scale. Hence, tests in an intermediate pilot scale process are usually completed to understand process feasibility and to identify parameters that control yield. It is pilot samples of the therapeutics that are submitted for pharmacological and toxicological studies during preclinical and clinical trials. Business strategies such as speed to market, early cash flow, and capturing value by extending sales under patent protection often necessitate engineering-only authorization or toll manufacturing while the clinical studies by the regulatory authorities are under way. Irrespective of the approach, biochemical engineers play a crucial role in the design of pilot plants, production fermenters, and a web of associated peripherals.

Multipurpose batch fermenters are typical installations in the toll manufacturing and pharmaceutical industries. The batch fermentation process provides economic and operational advantages because a single fermenter can produce multiple products. Although most of the fermentation is carried out using fed-batch processes, biological wastewater treatment commonly utilizes large-scale continuous processing to treat a vast amount of water. In this case, a series of configurations of continuous stirred tank fermenters possesses advantages such as sequential treatment of multiple substrates, reasonable residence times for high conversion efficiency under flow-through conditions, and

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120025014

improved volumetric reaction rates due to high substrate concentration.

TYPES OF FERMENTERS

Mechanically agitated and pneumatically agitated fermenters are commonly used in the bioprocessing industries. Figs. 1–5 and Table 1 show the schematics of these bioreactors and their specific usage based on fermentation criteria outlined by Storhas.[1]

Mechanically Agitated Fermenters

A stirred tank fermenter consists of a centrally mounted agitation system inside a cylindrical vessel. Typically, the agitation system is composed of either multiple radial flow impellers (see Fig. 4A) or a combination of radial and axial flow impellers as shown in Fig. 4B. A gas sparger is located below the radial gas dispersing impeller. The role of the bottom radial impeller is to break the sparged gas stream into smaller bubbles. Axial, down pumping impellers establish a synergistic flow pattern with the radial impeller that includes upward flow near the wall and downward flow in the core region of the tank. Multiple radial flow impellers create undesirable compartmentalized flow regions in the tank.

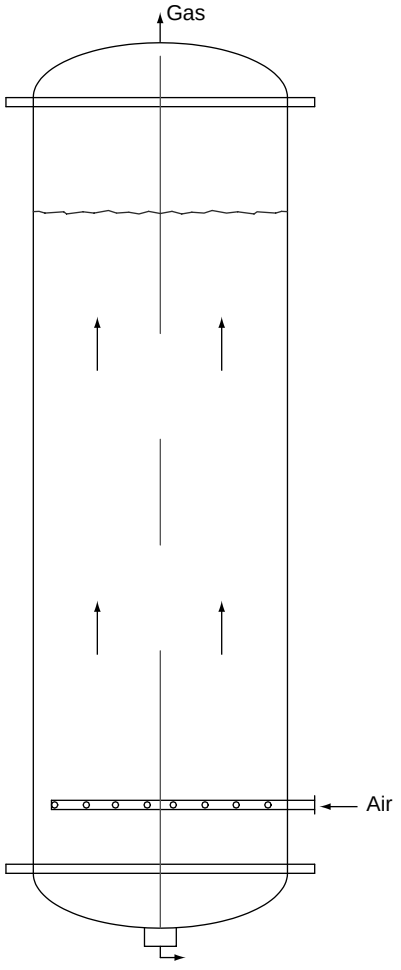

Fig. 1 Bubble column fermenter. *(View this art in color at www.dekker.com.)*

Stirred tanks are commonly used as the most efficient and reliable gas–liquid contactors for mass transfer limited aerobic processes in the biochemical industries. More than 90% of today's bioproducts are produced in stirred tank fermenters. Typical applications range from the large-scale production of such industrial enzymes as amylases and lipases, antibiotics or amino acids to the smaller-scale production of value-added specialty recombinant DNA therapeutic proteins and vaccines. The key advantages of stirred tank fermenters are enhanced mass transfer due to intimate gas–liquid turbulent mixing, improved heat removal through external heat transfer jackets and internal heat exchangers, and shear induced thinning of the pseudoplastic viscous media. Stirred tank fermenters are easily scaleable from the pilot to the large industrial scale. However, stirred tanks are not ideal for shear sensitive microorganisms and cannot be aerated at high rates because of impeller flooding. Poorly designed, tall, stirred tank fermenters may create regions of slow flow or stagnation, which lead to zones of poor oxygen transfer.

For low-viscosity media, the draft-tube–impeller combination in a stirred tank achieves better mass transfer performance than a conventional stirred tank fermenter. A cocurrent flow of gas and liquid is induced down through the draft tube and exits at its bottom. This flow pattern provides intimate gas–liquid contact and a high gas–liquid mass transfer rate. Consequently, bioreactors can consist of a tank, a draft tube, and an agitation system with axial and radial flow impellers as shown in Fig. 5. Dual axial flow impellers are located inside the draft tube and pump the fluid down toward the radial flow impeller. The radial gas dispersing impeller is located above the gas sparger ring. This configuration confines aeration to the annular zone and establishes a highly directional flow pattern in the tank. An optimized design draft-tube–impeller agitation system allows higher aeration rates before the onset of flooding.

Pneumatically Agitated Fermenters

The airlift fermenter relies on air as the principal means of achieving various transport requisites. It is composed of a vertical cylindrical vessel and a concentric draft tube into which air or other suitable oxidation gases are injected (see Fig. 2). Reduced bulk density causes the contents of the central riser to move upward. This action displaces the contents of the

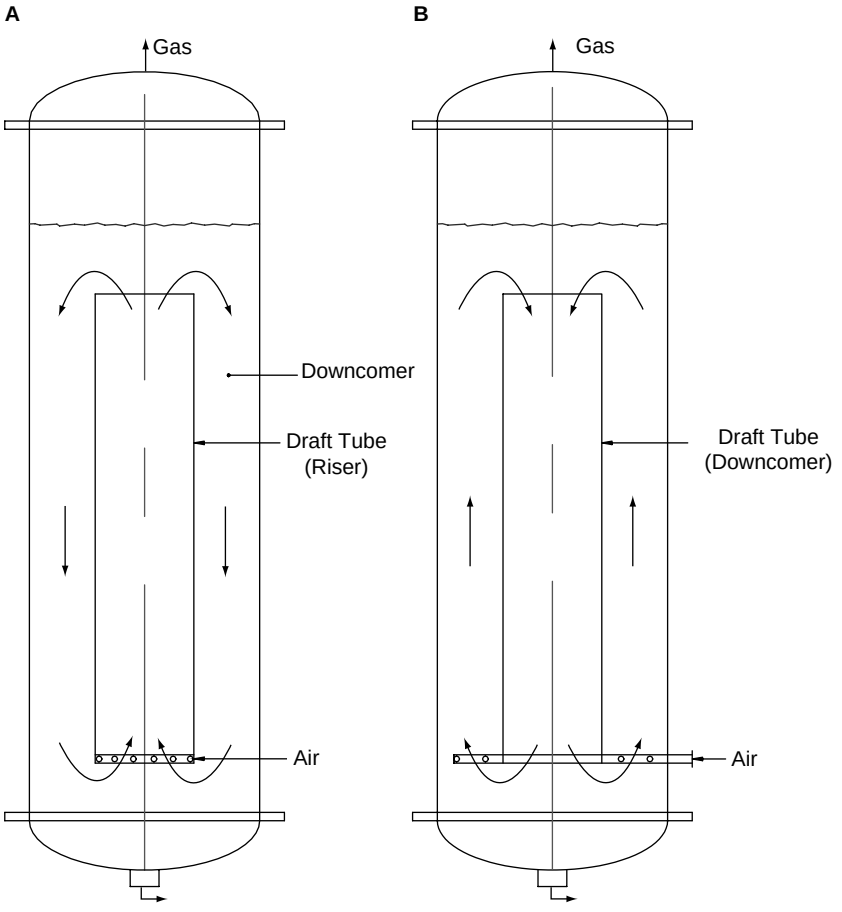

Fig. 2 Concentric tube airlift fermenters: (A) draft-tube sparged and (B) annulus sparged. *(View this art in color at www.dekker.com.)*

surrounding downcomer and moves them downward to complete the fermenter circulation cycle.

Airlift bioreactors have the advantages of generating liquid mixing and gas transfer without the use of a mechanical agitator. The special characteristics of airlift fermenters make them most suitable for some processes, especially those cultivating shear sensitive cultures such as mycelial fungi, filamentous bacteria, and certain mammalian cell lines. The system fluid dynamics ensure satisfactory mass and heat transfer together with an even distribution of shear stress. This offers advantages for both high-volume, low-cost processes and low-volume, high-value-added processes like those producing animal and cell cultures. Airlift fermenters are basically simple, low-capital-investment units.

There have been many simple modifications to airlift bioreactors for specific applications. For example, a novel airlift loop fermenter (schematic unavailable in the literature) utilizes a side arm. The external loop in this integrated system overcomes the problem of ethanol inhibition by continuously stripping ethanol from the fermentation broth and recovering it by condensation. This is suitable for the simultaneous production and recovery of ethanol.[2]

Mechanically stirred hybrid airlift reactors (see Fig. 6) are well suited for use with shear sensitive fermentations that require better oxygen transfer and mixing than is provided by a conventional airlift reactor. Use of a low-power axial flow impeller in the downcomer of an airlift bioreactor can substantially enhance liquid circulation rates, mixing, and gas–liquid mass transfer relative to operation without the agitator. This enhancement increases power consumption disproportionately and also adds other disadvantages of a mechanical agitation system.

Fig. 3 shows a modified airlift fermenter consisting of an external loop where gas is injected into the recycled broth through a gas-dispersing nozzle. In the working media inside the downcomer, two-phase discharge from the nozzle creates a jet of microbubbles. Jet-nozzle airlift fermenters provide better mass transfer but the accompanying high-shear bubble breakup is detrimental to the growth of most microorganisms.

The bubble column in Fig. 1 is the simplest of the pneumatically agitated bioreactors. Typical installations provide low-cost oxygen transfer in low-viscosity media where mass transfer is not limiting. Bubble columns are ideal for extremely shear sensitive microorganisms

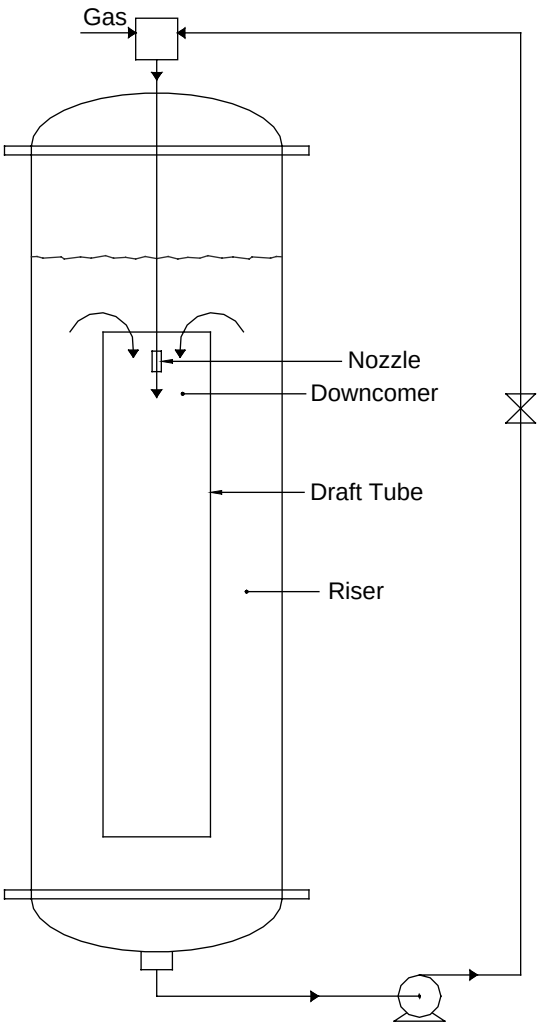

Fig. 3 External loop-jet nozzle airlift fermenter. *(View this art in color at www.dekker.com.)*

because their simplicity makes sterilization and maintenance of an aseptic environment simple. Because most bioprocessing applications are known to be mass transfer limited, bubble columns are rarely used for fermentation despite their obvious advantages.

Tubular fluidized and fixed bed fermenters are deviations from the simple bubble column fermenter. Often utilized in producing beer and ciders, these fermenters contain immobilized microorganisms or microbial films on support surfaces. Microbes lost with the product are continuously replenished by adding fresh microorganisms into the packed bed fermenters. In the fixed bed case, slow downward flow of the medium significantly reduces the shear removal (mobilization) of the microbes from the support materials and increases the residence time in the packed column. This is a typical characteristic of the trickle bed fermenter for continuous operation. Readers are referred to the packed bed reactor entry in this volume for a more comprehensive understanding of packed bed fermenter operations as they are not discussed in this entry.

SCOPE

The focus of this entry is limited to the design of aerobic fermenters, i.e., stirred tank and concentric tube airlift fermenters, which are commonly utilized in the bioprocessing industries. Design principles and the basic calculations are described with a couple of industrial examples. Readers with a limited background in mixing technology are referred to the gas–liquid contactor entry of this encyclopedia for a more comprehensive understanding of fluid flow and mass transfer characteristics in stirred tank reactors and bubble columns.

DESIGN PRINCIPLES

Oxygen Transfer Rate

Gas–liquid mass transfer is commonly modeled in terms of a gas film (between the bulk gas and interface) and a liquid film (between the interface and bulk liquid). Hindrance to mass transfer causes soluble gas (e.g., O_2) concentrations to decrease across these films. The highest mass transfer resistance usually exists in the liquid film; therefore, it controls the overall oxygen transfer rate (OTR). In aerobic fermentation, an effective fermenter design achieves an efficient OTR through intimate gas–liquid contact. OTR is described in terms of oxygen concentration and characteristics of the gas–liquid interface, as follows:

$$\mathrm{OTR} = k_{\mathrm{L}}a\Delta c = k_{\mathrm{L}}a(c^* - c_{\mathrm{L}}) \tag{1}$$

In this equation, k_{L} is the mass transfer coefficient in the liquid film, a is the gas–liquid interfacial area per unit liquid volume, c^* is the oxygen concentration near the gas–liquid interface, and c_{L} is the oxygen concentration in the bulk liquid.

Henry's law (i.e., $c^* = p_{\mathrm{G}}/H$) relates the equilibrium oxygen solubility in the liquid (c^*) to oxygen partial pressure in the gas (p_{G}) by the corresponding Henry's law constant (H). Because the liquid film mass transfer coefficient, k_{L}, is difficult to measure independently, $k_{\mathrm{L}}a$ (i.e., k_{L} times a) is used. It is a lumped parameter known as the volumetric mass transfer coefficient to characterize the overall mass transfer rate.

Because c^* is a function of hydrostatic head, a log-mean concentration difference generally replaces the Δc term used in the earlier equation:

$$\mathrm{OTR} = k_{\mathrm{L}}a\Delta c_{\mathrm{ln}} \tag{2}$$

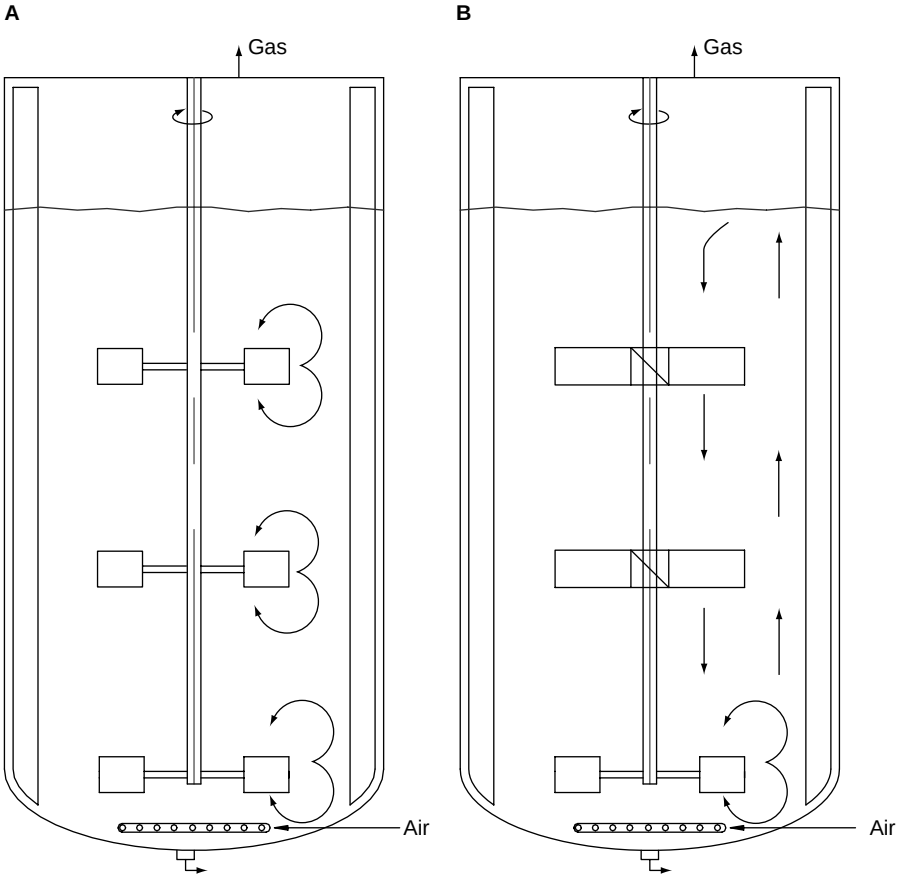

Fig. 4 Stirred tank fermenters: (A) with multiple radial impellers and (B) with axial and radial impellers. *(View this art in color at www.dekker.com.)*

where

$$\Delta c_{\ln} = \frac{(c_1^* - c_L) - (c_2^* - c_L)}{\ln((c_1^* - c_L)/(c_2^* - c_L))} \quad (3)$$

The average logarithmic concentration difference is calculated with the oxygen gas concentrations in the bulk liquid phase and saturation conditions at the inlet (1) and outlet (2). In this application the value of c_L is commonly assumed to be 0 ($c_L \ll c^*$).

Several simple theories of interaction at the gas–liquid interface are pertinent to the design of pneumatically and mechanically agitated fermenters, and are now discussed.[3]

The first is the penetration theory of Higbie (1935). If the liquid immediately adjacent to a rising bubble is assumed to rise with the bubble, i.e., the relative velocity between the bubble and the liquid is 0, the mass transfer conditions are those of unsteady-state molecular diffusion. The mathematical solution of this problem leads to

$$k_L = 2\sqrt{\mathscr{D}_L/\pi\theta} \quad (4)$$

where k_L is the liquid film mass transfer coefficient over the bubble lifetime (θ), and $\mathscr{D}_L$ is the coefficient of molecular diffusion.

The second is the surface renewal theory of Danckwerts (1951). If turbulent mixing occurs in liquid near a bubble, it is likely that unsteady molecular diffusion will take place in individual eddies. In these conditions, mathematical analysis leads to

$$k_L \propto \sqrt{\mathscr{D}_L s} \quad (5)$$

where s is the rate of surface renewal, i.e., the rate at which eddies sweep the interfacial boundary layer. Because the surface renewal rate incorporates the eddy lifetime (θ), it increases with increased turbulence intensity just as θ does in Higbie's penetration theory.

Because of the absence of mechanical agitators, airlift fermenters are generally unable to produce the turbulence necessary for high mass transfer rates. Superficial gas velocity and liquid circulation rate in the risers determine the relative velocities of rising bubbles and adjacent liquid and, in turn, the volumetric mass transfer coefficient, $k_L a$. Increasing the gassing rate increases the liquid circulation rate indirectly by increasing the hydrostatic pressure on top of the downcomer. Decreasing the downcomer pressure drop by increasing the ratio of downcomer to riser cross-sectional area also increases the circulation rate. Unfortunately, other challenges arise if higher liquid

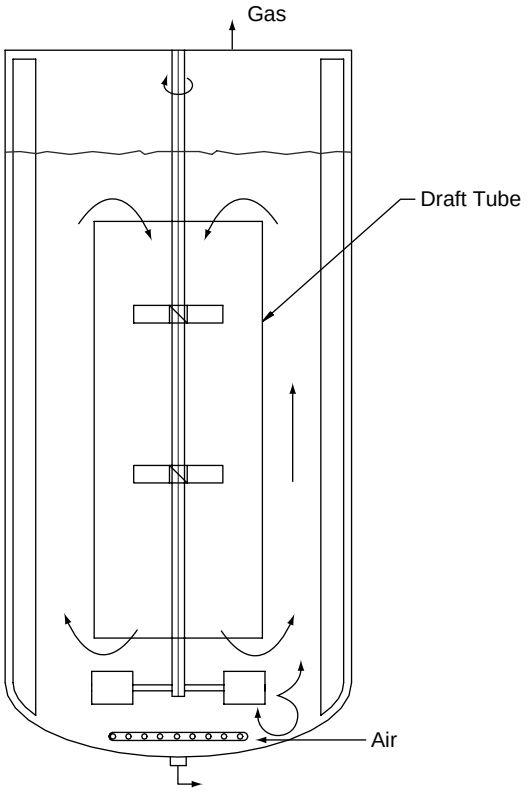

Fig. 5 Draft-tube–impeller stirred tank fermenter. *(View this art in color at www.dekker.com.)*

circulation rates shift the liquid conditions from bubbly flow to churn flow. Although this transition contributes to turbulence and bubble surface transience, bubble surface renewal also increases coalescence and bubble streaming along the wall, thus reducing specific interfacial area, a, and $k_L a$. Particularly in concentric draft-tube airlift fermenters, designers must maintain bubbly flow in the riser by optimizing gassing rate and liquid circulation rate. Typically, industrial fermenters have an a_r/a_d ratio of 0.8–1.2 (preferably $d_t/d_c = 0.7$) and a superficial gas velocity, u_g, of 0.02–0.10 m/sec.

The gas–liquid interfacial area per unit volume, a, increases as bubble size decreases. Hence, the design and location of gas spargers (aerators) are critical to the success of aerobic fermenters, particularly those with pneumatic agitation. Ring spargers, rake spargers, and porous plates are used as aerators in airlift fermenters. In the case of stirred tank fermenters, energy dissipation from the gas dispersing radial impellers normally controls bubble size. Ring spargers are typical aerators in mechanically agitated fermenters. Irrespective of the sparger holes, bubble size distribution depends on the media rheology, interfacial tension, and turbulent intensity. Increased broth viscosity reduces diffusivity, increases bubble size (i.e., under turbulent conditions Sauter mean bubble diameter, d_{b32}, is proportional to $\mu_L^{0.1}$), and decreases bubble-specific surface area a.[4] Therefore, it significantly decreases $k_L a$. Generally, $k_L a$ decreases with decreases in pressure and temperature and with increases in gas–liquid interfacial tension and liquid viscosity.

Designing fermenters that produce high yields with such viscous media as polysaccharides is a challenge. In batch fermenters, for example, agitation initially disperses the sparged gas as tiny, well-distributed bubbles. The viscous media stabilize these bubbles and extend their lifetime beyond that required for oxygen mass transfer. The extended lifetime of these bubbles hinders subsequent oxygen transfer, and thus fermenter productivity, by dampening agitation and its ability to continue dispersing fresh sparged gas. The resulting mass transfer coefficient falls off dramatically with continued batch time. A much higher energy input is needed to generate fine bubbles from the sparged gas and prevent them from coalescing.

Microbial Metabolic Heat

In some cases, heat is added to the initial broth to promote the desired microbial activity. During metabolism, however, thermodynamics of the overall microbial activity generates heat in such quantities that, if not removed, it would raise broth temperature beyond the system optimum. Elevated temperatures affect the fermenter by producing everything from a slight productivity decrease to widespread microbe death.

Metabolic heat evolution is determined from small-scale laboratory experiments and used for the appropriate design of heat transfer elements. When data are not available, heat evolved during bacterial fermentation can be estimated using the following correlation:[5]

$$\dot{Q}_f \cong 0.12 \times \text{OUR} \tag{6}$$

where $\dot{Q}_f$ is heat evolution (kcal/L/hr) and OUR is the oxygen uptake rate (mmol O_2/L/hr).

Addition and removal of heat is achieved by such means as a fermenter jacket, internal heat transfer coils (horizontal or vertical), and/or an external heat exchanger. A fermenter jacket provides insufficient heat removal by itself, especially in large microbial fermenters. Internal cooling parts may be particularly necessary in slender tanks despite their impedance to cleaning, sterility, and intermixing. Appropriately designed vertical heat transfer coils often serve as baffles in mechanically agitated fermenters, thus minimizing extraneous structures inside the vessel. Sterilization difficulties and asepsis also make external heat exchangers with multiphase pumping a last resort for

heat removal. When an external heat exchanger is implemented, its design and materials of construction must allow it to withstand thermal stress cycling and chemical cleaning.

In the case of stirred tank fermenters, heat that must be dissipated includes not only that generated by microbial metabolic activity but also that evolved from agitation power (i.e., 2500 Btu/shp-hr) and expansion of sparged gas. This can lead to scale-up problems because vessel volume is proportional to vessel diameter cubed, while heat transfer area is proportional only to vessel diameter squared.

Sterilization and Asepsis

For most aerobic fermentation processes, maintenance of absolute sterility is critical to cell growth and biomass production. Culture growth rate determines susceptibility to culture contamination. Mammalian cells divide in a day, while microbials divide in an hour or less. The difference in growth rate makes slower-growing mammalian cell cultures more susceptible to contamination than faster-growing bacteria or yeast cultures, which can out-compete contaminating microorganisms. Substrates that include such heat-labile nutrients as vitamins or enzymes are often added to the media as sterilizing agents and growth enhancers.[6] Prior to fermenter operation, standard operating practice usually includes a caustic wash and/or superheated steam cleaning of the vessel and gas sparger.

Typical sources of contamination include the steady bearing, mechanical seal, sparger, and fasteners. Because bushing interfaces and the shaft wear-sleeve of a steady bearing are prone to biomass deposition, their design is given special attention. Use of steam-purged or dry seals minimizes biomass contamination. Type 316L stainless steel is the most common construction material for bioreactor applications. Because microcrevices are known to harbor bacteria and contaminants, the surface of the tank walls and internals are electro-polished to a minimum surface finish of 0.6 μm (average roughness). To prevent the influx of air, which can compromise aseptic conditions, fermenters normally operate with a positive internal pressure.

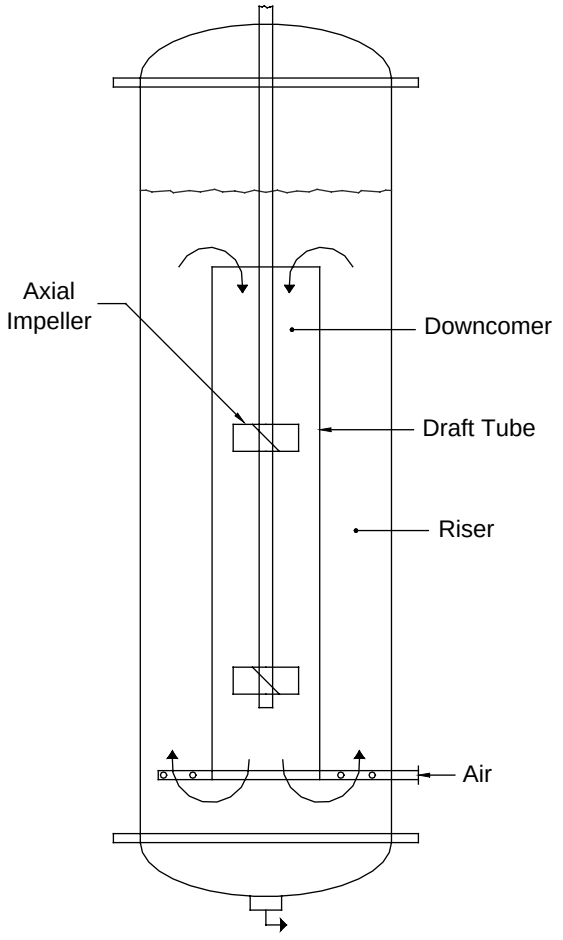

Fig. 6 **M**echanically agitated hybrid airlift fermenter. *(View this art in color at www.dekker.com.)*

A high level of positive pressure also has the advantage of increased oxygen partial pressure and, consequently, mass transfer rate.

Turbulence and Shear Tolerance

Prior knowledge of cell sensitivity to shear fields and turbulence is critical in designing mechanically agitated fermenters. Morphology dictates the tolerance of microorganisms to turbulence intensity and shear stress though most microorganisms are too small (typical sizes: bacteria 1–5 μm) to be destroyed by turbulent microscale eddies or local shear forces. Secondary metabolites with spherical, ellipsoidal, and rod-like structures are not susceptible to mechanical degradation, while filamentous microbes such as *Spinosad* mycelia and fungi are degraded by shear. Mammalian cells, because of their lack of cell wall and larger size (>5 vs. 1 μm), are more shear sensitive than microbial cells. Hydrodynamic shear stresses or shear rates also affect the production of extracellular microbial polysaccharides. During pilot scale fermentation, potential cell damage due to high specific energy must be considered. Intense shear fields can disrupt even the most robust microorganisms, but the likelihood of cell damage can be safely ignored if the Kolmogoroff length of a microvortex is greater than the effective size of the microbe in question.

According to Kolmogoroff, the size of the microvortex, λ', can be determined using the following equation:

$$\lambda' = \left(\frac{\nu_L^3}{\varepsilon_{loc}}\right)^{1/4} \tag{7}$$

Media Rheology

Flow properties of biofluids and slurries fall into two categories:

1. Newtonian fluids such as water, and most bacterial and yeast fermentation broths.
2. Non-Newtonian media such as polysaccharide fermentations and broths of *Streptomyces, Aspergilli*, and *Penicillia*.

The viscosity of Newtonian suspensions of yeast and bacteria growing as individual cells in a water-like medium can be estimated from the following empirical equation proposed by Thomas.[7]

$$\mu_{susp} = \mu_L\left(1 + 2.5c_s + 10.05c_s^2 + 0.00273\,e^{16.6c_s}\right) \tag{8}$$

where c_s is the volume fraction of solids.

While working media can be Newtonian or non-Newtonian, most high-viscosity non-glucose-based broths containing microorganisms demonstrate pseudoplastic or shear thinning behavior. For fungal suspensions (2–10 kg/m^3 dry biomass) such as *Aspergillus niger*, in the power law model, $\tau = k\dot{\gamma}^n$, the flow behavior index n varies from about 0.6 to 0.16, while the consistency index k increases from 0.17 $Pa\,sec^{0.6}$ to 9.1 $Pa\,sec^{0.16}$.[8] While *Acetobacter* fermentation is highly aerobic, the fermentation broth itself is viscous, even viscoelastic in certain instances. Although the fluid's turbulence does not seem to significantly affect the biomass or its productivity, the quality of the polymer produced is distinctly shear stress dependent. To ensure sufficiently long polymer microfibrils, the shear must be kept low.[9]

For high-viscosity applications, lack of turbulence adjacent to the bubble, and the general difficulty in pumping around the draft tube (riser), prevent the use of simple pneumatically agitated airlift fermenters. Stirred tank fermenters are typically used for media with a viscosity exceeding 100 cP. As noted before, an

increase in viscosity results in a substantial decrease in the mass transfer coefficient, all other parameters being equal. Fig. 7, a graph of k_La vs. apparent viscosity for a penicillin slurry, illustrates this trend.[10] To illustrate further, achieving a reasonable mass transfer coefficient ($>0.1\,sec^{-1}$) typically requires two to three times more specific power in a high-viscosity broth ($>1000\,cP$) than in low-viscosity ($<100\,cP$) media. In viscous broth fermentation, yield is often limited by oxygen starvation.

Blending and Homogeneity

Uniformly distributing air bubbles, nutrients, and microbes within a broth are of paramount importance for the successful cultivation of microorganisms. Airlift fermenters are ideal for achieving homogeneity in broths with a low solids content, while mechanically agitated fermenters are suitable for high solids (slurry) broths. In spite of the possibility of localized non-homogeneity due to slow flow regions in stirred tanks, mechanically agitated fermenters are preferred over pneumatically agitated ones. An appropriately designed draft-tube–impeller agitation system (shown in Fig. 5) overcomes the uniform blending deficiency of the standard stirred tank fermenter. Configuration and location of tank internals such as agitators, baffles, feed pipes, and heat transfer coils/plates are critical for blending and efficient heat transfer. Fermentation yield depends strongly on the homogeneity of pH and temperature in the working media.

Fed batch fermentation is widely practiced in the industry. Substrates including nutrients such as glucose are continuously fed through dip pipes as the fermentation proceeds. For instantaneous or fast dispersion, these ingredients must be added in high-turbulence regions in the vessel. It must be noted that a local surplus of glucose can cause excessive biomass or by-products to be produced, which can negatively impact the yields of the desired products, e.g., antibiotics. In this regard, selection of the broth, its feed point, and the feeding rate strategy are important.

Gas Holdup and Foam Formation

In vessel design work, size and geometry must account for the fact that aerobic fermenters experience significant gas holdup owing to finely dispersed bubbles in the broth. Gas holdup can be in the range of 10–30% depending on the media viscosity and the presence of surface-active substrates. Because of much higher turbulent intensity, mechanical agitated fermenters have a much higher gas holdup than pneumatically agitated fermenters. As with the mass transfer coefficient, gas holdup in a given media depends on the specific power input ε and the superficial gas velocity u_g.

From the mass transfer point of view, airlift fermenters should be designed and operated in such a way that carryover of air from the riser into the downcomer is kept as low as possible. Gas in the downcomer liquid contributes little to oxygen transfer. It reduces the effective density difference between the contents of the riser and downcomer, however, which reduces the liquid circulation rate and also impairs the mixing performance of the fermenter. In fermentations where even a momentary lack of oxygen can very seriously affect productivity, some air is essential to maintain aerobic conditions and sustain fermentation in the downcomer.

Foaming is a major concern in aerobic cell cultures because excessive foaming significantly reduces broth volume and impedes bioreactor productivity. Normally, silicon-based or oil-based antifoam agents (e.g., corn oil, silicone antifoam emulsions such as GE AF-72, Dow Corning's FG-10, DC-1510/1520-US, etc.) are added to suppress foaming. In choosing a foam inhibitor, one must be aware of possible adverse impact on the cells, products, or downstream processes and on pertinent regulatory (Food and Drug

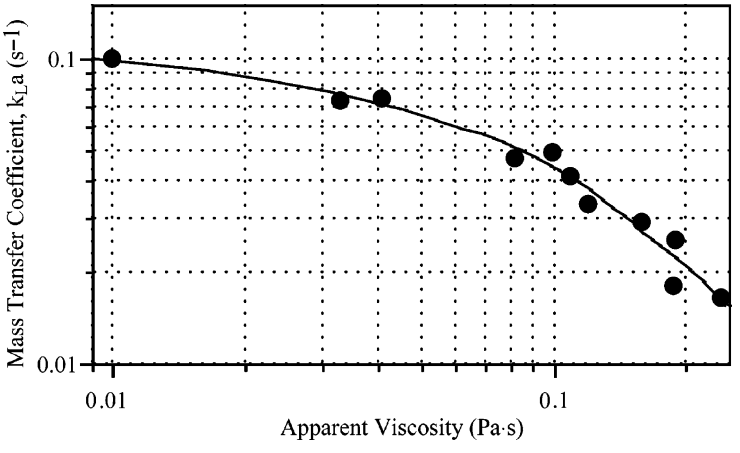

Fig. 7 Mass transfer coefficient (k_La) as a function of apparent viscosity of penicillin broth at a specific energy of 3 W/kg. (From Ref.[10].)

Administration) and/or kosher requirements. High molecular weight antifoam agents, when used in the low-viscosity broth, typically reduce the gas–liquid mass transfer coefficient.

Biological Safety

In the fermentation plant, the vent gas system commonly contains a backpressure valve to maintain positive pressure on the bioreactor. The vent is usually piped to a scrubber, which scavenges microbes from the fermenter off-gas. In addition to the scrubber, fermenters are equipped with an overhead safety relief device for potential loss of containment. With the advent of genetic engineering and the targeting of proteins from mammalian cells, biological safety standards have been extended to overcome unforeseen health issues. In this case, all U.S. large-scale bioreactors must comply with the Good Large-Scale Practice (GLSP) guidelines set forth by the U.S. National Institutes of Health (NIH). When using an organism covered by Biological Safety Level (BSL) classifications, BSL-1 or BSL-2, it is necessary to ensure that the cell is contained within the bioreactor's hygienic envelope. BSL-1 containment commonly requires inactivation of the organism by means of heat or chemicals (pH kill) in a separate tank.[5,6]

DESIGN GUIDELINES

The design basis is the most important consideration when determining the size of a fermenter. Factors to consider are the final product, the growth rate and oxygen requirement of the microorganism, the product expression concentration or titer, and the nature of the product expression.

Choosing an optimal bioreactor configuration for a given fermentation depends on a number of factors including oxygen transfer and mixing requirements, and the acceptable range of shear rates. Some of these factors are mutually contradictory. For example, while a given fermentation may require a very high gas–liquid OTR, which is generally increased by increasing turbulence and shear, its tolerance to such shear may be low. In such cases, successful bioreactor design obviously involves a careful balance of these contradictory factors.

The two sections that follow describe the designs of a stirred tank fermenter and a concentric tube airlift fermenter. Each design is for a given range of operating variables and includes the selection of geometric parameters. Important correlations and formulae are presented and followed by an example design case. The design process actually requires multiple iterations to simultaneously satisfy both geometric and mass transfer requirements. Such iteration has become almost trivial, however, with the advent of such tools as spreadsheet-based "goal–seek" computations.

Stirred Tank Fermenter

This, the first of two fermenter design examples, deals with a stirred tank fermenter. Nondimensional parameters that are applied in this example are defined as follows.

Nondimensional parameters

N_P	power number, $P/(\rho N^3 D^5)$
Na	aeration number, $\dot{V}_g/ND^3$
Fr	Froude number, N^2D/g
K	k-factor, P_g/P_{ug}
R	diameter ratio, D/T
S	impeller spacing ratio, s/D
C	impeller bottom clearance ratio, c_{btm}/D
Φ	gas holdup, $V_g/(V_g + V_L)$
μ_{sr}	suspension viscosity ratio, μ_{susp}/μ_w
Nu	Nusselt number, $\alpha_w T/\lambda$
Re	Reynolds number, $N_g D^2/\nu_L$
Re_o	orifice Reynolds number, $v_o d_o/\nu_g$
Pr	Prandtl number, $\mu c_p/\lambda_w$

Mass transfer

The relationship between the volumetric mass transfer coefficient, specific aerated shaft power, superficial gas velocity, and suspension viscosity ratio is given as follows:

$$k_L a_{20} = \alpha\, \varepsilon_g^{\beta}\, u_g^{\gamma} \left(\frac{\mu_{susp}}{\mu_w}\right)^{\kappa} \tag{9}$$

The following model parameters are specific to proprietary glucose-based fermentation media that were correlated with the above $k_L a$ model for $1.5 \leq \varepsilon_g \leq 3.5\,\mathrm{W/kg}$:

$\alpha = 0.258$, $\beta = 0.562$, $\gamma = 0.232$, and $\kappa = -0.333$

Using Eq. (8), the viscosity of the suspension is determined from the broth viscosity and volumetric concentration of solids.

The $k_L a$ value determined with the above model is valid at a constant temperature of 20°C. The mass transfer coefficient at actual operating temperatures is given by

$$k_L a = k_L a_{20} \frac{1}{1.024^{(20-t)}} \tag{10}$$

Stirrer power under gassed conditions is shown below:

$$P_g = \varepsilon_g m_{Broth} = \varepsilon_g \rho_{Broth} V_{Broth} \quad (11)$$

Gas holdup

Similar to the mass transfer model, gas holdup may also be expressed as a function of the specific power ε_g, the superficial gas velocity $\bar{u}_g$, and the viscosity ratio. Model parameters (α, β, γ, and κ) obtained from the gas holdup expression are neither related to nor interchangeable with those obtained in the mass transfer model:

$$\Phi_g = \alpha \varepsilon_g^{\beta} \bar{u}_g^{\gamma} \left(\frac{\mu_s}{\mu_w}\right)^{\kappa} \quad (12)$$

The following parameters are specific to the broth used in fitting the above gas holdup model. In this example these parameters have values of:

$\alpha = 0.500, \quad \beta = 0.143,$
$\gamma = 0.197,$ and $\quad \kappa = -0.333$

The k-factor

A common way to determine the agitator power under gassed conditions is to use the k-factor, sometimes called the relative power demand, defined as the ratio of gassed to ungassed shaft power:

$$\text{k-factor: } K \equiv \frac{P_g}{P_{ug}} \quad (13)$$

For a stirred system with multiple impellers of different types, the overall k-factor can be experimentally determined as in Fig. 8 (k-factor vs. aeration number at different Reynolds numbers), or can be approximated by adding weighted k-factors for the individual impellers, as follows:

$$K = \frac{N_{P_R}}{N_P} K_R + \frac{N_{P_A}}{N_P} K_A \quad (14)$$

The first term on the right represents the radial, bottom impeller and the second term on the right applies to axial, down-flow impeller(s). The following relationships are used in the design:[11]

$$K_R = 1 - (b' - a'\mu_{b'}) Fr_R^{d'} \tanh(c' \mathrm{Na}_R) \quad (15)$$

Values of the constant parameters a', b', c', and d', as shown in Table 2, depend on the radial impeller type.

$$K_A = 1 - (a'' + b'' Fr_A) \mathrm{Na}_A^{c'' + 0.04 Fr_A} \quad (16)$$

The parameters a'', b'', and c'' in the K_A relationship are not constant, but depend on the impeller to tank diameter ratio D/T:

$$a'' = 5.3\, e^{-5.4(D_A/T)}$$
$$b'' = 0.47(D_A/T)^{1.3}$$
$$c'' = 0.64 - 1.1(D_A/T)$$

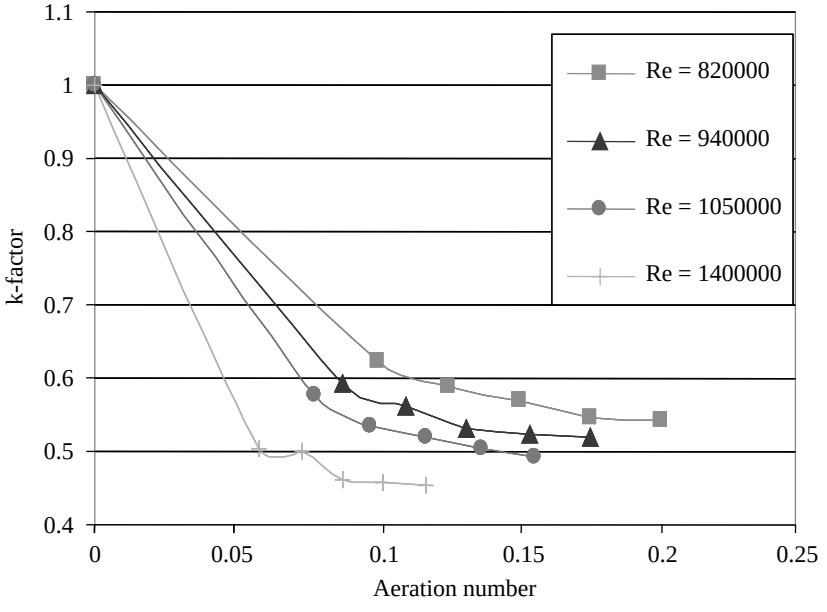

Fig. 8 k-Factor of multiple impeller system (Rushton + PBT) as a function of aeration number. *(View this art in color at www.dekker.com.)*

Table 2 Constants for Eq. (15)

Blade type	a'	b'	c'	d'
Flat	0.72	0.72	24	0.25
Concave	0.12	0.44	12	0.37

(From Ref.[11].)

Eqs. (15) and (16) are valid for

$$0.40 < D/T < 0.65$$
$$0.50 < Fr < 2.0$$
$$0.05 < Na < 0.35$$

$$P_{ug} = \frac{1}{K} P_g \tag{17}$$

Motor and gear box design normally assumes an 80% drive system efficiency ($\eta_m = 0.8$).

$$P_m = \frac{P_g}{\eta_m} \tag{18}$$

At a fixed agitation rate, the gassed power, P_g, is generally less than the ungassed power, P_{ug}. Consequently, the ungassed agitation rate is typically lower than the gassed agitation rate, i.e., $N_{ug} < N_g$. If gas feed suddenly stopped while operation continued at the gassed agitation rate, the mixer drive system would likely be overloaded and damaged.

Gas flooding

A stirred tank fermenter has power introduced through both the agitation system and the expanding gas. With the assumption of fast temperature equalization, an isothermal expansion of the gas (air) takes place. The gas power is:

$$P_{gas} = \dot{m}_{gas} \frac{RT}{M_{gas}} \ln\left(\frac{p_1}{p_2}\right) \tag{19}$$

where R is the gas constant (8.314 kJ/kmol/K), T is the absolute temperature at operating conditions, and M_{gas} is the molecular weight of gas. The pressure ratio is given at inlet (1) and outlet (2) tank locations.

For high aeration values, gas expansion power P_{gas} can reach the magnitude of the aerated agitator power P_g. If gas expansion power is greater than or equal to the stirrer power, there is the likelihood of impeller flooding, which limits gas dispersion to the central region of the tank.

To avoid potential flooding, it is recommended that

$$(P_g/P_{gas})_{design} \geq 3 \tag{20}$$

Design example

The design of a stirred tank fermenter for the production of an industrial enzyme at an annual rate of 800 ± 5% mt/yr is illustrated below. Product recovery efficiency is 80% and the expected yield (product concentration) is 75 kg/m^3. Maximum oxygen uptake demand is 185 mmol O_2/L/hr. Operational parameters and media physical properties are listed as follows.

Batch length = 3 days.
Fermenter turnaround rate = 2 days.
Number of operating days per year = 320.
Annual fermenter output = required production/recovery efficiency = 800 mt/yr/0.8 = 10^3 mt/yr.
Required batch size = (annual fermenter output/titer) × (total batch duration/yearly operation) = (10^6/75) (5/320) = 208 m^3.
Number of bioreactors = 2.
The required batch size per fermenter = 208/2 = 104 m^3.
Assuming a tank volume utilization of 80% the size of the bioreactor is 130 m^3.
The nominal tank size is 140,000 L.

Broth properties of Newtonian fluids

Effective glucose broth (liquid) viscosity = 5×10^{-3} Pa sec.
Effective media (suspension) viscosity = 15.3×10^{-3} Pa sec.
Density = 993 kg/m^3.
Interfacial tension (gas–liquid) = 7.1×10^{-2} N/m.
Thermal conductivity = 0.617 W/m/K.
Specific heat capacity = 4.118 kJ/kg/K.
O_2 broth diffusion coefficient = 4.3×10^{-9} m^2/sec.

Additional conditions for fermentation and heat removal, as determined at the pilot scale, are presented in Table 3. The state-of-the-art aerobic fermenter agitation system design recommendations are shown in Table 4. Based on the required fermentation batch size and agitator design recommendations listed in Table 2, dimensions of the fermenter and its internals are summarized in Tables 5 and 6, respectively. Drive system specifications for satisfactory OTR are calculated using pertinent design equations and correlations (see Table 7). Fig. 9 shows a schematic of the designed production fermenter. For details of the mechanical design, readers are referred to the publication by Charles and Wilson.[12]

Gas sparger design

Some basic guidelines for the sparger design are presented in the ''Gas Liquid Contactor'' entry.

Table 3 Production fermenter design parameters

Batch operation parameters	
Temperature (°C)	32
Head space pressure [bar (gage)]	0.689
VVM i.e. V_g/V_L (standard conditions) (1/min)	1.3
Solid concentration (vol%)	30
Respiration ratio (mol CO_2/mol O_2)	0.8
Heat transfer conditions	
Reaction heat liberation (kJ/mol O_2)	500
Chilled water supply temperature (°C)	12
Max. chilled water flow (m^3/h)	650
Thermal conductivity (W/m/K)	16
Fouling coefficient on product side (m^2 K/W)	0

The recommended sparge ring to impeller diameter ratio is 0.65–0.8, while the ring sparger orifice diameter is in the range of 2–10 mm, and the gas velocity through the orifice is between 15 and 30 m/sec.[13]

Pressure drop across a perforated disperser or orifice is estimated by the conventional orifice equation:

$$\Delta_{P_o} = \rho(\nu_o/c_v)^2/2 \quad (21)$$

The above equation neglects velocity of approach to the orifice. Typically, the coefficient of velocity, $c_{v,}$ is assumed to be 0.8.

To ensure uniform flow through all the orifices or holes, rules of thumb for the gas sparger design call for satisfaction of the following criteria.[14] First, the pressure drop ratio between the total pressure loss along the pipe, Δp_p, and the pressure loss across each hole, Δp_o, should be:

$$\Delta_{P_p}/\Delta_{P_o} \leq 0.1 \quad (22)$$

where

$$\Delta_{P_p} = [(4fL_p/3d_p) - 1](\rho u_{in}^2/2) \quad (23)$$

and f is the Fanning friction factor.

Second, the ratio of kinetic energy of the gas at the inlet of the pipe, and the pressure drop across each hole should be:

$$KE_{in}/\Delta_{P_o} \leq 0.1 \quad (24)$$

where

$$KE_{in} = 1.05(\rho u_{in}^2/2) \quad (25)$$

Details of the ring sparger design are summarized in Table 8. A schematic of the sparger is shown in Fig. 10.

isothermal conditions in the tank. As mentioned earlier, a gas–liquid stirred tank bioreactor has three sources for heat generation. These are the gas expansion power, the agitation power under gassed conditions, and the heat liberated by the bioreaction. The amount of heat to be removed can be expressed as:

$$\dot{Q} = P_{gas} + P_g + \dot{Q}_f \tag{26}$$

The last term, $\dot{Q}_f$, is the heat of formation in the fermenter. It is directly proportional to the OUR and normally much higher than the gas expansion and agitation power. For enzyme production, the relationship between heat of formation and oxygen demand, $\dot{n}_{O_2}$, is:

$$\dot{Q}_f \quad (\text{kW}) \approx 500\Delta\dot{n}_{O_2} \quad (\text{kmol/sec}) \tag{27}$$

Whether the heat duty can be removed depends on the different heat resistances discussed in the following section.

The heat duty is described as:

$$\dot{Q} = UA\Delta T_{ln} \tag{28}$$

where U is the overall heat transfer coefficient and A is the heat transfer area. ΔT_{ln} is the average logarithmic temperature difference defined as follows.

$$\Delta T_{ln} = \frac{\Delta T_1 - \Delta T_2}{\ln(\Delta T_1/\Delta T_2)} \tag{29}$$

ΔT_1 and ΔT_2 are the temperature difference between the cooling medium and tank contents at the inlet (1) and the outlet (2) of the cooling or utility flow. The overall heat transfer coefficient, U, is determined as follows:

$$\frac{1}{U} = \frac{1}{\alpha_p} + f_p + \frac{\delta_w}{\lambda_w} + f_j + \frac{1}{\alpha_j} \tag{30}$$

where, δ_w is the wall thickness, and α_p, and α_j are the heat transfer coefficients for the process side and jacket side, respectively.

For large-scale fermenters with multiple impellers, there are very few heat transfer correlations available. Most of the experimental investigations have been done with Newtonian liquids with a single, standard impeller. The following ungassed liquid phase Nusselt number correlation for heat transfer at the tank wall, in different vessel geometries with four standard baffles and a Rushton turbine, was developed by Strek.[15]

$$Nu_{pw-ug} = 1.01\left(\frac{D}{T}\right)^{0.13}\left(\frac{c_{bot}}{T}\right)^{0.12} Re^{2/3} Pr^{1/3}\left(\frac{\mu_L}{\mu_w}\right)^{0.14} \tag{31}$$

where pw represents process side locations near the wall (i.e., heat transfer surface).

Under gassed conditions, using a ring sparger in a similar system, Kurpiers and Steiff developed the

Under gassed conditions, using a ring sparger in a similar system, Kurpiers and Steiff developed the following correlation:[16]

$$Nu_{\mathrm{pw-g}} = 0.1\left\{\xi\left(\frac{T}{D}\right)\left(\frac{T^3}{V_{\mathrm{broth}}}\right)N_{P,\mathrm{g}}Re^3 \left[1 - 2\left(\frac{D}{T}\right)\left(\frac{D}{H_{\mathrm{ug}} - H_{\mathrm{sp}}}\right)N_{P,\mathrm{g}}^{0.5}Fr\right]\right\}^{0.25} \mathrm{Pr}^{0.4}\left(\frac{\mu_{\mathrm{L}}}{\mu_{\mathrm{W}}}\right)^{0.23} \quad (32)$$

The constant ξ changes linearly from $0.2(T/D = 3)$ to $0.37(T/D = 1.9)$.

Eq. (32) is used to determine the internal heat transfer coefficient ($\alpha_{\mathrm{pw-g}}$) under gassed conditions in a jacketed stirred tank. After appropriate corrections, it can also be used to approximate the process side heat transfer coefficient ($\alpha_{\mathrm{p-g}}$) in the presence of an internal heat exchanger. A multiplying correction factor, the ratio of measured heat transfer coefficients under ungassed conditions ($\alpha_{\mathrm{p-ug}}/\alpha_{\mathrm{pw-ug}}$), is used as indicated in Eq. (33). In this case, $\alpha_{\mathrm{p-ug}} = \alpha_{\mathrm{pw-ug}}$.

$$\alpha_{\mathrm{p-g}} = \alpha_{\mathrm{pw-g}}\frac{\alpha_{\mathrm{p-ug}}}{\alpha_{\mathrm{pw-ug}}} \quad (33)$$

The biggest challenge in using Eq. (28) is the lack of reliable values of the overall heat transfer coefficient U. It depends on a number of factors including rheology of the broth, thermal properties of the broth and utility fluid, aeration and agitation levels, and the nature of the heat transfer surfaces (e.g., jacket, dimpled jacket, coils, or tube bundles). Because so few applicable correlations exist for aerated fermenters, experience and a conservative approach are essential for their design. Design guidelines for a typical half-pipe jacket are discussed here. Based on the fermentation heat duty (see Table 9), half-pipe coil design results are summarized in Table 10.

Heat transfer in a half-pipe jacket

According to Stein and Schmidt a few adaptations make it possible to use correlations for horizontal tube coils to estimate heat transfer in a vessel with a half-pipe jacket.[17] Necessary adaptations include using the thermic diameter $d_{\mathrm{th}} = (\pi/2)d_{\mathrm{i}}$ instead of the tube inner diameter d_{i} to calculate the Reynolds and Nusselt numbers, and replacing the bending ratio ($d_{\mathrm{be}}/D_{\mathrm{b}}$) with the ratio of $d_{\mathrm{i}}/2(T + 2\delta_{\mathrm{w}})$.[1,2]

The geometry with the main dimensions of the coil is shown in Fig. 11. Here, d is the inside diameter of the coil tube and h is the pitch of the coil. D_{w} is the average diameter of the coil.

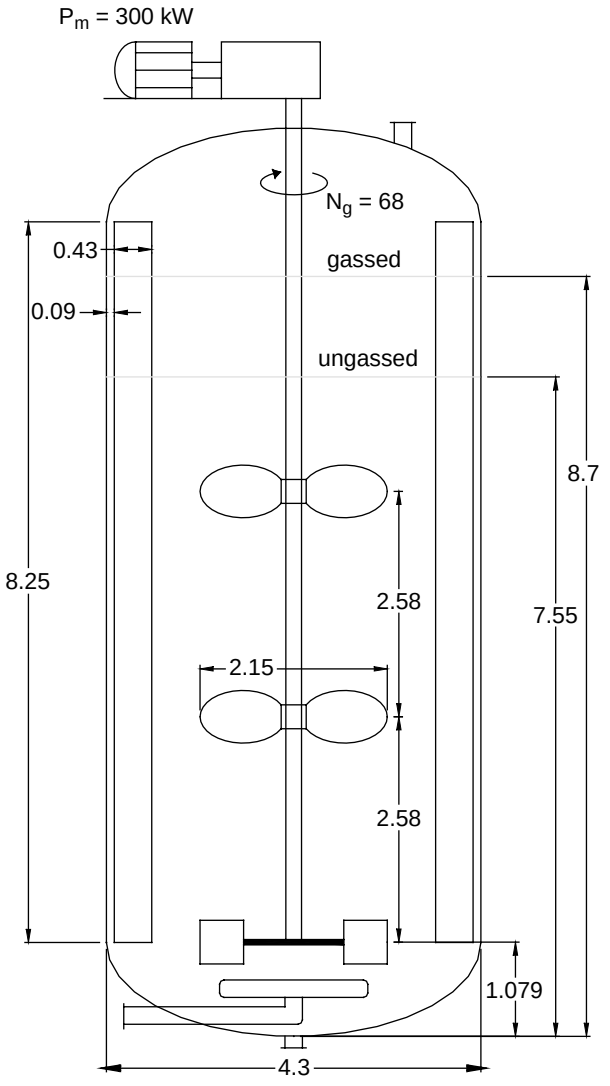

Fig. 9 Schematic of the production fermenter (dimensions in meters). *(View this art in color at www.dekker.com.)*

Another characteristic parameter used to describe the coil geometry is the bending ratio $d_{\mathrm{hc}}/D_{\mathrm{b}}$, with D_{b} as the average bending diameter of the coil. The calculation of D_{b} and that of the heat transfer coefficient are described next.

The average turning diameter D_{t} of a coil can be determined for a tube with length l, and n turns of slope h:

$$D_{\mathrm{t}} = \frac{l}{n\pi} \quad (34)$$

With a right triangle configuration of the coil, the average diameter of the coil (shown in Fig. 11) is calculated to be

$$D_{\mathrm{w}} = \sqrt{D_{\mathrm{t}}^2 - \left(\frac{h}{\pi}\right)^2} \quad (35)$$

Table 8 Gas sparger design results

Variable	Equation	Value
Diameter of sparge ring (m)		1.7
Sparge pipe inside diameter (m)		0.20
Sparger to bottom impeller diameter ratio		0.79
Sparger bottom clearance (m)		0.55
Number of holes		570
Hole diameter (mm)		8.00
Velocity through each orifice (m/sec)		36.55
Number of drain holes		16
Size of drain holes (mm)		16
Pressure drop per orifice (Pa)	21	4500
Pressure drop in the pipe ($f = 0.005$) (Pa)	23	127
Sparge pipe velocity (m/sec)		16.03
Sparge feed pipe inside diameter (m)		0.33
Sparge feed pipe velocity (m/sec)		11.86
Pressure drop ratio pipe to hole	22 (check)	0.03

The average bending diameter D_b of the coil that is used in calculating the bending ratio d_{hc}/D_b is obtained from

$$D_b = D_w\left[1 + \left(\frac{h}{\pi D_w}\right)^2\right] \tag{36}$$

In contrast to a straight pipe, the critical Reynolds number for the transition from laminar to turbulent flow in a coiled pipe increases with increasing bending ratios. For the critical Reynolds number, Schmidt found that

$$Re_{crit} = 2300\left[1 + 8.6\left(\frac{d_{hc}}{D_b}\right)^{0.45}\right] \tag{37}$$

Based on the value of the critical Reynolds number or flow regime, different heat transfer correlations are applied. For laminar flow with $Re < Re_{crit}$, the Nusselt number is correlated to:

$$Nu_{lam} = \left(3.66 + 0.08\left[1 + 0.8\left(\frac{d_{hc}}{D_b}\right)^{0.9}\right]Re^m Pr^{1/3}\right)\left(\frac{Pr}{Pr_w}\right)^{0.14} \tag{38}$$

with

$$m = 0.5 + 0.2903\left(\frac{d_{hc}}{D_b}\right)^{0.194} \tag{39}$$

Here, previous definitions have been slightly altered as follows: $Nu = \alpha_c d_{hc}/\lambda_{cool}$, $Re = w d_{hc}\rho_{cool}/\mu_{cool}$, and $Pr = \mu_{cool} c_{p,cool}/\lambda_{cool}$.

For heat transfer in the turbulent flow regime, i.e., $Re > 2.2 \times 10^4$, the Nusselt number is determined from the following equation:

$$Nu_{turb} = \frac{\xi/8 Re \times Pr}{1 + 12.7\sqrt{\xi/8}(Pr^{2/3} - 1)}\left(\frac{Pr}{Pr_w}\right)^{0.14} \tag{40}$$

with

$$\xi = \frac{0.3164}{Re^{0.25}} + 0.03\left(\frac{d_{hc}}{D_b}\right)^{0.5} \tag{41}$$

The installed area of half-pipes can be calculated as:

$$A_{inst} = n_{coil} d_o L_{coil} = n_{coil} d_o n_{tc}\pi(T + 2\delta_w) \tag{42}$$

where d_o is the outside diameter of the half-pipe.

The effective area for heat transfer is linearly proportional to the gassed height of the cylindrical portion in the tank:

$$A_{eff} = A_{inst}[(H_g - H_{btm})/n_{coil} h_{coil}] \tag{43}$$

The heat removal duty from the tank is:

$$\dot{Q} = UA_{eff}\Delta t_{ln} = UA_{eff}\frac{(t - t_1) - (t - t_2)}{\ln((t - t_1)/t - t_2)} \tag{44}$$

$$\dot{Q} = \dot{m}_{cool} c_{p,cool}(t_2 - t_1) \tag{45}$$

The cooling medium volumetric flow is:

$$\dot{V}_{cool} = w\left(\frac{\pi}{4} d_i^2 n_{coil}\right) \tag{46}$$

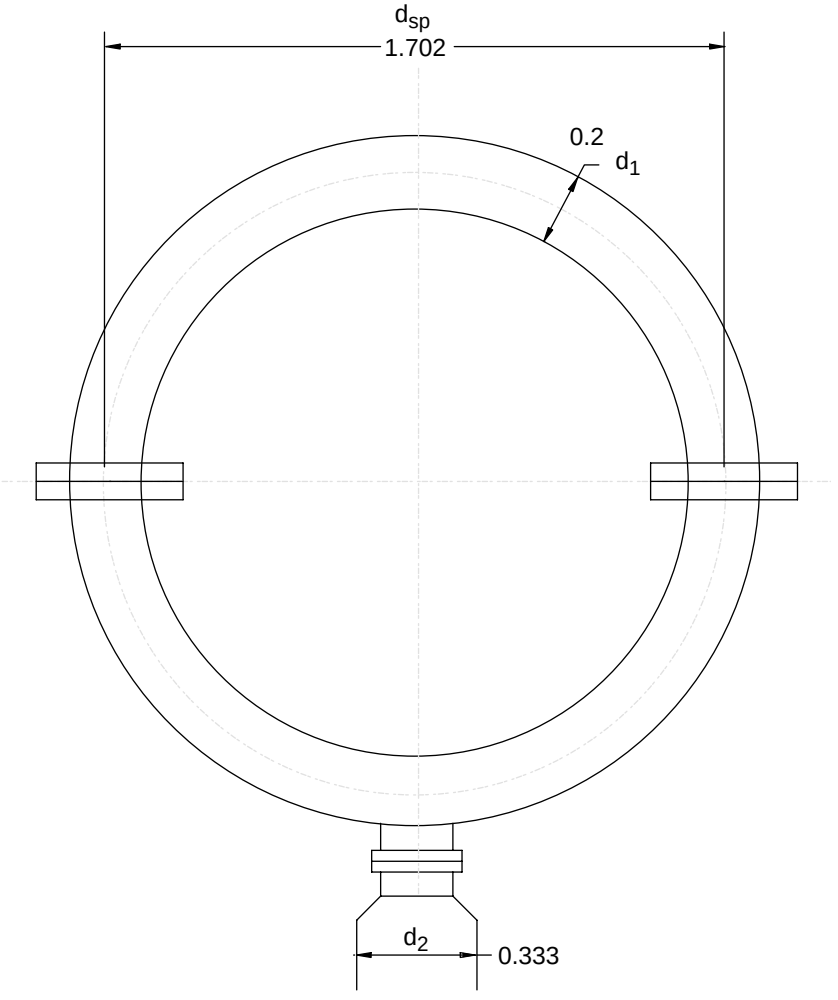

Fig. 10 Schematic of sparger ring (dimensions in meters). *(View this art in color at www.dekker.com.)*

where w (assumed 2 m/sec) is the velocity of the utility fluid in the half-pipe. The cooling medium return temperature t_2 is:

$$t_2 = \frac{UA_{\text{eff}}\Delta t_{\text{ln}}}{\dot{m}_{\text{cool}}c_{\text{p,cool}}} + t_1 \tag{47}$$

Concentric Tube Airlift Fermenter

This, the second of two fermenter design examples, deals with a concentric tube airlift fermenter. Nondimensional parameters applicable in this example are defined as follows.

Nondimensional parameters

R	diameter ratio, d_c/d_t
S	slenderness ratio, l_t/d_c
M	bubble separation group, $d_s/4d_c$
X_t	draft-tube bottom clearance ratio, $c_{t\text{-}b}/d_t$
Y_t	draft-tube top clearance ratio, $c_{t\text{-}t}/d_t$
Φ_g	gas holdup, $V_g/(V_g + V_L)$
DR	disengagement ratio, $(d_c/d_s)\ \{(R^2 - 1)/R\}$
Eu'	modified Euler number, $\Delta P/\rho u_g^2$
Fr	Froude number, $u_g/(gd_c)^{0.5}$ [also defined as $u_g^2/(gd_c)$]
Ga	Galileo number, $g\rho_L^2 d_c^3/\mu^2$
Gr	Grashoff number, $g\rho_L(\rho_L - \rho_g)d_b^3/\mu_L^2$
Sc	Schmidt number, $\mu_L/(\rho_L D_L)$
Sh	Sherwood number, $k_L a d_c^2/D_L$
We_o	Weber number for the orifice, $v_o^2 d_o \rho_o/\sigma$

Mass transfer correlations

The following nondimensional mass transfer correlation, represented by the Sherwood number, is valid for the draft-tube sparged concentric tube airlift fermenter.[18]

$$Sh = 17.3 \times 10^3 Fr^{0.9} M^{-3.4} Ga^{0.13} X_t^{-0.07} Y_t^{-0.18} \tag{48}$$

The influence of apparent viscosity, represented by Ga, reflects the expected decrease in mass transfer rate with

Table 9 Fermentation heat duty

Variable	Equation	Value
Agitation power (kW)	From Table 7	238
Gas expansion power (kW)	From Table 7	80
Reaction heat liberation (kJ/mol O_2)		500
Reaction heat liberation (kW)	27	2676
Total heat to be removed (MW)	26	3

an increase in viscosity. Both draft-tube bottom and draft-tube top clearances, i.e., X_t and Y_t affect the mass transfer rate only modestly while the bubble separator to column diameter ratio, M, is obviously ascribed the greatest influence.

Gas holdup correlations

The following correlations are recommended for calculating gas holdup in the riser, downcomer, and separator, respectively.

$$\Phi_r = 1.5Fr^{0.87}M^{-0.4}X_t^{-0.19}Y_t^{-0.2} \quad (49)$$

$$\Phi_d = 4.76Fr^{1.3}Ga^{-0.09}M^{-3.8}X_t^{0.65} \quad (50)$$

$$\Phi_{to} = \Phi_s = 0.29Fr^{1.05}M^{-2.5}X_t^{0.1}Y_t^{-0.07} \quad (51)$$

The main variable is Fr, which represents the influence of gas input rate (and also the energy input rate). Its effect on holdup is much stronger in the downcomer than in the riser, and the balance between the two gives an exponent of almost 1 (1.05) for the total holdup. Interestingly, the behavior of holdup in the gas separator is very close to that of total holdup. As draft-tube bottom clearance c_{t-b} increases, Φ_r decreases.[18]

Dynamic pressure drop correlations

According to Merchuk et al., the following correlation is satisfactory for the prediction of pressure drop in

Table 10 Results of half-pipe external heat transfer jacked design

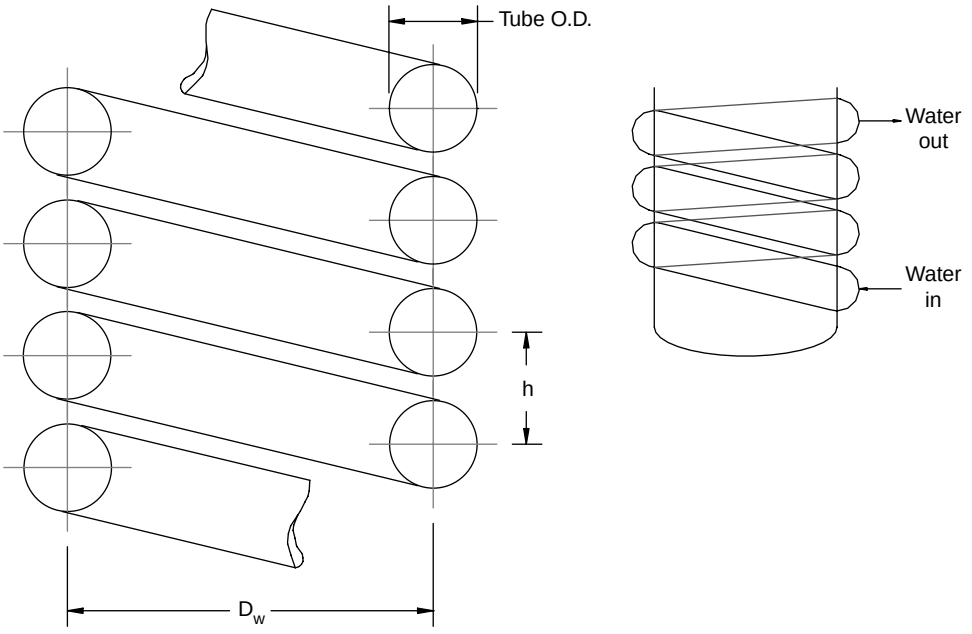

Fig. 11 Schematic of half-coil jacket. *(View this art in color at www.dekker.com.)*

concentric tube airlift fermenters over a wide range of physicochemical, geometrical, and operating variables.[18]

$$Eu' = 0.858 Fr^{-1.51} Ga^{0.06} X_t^{-1.1} M^{4.2} \quad (52)$$

Substituting the definitions of Eu' and Fr into this expression shows pressure drop to be a function of $u_g^{0.5}$. The bottom clearance ratio, X_t, and the bubble separation group, M, have a strong influence on the pressure drop because of their effect on liquid velocity.

Note that all these correlations (mass transfer, gas holdup, and dynamic pressure drop) are valid only within the following operating ranges:

$$6 \times 10^{-4} < Fr < 3.5 \times 10^{-2}$$
$$3 \times 10^{7} < Ga < 6 \times 10^{11}$$
$$0.04 < X_t < 0.4$$
$$0.22 < M < 0.34$$

Shear rate correlations

The rate of shear in the airlift bioreactor remains the subject of speculation. The disparity in "average shear rate'' ($\dot{\gamma}$), as calculated with several available correlations, is shown by Chisti.[8] Several investigators (Nakanoh and Oshida) have accepted the following conservative expression for use in airlift bioreactor:[19]

$$\gamma = 5000\, u_{gr} \text{ for } 0.04 \leq u_{gr} \leq 0.1\,\text{m/sec} \quad (53)$$

However, Schumpe and Deckwer and Moo-Young et al. proposed the following equations, respectively, for average shear rate:[20,21]

$$\dot{\gamma} = 2800 u_{gr} \quad \text{for } u_{gr} \leq 0.08\,\text{m/sec} \quad (54)$$

$$\dot{\gamma} = 1000 u_{gr} \quad \text{for } u_{gr} \leq 0.04\,\text{m/sec} \quad (55)$$

These expressions show shear rate dependence on superficial gas velocity, but not as a function of specific energy, which is responsible for turbulence. In an airlift bioreactor, pneumatic power input is given by the following equation:[22]

$$P_g/V_L = \rho_L g u_{gr} [a_r/(a_r + a_d)] \quad (56)$$

Incorporating this definition of pneumatic power into Eqs. (53) and (55) produces the following modified

Table 11 Maximum gas flow rates for separate bubbling

Orifice diameter, $d_o \times 10^3$ (m)	Orifice area, $a_o \times 10^6$ (m^2)	Gas rate/orifice, $q_o \times 10^6$ (m^3/sec)
0.25	0.05	0.275

10.16	81.03	6.679

and corrected shear rate correlations:[23]

$$\dot{\gamma} = [5000\,P_g/(V_L\rho_L g)][(a_r + a_d)/a_r] \quad \text{for } u_{gr} \geq 0.04\,\text{m/sec} \tag{57}$$

$$\dot{\gamma} = [1000\,P_g/(V_L\rho_L g)][(a_r + a_d)/a_r] \quad \text{for } u_{gr} < 0.04\,\text{m/sec} \tag{58}$$

Sparger design equations

For satisfactory gas distribution from a ring sparger,[24] Weber number for the orifice,

$$We_o = \left(v_o^2 d_o \rho_o/\sigma\right) > 2 \tag{59}$$

In the case of gas emerging from a simple submerged orifice at very low flow rates, bubbles periodically form at the orifice, grow to a certain size, and break away. For media with a reasonably low viscosity, bubble diameter is a function of the interfacial tension and density as indicated below:

$$d_b = 1.82\left[\frac{d_o\sigma g_c}{(\rho_L - \rho_g)g}\right]^{1/3} \tag{60}$$

This relationship holds for "slow" bubbling in the "constant volume" region, although the exponent may be nearer $\frac{1}{4}$ when static surface tension data are

used. Bubble size is independent of flow rate while bubble frequency is proportional to it. At higher gas flow rates, the frequency levels off and bubble volume increases. Finally, a point is reached where distinct bubble formation is replaced with a chain bubbling process. This undesirable phenomenon is avoided by keeping the overall gas rates below those shown in Table 11.[24] The turbulent churn flow regime typically sets in as superficial gas velocity, u_g, exceeds 0.08 m/sec.

As cited by Bhavaraju, Russel, and Blanchard, Davidson obtained the following correlation for bubble diameter using orifices ranging in diameter from 0.001 to 0.01 m:[25]

$$d_b = 0.19 d_o^{0.48} Re_o^{0.32} \quad (61)$$

Design example

The design of a concentric tube internal loop airlift fermenter for the production of a biocatalysis enzyme at an annual rate of 8000 ± 5% kg/yr is illustrated below. Product recovery efficiency is 80% and the titer (product concentration) is 20 g/L. Maximum oxygen uptake demand is 10 mmol O_2/L/hr. Operational parameters and media physical properties are as follows:

Batch length or growth rate = 5 days
Bioreactor turnaround rate = 2 days
Number of operating days in a year = 300.
Annual fermenter output = required production/recovery efficiency = 10,000 kg/yr.
Required batch size = (annual fermenter output/titer) (total batch duration/yearly operation) = 11,667 L = 12,000 L.
Number of bioreactors = 3 (assumed).
Size of each bioreactor = 4000 L.

Broth properties of Newtonian fluid

Effective viscosity = 5×10^{-3} Pa sec (glucose media Newtonian).
Density = 1000 kg/m^3.
Interfacial tension (gas–liquid) = 7.2×10^{-2} N/m.
O_2 broth diffusion coefficient = 4.3×10^{-9} m^2/sec.

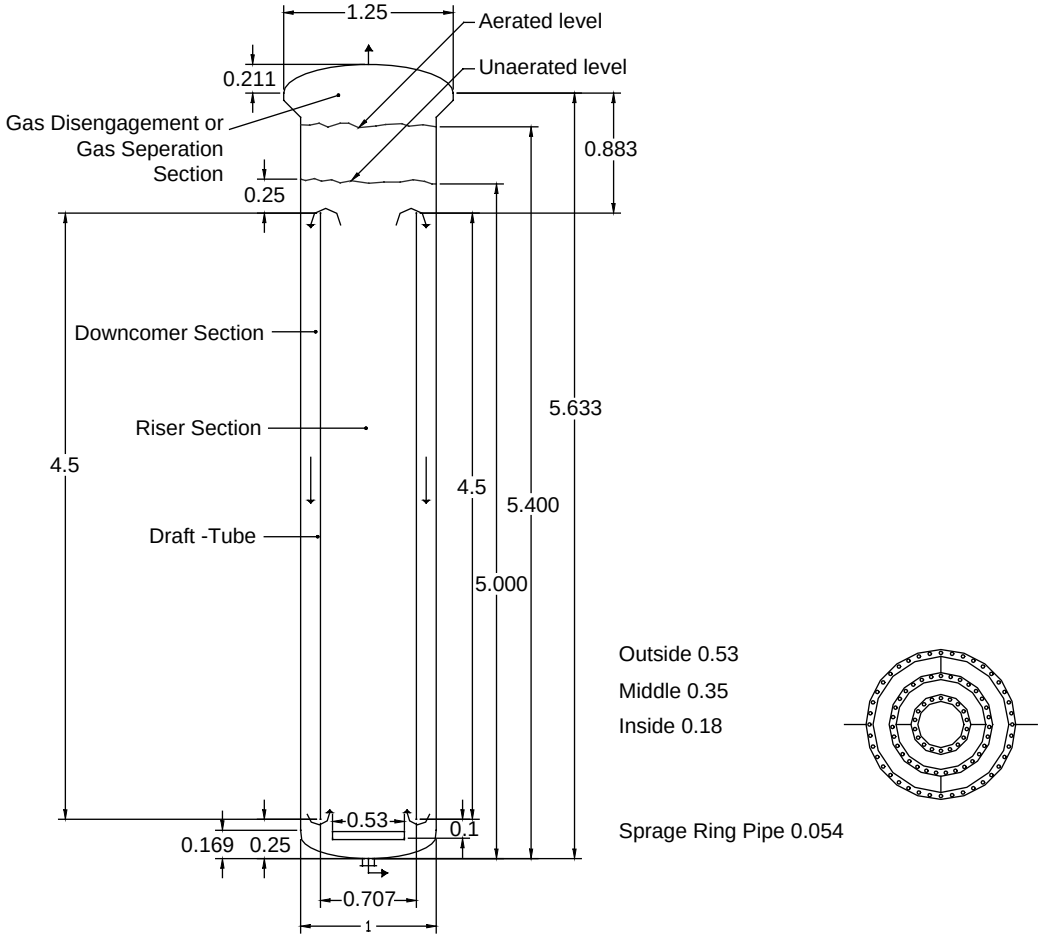

Fig. 12 Schematic of the airlift fermenter and its triple ring sparger (dimensions in meters). *(View this art in color at www.dekker.com.)*

Table 13 Sparger design results

Variable	Equation	Value
Type: three-ring air sparger		
Actual volume of gas (m^3)		0.23
Ratio of column to draft-tube area		2
Superficial gas velocity in the riser (m/sec)		0.085
Number of orifices		450
Orifice diameter (m)		2.54×10^{-3}
Velocity through orifice (m/sec)		14.6
Orifice Weber number	59 (check)	9
Total cross-sectional area of the orifices (m^2)		2.28×10^{-3}
Minimum sparger pipe diameter (m)		0.054
Orifice velocity coefficient		0.8
Pressure drop across the orifice (Pa)	21	201
Bubble size (noncoalescing media) (m)	61	0.005
Orifice Reynolds number		2.5×10^3
Outer sparger diameter (m) and number of orifices		0.53, 225
Middle sparger diameter (m) and number of orifices		0.35, 150
Inner sparger diameter (m) and number of orifices		0.18, 75

Based on the above fermentation volume, important fermenter dimensions are initially estimated. The required mass transfer coefficient is calculated from the oxygen uptake rate (OUR). Superficial gas velocity is computed from the Sherwood number–Froude number correlation [Eq. (48)]. Final column dimensions are determined iteratively while ensuring that bubbly flow (as indicated by superficial gas velocity) is maintained within the riser. After finalizing column dimensions, the required volume is calculated and the sparger is designed according to accepted rules of thumb. These and other details of the iterative solution procedure are tabulated in Table 12. Fig. 12 shows a schematic of the production scale concentric tube airlift fermenter. The detailed design specification for the triple-ring sparger is presented in Table 13.

EMERGING UNCONVENTIONAL FERMENTERS

The yield of secondary metabolites in a large-scale fermenter typically ranges from 0.1 to 10 g/L of broth. Such poor yield leads to cumbersome and expensive processes for both product separation and broth disposal. Within the last decade, several novel bioreactors have been developed for the intensification of fermentation processes. Examples include a centrifugal bioreactor, a rotating packed bed fermenter, and a sonobioreactor.[26,27] Most of these, however, are yet to be implemented on a production scale because they generally lack practicality and well-defined scale-up criteria.

CONCLUSIONS

Even though the bioreactor itself may not be the most costly piece of process equipment, it determines the technical feasibility of the entire process. The attention paid to bioreactor design, scale-up, and operating parameters reflects its central role in successful commercial ventures.

This chapter discusses important controlling parameters of aerobic fermenters, and provides design methodology and appropriate correlations for commonly practiced mechanically agitated and concentric tube airlift fermenters. Two complete design examples for the production of biocatalysis enzymes are presented. Aspects that were not discussed in detail include mass transfer and gas holdup correlations for high-viscosity or pseudoplastic fluids. In this regard, readers are referred to the open literature, which includes such works as those of Kilonzo and Margaritis and Kawase and coworkers[4,28–30]

Fluid Flow

T. Reg. Bott
School of Engineering, Chemical Engineering, University of Birmingham, Birmingham, U.K.

INTRODUCTION

Most processes involve the flow of fluids (gases and liquids) either as material being processed or as an agent used to transport particles or droplets that are themselves being processed in the equipment making up the plant. Because the fluid is contained within the system in pipe lines, mixers, heat exchangers, reactors, and so on, the confining walls generally influence the character of the flow. Furthermore, the physical properties of the fluid, particularly the viscosity, also have a profound influence on the behavior of the fluid in the process plant.

The movement of the fluid on its journey through the various items of equipment requires energy that usually, although not always, is applied through some sort of pump. The amount of energy involved will again be dependent on the physical properties of the fluid and the design of the equipment through which it flows. A major cause of energy dissipation is through friction, either within the fluid itself or through its contact with the solid confining wall. It is essential that, at the process plant design stage, a reliable estimate of the likely pressure loss can be made, so that the pump capacity and power requirement can be calculated. The energy consumption involved could represent a substantial constituent of the future plant operating costs. The quality of the fluid flow can also have a profound effect on the efficiency of the various pieces of equipment operating in the process plant. For instance, the efficiency of heat transfer is strongly dependent on the characteristics of the flow within the heat exchanger involved. In distillation and absorption columns effective mass transfer depends on the characteristics of the fluid flow within the equipment.

There are two definitions that are usually applied to fluids. They are ''compressible'' and ''incompressible'' fluids. If the volume of a fluid is not dependent on the applied pressure and its temperature, the fluid is said to be incompressible. Although not strictly true, it is usual to assume that liquids are incompressible, when estimates involving fluid flow are made. On the other hand gases are usually considered to be compressible, because large changes in volume are apparent with changes in pressure and temperature. For calculation simplification, however, for small changes in pressure and temperature, a gas can often be regarded as incompressible.

FLOW IN RELATION TO SURFACES

When a fluid flows across a solid surface, the drag (the resistance to flow) produced by the presence of the surface in contact with the fluid creates a velocity distribution through the bulk fluid. The fluid velocity increases with the distance from the solid surface. The flow may be visualized by so-called streamlines that represent the paths of parcels of fluid. Each streamline represents fluid with the same velocity. Fig. 1 shows the velocity profile with a fluid flowing across a solid surface. The difference in flow rate between adjacent streamlines is always the same when the streamlines are equidistant.

Fig. 2 shows increased velocity around a submerged object by streamlines that are closer together compared to the region where there is no submerged object. The concept of streamlines can help to define two different flow regimes:

1. Laminar flow where movement of particles of fluid between streamlines is solely by molecular diffusion.
2. Turbulent flow in which the transfer of fluid in the direction perpendicular to the flow occurs as a result of the physical movement of fluid, although the time average of flow rate remains constant.

FLOW IN PIPES

Pioneering work by Osborne Reynolds in the late 19th century[1] added considerably to the understanding of fluid flow in relation to surfaces, and established concepts on which subsequent theoretical, empirical, and practical work could be based. The principal finding was in connection with fluid flow in pipes, visually demonstrating the difference between laminar and turbulent flow. Reynolds discovered that the dimensionless number that now bears his name, the Reynolds number (Re), defined the flow condition in a tube,

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120019080

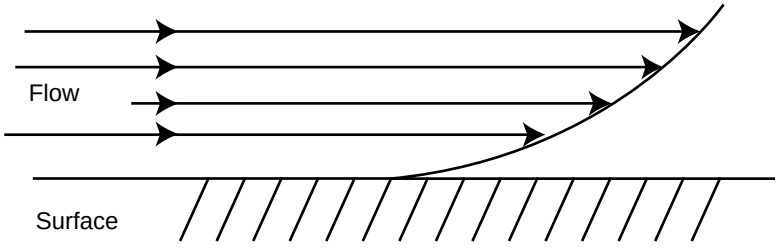

Fig. 1 Velocity profile of a fluid flowing across a surface.

where

$$Re = \frac{Dv\rho}{\mu} \quad (1)$$

where D represents the tube internal diameter, v is the fluid velocity, and ρ and μ are the fluid density and viscosity, respectively.

In general terms the Reynolds number can be considered a ratio of the forces acting on the fluid, i.e.,

$$\frac{\text{Momentum forces}}{\text{Viscous forces}}$$

It has been found that for values of the Reynolds number less than 2000 the flow regime is usually laminar. Turbulent conditions are usually encountered when the Reynolds number is greater than 4000. The transition from laminar to turbulent flow occurs gradually between these two values of Reynolds number. The point when it can be stated with confidence that the transition is complete will depend on the pipe geometry and the roughness of the pipe surface in contact with the flowing fluid. Exceptions to the establishment of turbulent flow at a Reynolds number of 4000 can occur if the fluid velocity in a given pipe is very gradually increased, say by a gradual reduction of the flow diameter of an exceptionally smooth surfaced tube. Under these conditions the streamline flow could be regarded as unstable, and a small disturbance in the flow conditions makes the system revert rapidly to turbulent flow.

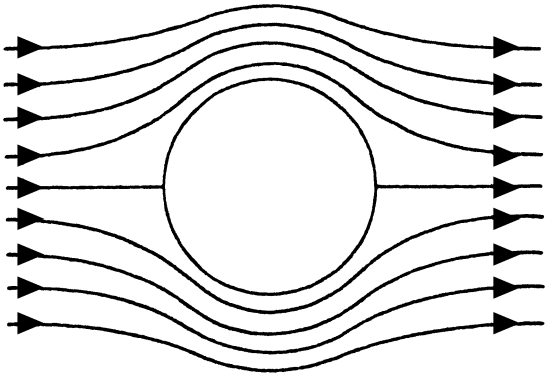

Fig. 2 Flow around a submerged object.

In pipe flow, the velocity profiles along a diameter for laminar and turbulent conditions are quite different as represented in Figs. 3 and 4, respectively. The profile can be seen to be much "flatter" for turbulent compared with laminar flow. It has to be stressed, however, that even under high turbulent conditions the fluid in direct contact with a confining surface is at rest, owing to the viscous drag on the fluid, and the adjacent layers of fluid will also be retarded in their flow. The velocity of the fluid in the neighborhood of a flat solid surface will change in a direction at right angles to the surface, increasing with distance from the solid surface. Under general turbulent conditions, eventually as the distance into the bulk of the fluid is increased, the fluid as a whole will be turbulent, but there remains a slow moving layer adjacent to the surface. Usually, this fluid layer is referred to as the "viscous sublayer." Because the mixing under laminar conditions at right angles to the flow direction is due to molecular diffusion alone, the viscous sublayer acts as a resistance to both mass and heat transfer. It will be appreciated that the magnitude of the resistance will depend on the thickness of the slow moving viscous sublayer, which itself is dependent on the flow conditions as defined by the Reynolds number. In general, the higher the Reynolds number of the bulk fluid, the thinner the viscous sublayer. Turbulent conditions are to be preferred where transport processes are required to be as effective as possible, i.e., increasing fluid velocity for a given pipe diameter and given fluid, although the choice of velocity has to be made in the light of the desired pressure drop through the equipment in any particular application.

The conditions referred to in the previous paragraph, however, are not instantly attained. As a fluid with a uniform velocity encounters a solid surface, a velocity gradient is established at right angles to the surface, owing to the influence of the viscous forces. The conditions referred to in the previous paragraph, however, are not immediately attained but a rapid change in velocity occurs near the surface, as illustrated in Fig. 5.

As the fluid continues its flow across the surface, the distance at right angles from the surface to where

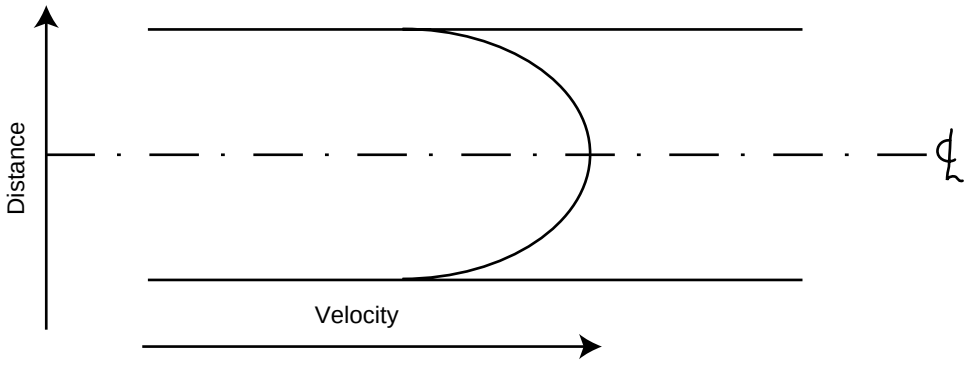

Fig. 3 Velocity profile of a fluid flowing in a tube—streamline flow.

the fluid can be considered to have reached the fully developed flow velocity v_f gradually increases. The locus of points where this occurs can be considered to divide the flow into two regions. In Fig. 5 the upper region can be considered to flow near or at the flow velocity v_f. The lower region where the velocity changes from 0 at the solid surface to the fully developed velocity v_f is called the "boundary layer." The mainstream velocity is approached asymptotically, and so it could be argued that the boundary layer has no exact limit. It can be assumed, however, that after a relatively short distance of flow across the surface, at the outer limit of the boundary layer, the fluid velocity has attained the stable flow velocity v_f. For this reason in most engineering calculations, for instance, the design of a tubular heat exchanger, the establishment of the boundary layer is not taken into account.

FLOW OF FLUIDS IN RELATION TO APPLIED STRESS

The viscosity of many fluids, μ, may be defined in terms of the shear stress τ and the rate of shear (dv/dy) where y is the distance from the surface. The relationship may be understood by reference to Fig. 6.

$$\tau = \mu \frac{dv}{dy} \tag{2}$$

$$\mu = \tau/(dv/dy) \tag{3}$$

For many fluids encountered in the process industries, the shear rate increases linearly with the shear stress over a wide range of shear and shear rate, and the viscosity is constant, as shown in Fig. 6, provided that there is no variation in temperature and pressure. Such fluids are usually referred to as "Newtonian fluids."

There are some industrial fluids that do not display the simple relationship between shear stress and rate of shear, that are classified as "non-Newtonian," and for which viscosity is not constant. Two examples are given in Table 1.

For some substances their viscosities may show time dependent changes. It may decrease with time under shear but return to its original value when the shear stress is removed. Such material is termed thixotropic. "Negative thixotropic" refers to substances that display the opposite behavior. Other fluids are solid-like and will not flow till some critical yield stress is exceeded. Such fluids are known as "viscoplastic."

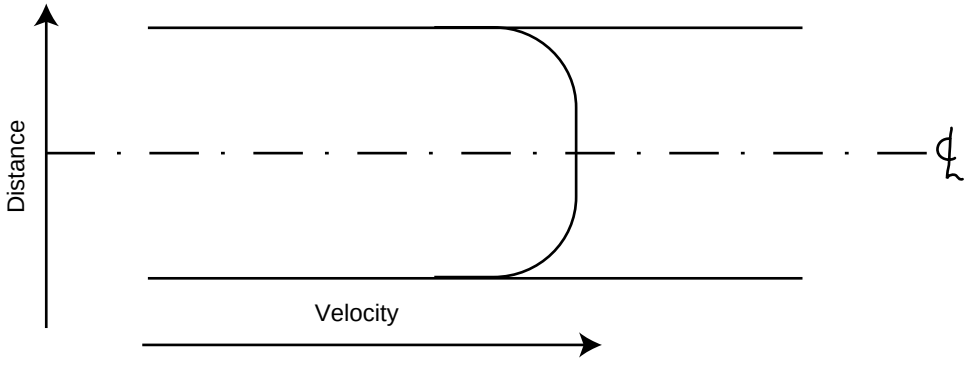

Fig. 4 Velocity profile of a fluid flowing in a tube—turbulent flow.

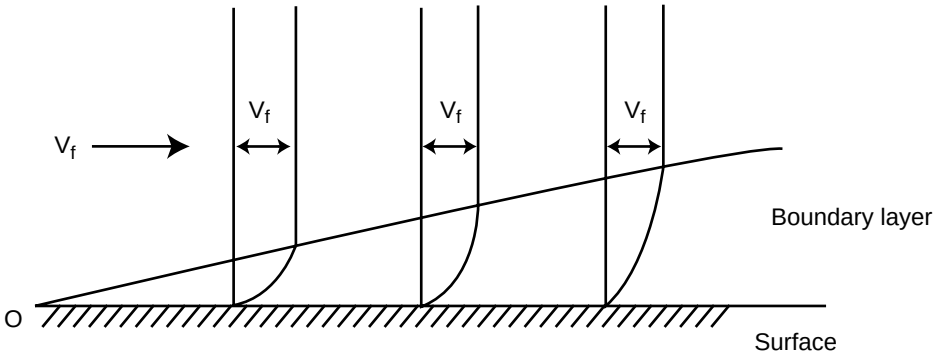

Fig. 5 The development of a boundary layer.

Other fluids display properties of elasticity and they are termed ''viscoelastic.''

The shearing characteristics of non-Newtonian fluids are illustrated in Fig. 7. Curves A and B represent viscoelastic behavior. Curve C illustrates the behavior if the fluid ''thins'' with increasing shear, generally referred to as ''shear thinning'' or ''pseudoplasticity.'' The opposite effect of ''shear thickening'' or ''dilatancy'' is shown as curve D.

PRESSURE LOSS THROUGH TUBES

As mentioned earlier, to estimate the energy requirements associated with a particular process plant in which fluids are moving, it is necessary to be able to make an estimate of the pressure loss through the equipment and in particular, through the linking pipe work. Research, in many respects as significant as that of Reynolds, was carried out by Stanton and Pannell early in the last century.[2] The results of the work provided the opportunity to make an estimate of the pressure loss due to friction, in a fluid flowing through a pipe. It involves the use of a dimensionless number plotted as a function of Reynolds number. The dimensionless number is termed the ''friction factor'' (Φ) defined as

$$\frac{R}{\rho v^2}$$

where R is the shear stress at the pipe wall.

A plot of $R/\rho v^2$ against $Dv\rho/\mu$ is presented in Fig. 8. There are two major regions on the diagram corresponding to laminar ($Re < 2000$) and turbulent ($Re > 4000$) flow conditions, with a transition region ($2000 < Re < 4000$) linking the two. It is apparent from Fig. 8 that in the turbulent region the surface roughness, as would be expected, affects the magnitude of the friction factor. In Fig. 8 it is taken into account by the dimensionless ratio e/D, where e is the height of the roughness and D the tube internal diameter. At very high Reynolds numbers the friction factor is independent of Reynolds number.

Making a force balance on the fluid flowing in a pipe of diameter D over a length L yields

$$\Delta P\left[\frac{\pi D^2}{4}\right] = R\pi DL \tag{4}$$

where ΔP is the loss of pressure. That is,

$$\Delta P = \frac{4RL}{D} \tag{5}$$

$$= \frac{4R}{\rho v^2}\frac{L}{D}\rho v^2 \tag{6}$$

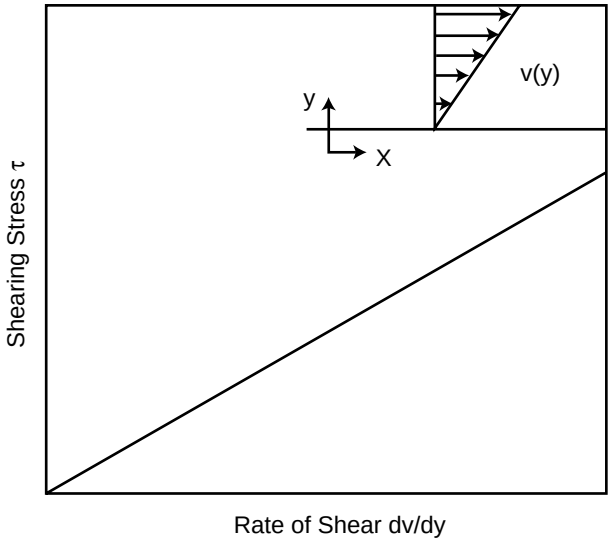

Fig. 6 The relationship between shearing stress τ and rate of shear (velocity gradient).

Table 1 Fluid viscosity change with increasing shear rate

Name	Viscosity
Pseudoplastic	Decreases
Dilatant	Increases

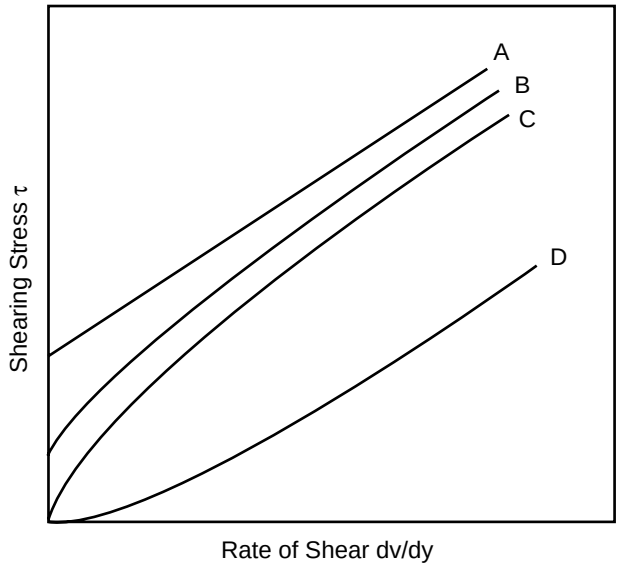

Fig. 7 The shearing characteristics of non-Newtonian fluids.

Assigning a value to e/D and calculating the Reynolds number, it is possible to obtain the value of $R/\rho v^2$ for inclusion in Eq. (6) with the known values of D, L, v, and the density of the fluid, ρ.

The pressure loss in terms of the height of the fluid (h_f) necessary to drive the fluid through the system at the stated velocity is given by:

$$h_f = \frac{\Delta P}{\rho g} = \frac{4R}{\rho v^2}\frac{L}{D}\frac{\rho v^2}{\rho g} \tag{7}$$

$$= 8\left[\frac{R}{\rho v^2}\right]\left[\frac{L}{D}\right]\left[\frac{v^2}{2g}\right] \tag{8}$$

The Bernoulli Equation

To calculate the pressure loss for a fluid flowing through a pipe work system, it is necessary to make an energy balance between the two points in the system between which pressure loss has to be determined. Neglecting forms of energy, such as magnetic or electrical energy, that are not generally associated with the flow of fluids, the energy contained in the system has three components:

1. Kinetic energy by virtue of the velocity of the fluid.
2. Potential energy due to the fluid being in the earth's gravitational field, i.e., the work that has to be done, against gravity, from some arbitrary datum (usually sea level) to transport it to its present position.

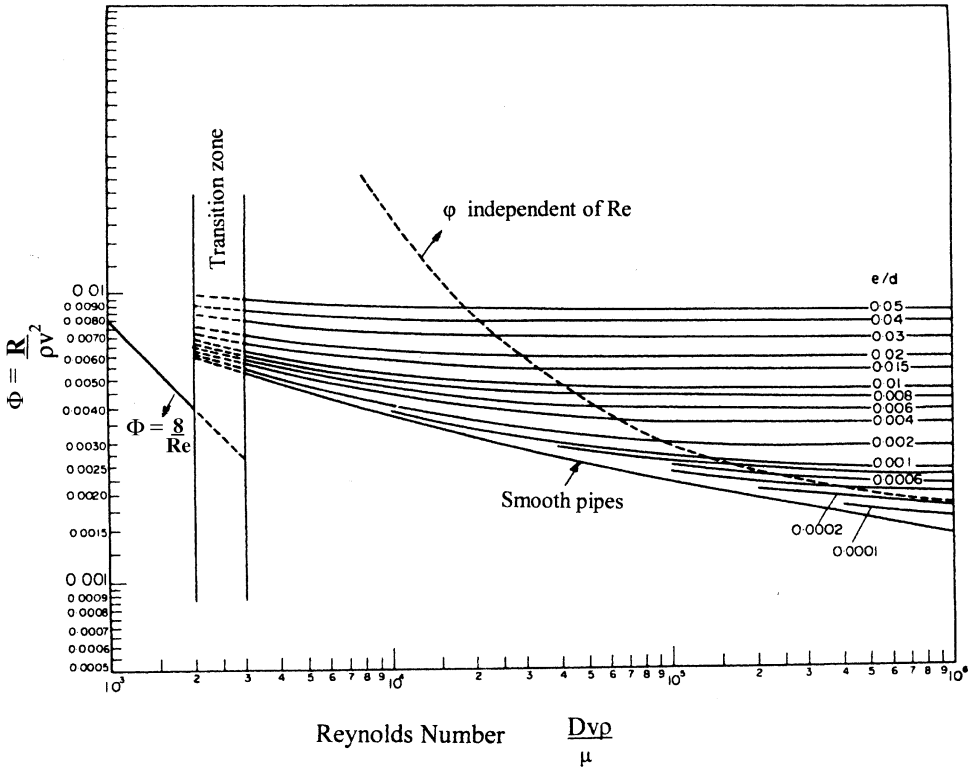

Fig. 8 Friction in pipes related to Reynolds number. (From Ref.[8].)

3. Pressure energy, i.e., the work done to bring the fluid into the system without change in volume.

In the light of the conservation of energy concept, the Bernoulli equation states that the sum of these three energies is constant. Generally, the three terms are referred to as "heads" having the dimensions of length.

$$\frac{PV}{g} + \frac{v^2}{2g} + Z = \text{a constant} \tag{9}$$

where P is the pressure, V is the volume of unit mass, v is the velocity, and Z is the height above the datum.

Under ideal conditions, as illustrated in Fig. 9, the Bernoulli equation written between points 1 and 2 yields

$$\frac{P_1V}{g} + \frac{v_1^2}{2g} + Z_1 = \frac{P_2V}{g} + \frac{v_2^2}{2g} + Z_2 \tag{10}$$

Under real conditions, however, rather than the idealized conditions of the above Eq. (10), energy is lost as a result of friction and energy could be added, say, by a pump. The energy balance then becomes:

$$\frac{P_1V}{g} + \frac{v_1^2}{2g} + Z_1 + W = \frac{P_2V}{g} + \frac{v_2^2}{2g} + Z_2 + F \tag{11}$$

where W represents the work done on the system, say, by the pump and F represents the frictional losses.

From this equation, knowing the frictional losses by calculation using Eq. (8) and the other terms, it is possible to estimate the energy required to transport the fluid from points 1 and 2 on a continuous basis. It should be noted that the term W has the units of length. To calculate the power required, W has to be multiplied by the flow of fluid and the acceleration due to gravity, g.

Pressure Loss Through Fittings

It is seldom that a fluid flows only along a straight length of pipe. The pipe run may involve many changes in direction and velocity resulting from changes in flow area, due to the effects of the presence of fittings that could include such items as bends, valves, tee junctions, expansion and contraction joints. As a result, a higher pressure loss than that associated with the straight length of pipe is encountered. In general, for turbulent flow, the effect of fittings is taken into account in terms of equivalent lengths of straight pipe that would give the same pressure loss as the fitting, under the same conditions. It is possible then in a practical example to add together all the equivalent lengths of pipe for the fittings and the straight runs of pipe, so that an estimate of the total pressure drop along the entire length of pipe between two chosen points may be made. Because the effect is related to pipe diameter, it is usual to quote the equivalent length in terms of the number of pipe diameters. To provide easy access to the Bernoulli equation it is possible as an alternative to quote the energy loss in terms of velocity heads. Table 2 is an adapted version of a table provided by Coulson and Richardson.[3]

Measurement of Flow Through Pipes

The loss of pressure through constrictions (where in addition to the loss of energy due to friction, there is conversion of pressure energy into kinetic energy) provides a method of measuring flow rate. Special devices have been used to measure flow. These include venturi meter, orifice plate, and nozzle meter. The pressure loss through the device may be measured by

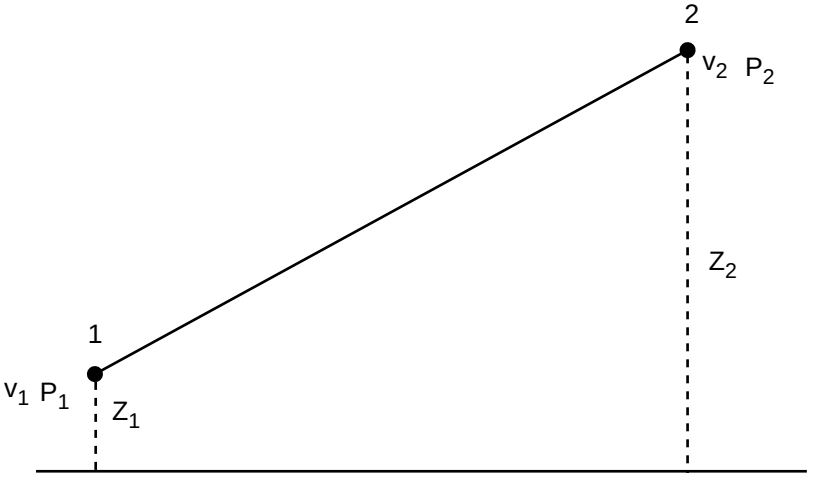

Fig. 9 Energy balance in a fluid flowing between two points.

Table 2 Friction losses in pipe fittings

Fitting	Equivalent length (number of pipe diameters)	Number of velocity heads
45° elbow	15	0.3
90° bend (standard radius)	30–40	0.6–0.8
90° bend (square)	60	1.2
Entry from leg of tee	60	1.2
Entry into leg of tee	90	1.8
Unions and pipe couplings	Negligible	Negligible
Fully open globe valve	60–300	1.2–6.0
Fully open gate valve	7	0.15

(From Ref.[3].)

a simple manometer, which is common in laboratories, or by a more sophisticated electronic technique used on process plant. Other devices are available and the choice will depend very much on the application and the cost.

Noncircular Pipes

In some process plants, fluid flows through noncircular pipes or ducts. For example air in air-conditioning systems is often made to flow through ducting of square cross section. A simple heat exchanger may comprise a double-walled pipe, with one fluid flowing through the annulus. In calculations involving these cross sections, the hydraulic mean pipe diameter may be used instead of the pipe diameter, in formulae normally associated with pipe flow. For instance, the Reynolds number would be $D_m v\rho/\mu$, where the hydraulic mean diameter D_m is defined as:

$$D_m = \frac{4 \times \text{cross-sectional flow area}}{\text{wetted perimeter}} \tag{12}$$

For a duct of rectangular cross section $l_1 \times l_2$

$$D_m = \frac{4l_1l_2}{2(l_1 + l_2)} = \frac{2l_1l_2}{(l_1 + l_2)} \tag{13}$$

For an annular section where D_o is the outer diameter of the inner pipe and D_i is the inner diameter of the outer pipe

$$D_m = \frac{4\left(\frac{\pi D_i^2}{4}\right) - \left(\frac{\pi D_o^2}{4}\right)}{\pi D_i + \pi D_o} \tag{14}$$

$$= \frac{(D_i^2 - D_o^2)}{(D_i + D_o)} \tag{15}$$

$$= \frac{(D_i - D_o)(D_i + D_o)}{(D_i + D_o)} \tag{16}$$

$$= D_i - D_o \tag{17}$$

Open Channels

Liquid flow in open channels is not common in a process plant, because of health and safety considerations, apart from the potential risk of contamination of the liquid itself. Open channels, however, are sometimes to be found in cooling water systems where large volumes of water are involved. Nevertheless, for the sake of completeness a brief treatment of the subject is included in this entry.

As with noncircular ducts the hydraulic mean diameter is employed in formulae that involve diameter. If a channel has a height of a and a width b, the flow area of the channel is ab. In the calculation of the wetted perimeter the free surface is not included so that the wetted perimeter is $2a + b$, and the hydraulic mean diameter

$$D_m = \frac{4ab}{(2a + b)} \tag{18}$$

In a simple system where the open channel is inclined, the difference in the head between two points will equal the friction losses for a uniform cross section between the two points, which will also dictate the flow rate.

TWO-PHASE FLOW

Two-phase flow concerns the interacting flow of two phases involving mixtures of solid/liquid, solid/gas, gas/liquid. The interface between the phases is affected by the motion of the phases. In general, two-phase flow consisting of liquid/gas (or vapor) can be considered to be the most common in the processing industries,

although the behavior of droplets in a gas stream has similarities to that of solid particles, except that droplets are susceptible to deformation under the influence of the operating conditions. Vapor/liquid two-phase flow is fundamental to the following industrial operations:

Boilers
Nuclear reactors
Flash evaporators
Condensers
Distillation columns
Absorption columns

The patterns, or regimes, that can be identified when gas (or vapor) and liquid flow together in a pipe will depend on not only the ratio of gas to liquid but also whether the flow is horizontal or vertical. It is to be anticipated that under vertical flow conditions, there will be dispersion of the gas within the liquid, the pattern dependent on the ratio of gas/liquid and the flow conditions. It will be appreciated that under horizontal flow conditions, there is a possibility of separation between the phases, with a tendency for the gas to flow above the flowing liquid. Again, the resulting pattern will depend on the ratio of the two phases in the mixture and the flow conditions.

Diagrams of flow patterns have been presented by Hewitt and Hall Taylor[4], and these are reproduced as Figs. 10 and 11.[4] These authors also describe the flow patterns. In consideration of Fig. 10 for vertical flow:

Bubble flow (sometimes referred to as bubbly flow): The gas phase is distributed as discrete bubbles throughout a continuous phase of liquid.

Slug flow (sometimes referred to as plug flow): Much of the gas phase is distributed in large bubbles that virtually have the same cross section as the pipe or channel in which they occur. The liquid between the large bubbles may contain a dispersion of smaller bubbles.

Churn flow: If the velocity of a two-phase mixture in slug flow is increased, the large slugs of gas will tend to become unstable, with the possibility of breakup. The result is the destruction of the slug flow pattern, with an oscillating characteristic being established.

Annular flow: The liquid phase flows along the pipe or channel walls, as a more or less continuous stream, with the gas phase acting as a "core." The gas phase may carry droplets of liquid that may be generated by the breakup of waves on the surface of the liquid film. Some liquid drops may fall back into the liquid phase, so that there may be a continuous liquid interchange between the continuous liquid phase and the gas phase. Furthermore, the liquid may contain entrained gas bubbles. The pattern detail will depend very strongly on the flow conditions in the system. Hewitt and Hall Taylor describe a subpattern of annu-

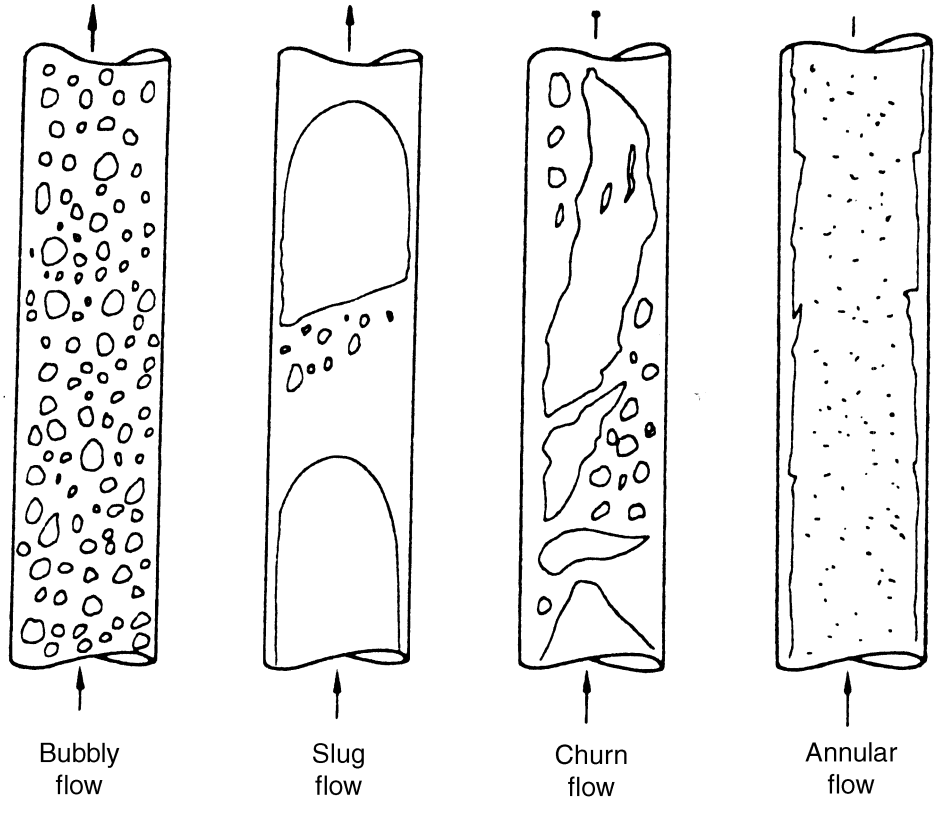

Fig. 10 Flow patterns in vertical two-phase flow. (From Ref.[4].)

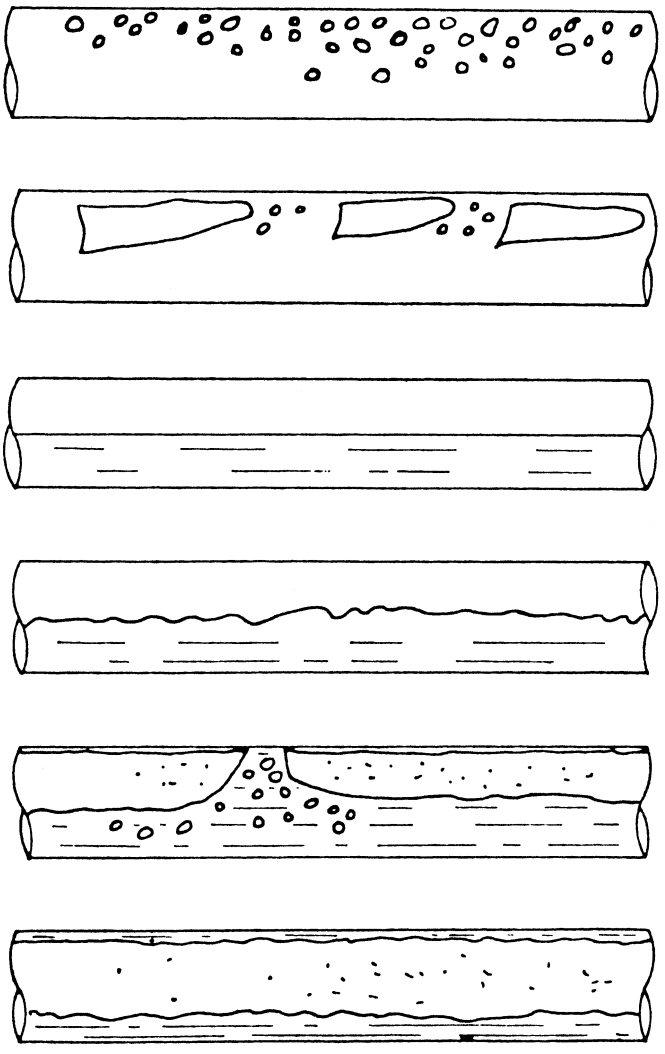

Fig. 11 Flow patterns in horizontal two-phase flow. (From Ref.[4].)

lar flow, which they call "wispy annular" flow.[4] In this pattern the entrained phase flows in large "lumps" or "wisps." The size of these lumps is gradually reduced if the gas velocity is increased.

Fig. 10 illustrates upward vertical flow through channels. It is possible of course that vertical downward flow may be encountered. It would be anticipated that the regimes would be modified under these conditions.

Fig. 11 defines flow patterns for horizontal (and inclined) flow:

Bubbly flow: Similar to that experienced in vertical flow, but with a tendency for the bubbles to accumulate in the upper part of the flow channel. It is possible for some of the bubbles to collide and form larger bubbles.

Plug flow: Again, similar to the pattern for vertical flow, but with the liquid film at the bottom of the channel tending to be thicker than at the top of the channel.

Stratified flow: As the name suggests, there is complete separation between the two phases: the liquid being in the lower part of the channel.

Wavy flow: With increased velocity in stratified flow, waves appear on the surface of the liquid layer. It is possible for droplets to be torn from the tops of the waves to be carried forward in the gas phase. Some droplets may coalesce and fall back into the liquid layer.

Slug flow: At higher velocities, the waves generated are so large that their crests can touch the upper surface of the channel, and it is possible that this surface will become wetted by the liquid under these conditions.

Annular flow: At still higher velocities the liquid is dispersed to the channel walls, where it forms a film that is thicker at the bottom of the channel. The gas flows as a "core."

Flow in inclined channels is not common, but it may be stated that the flow patterns of two-phase flow systems in inclined channels fall between those for horizontal and vertical flow. The detail of the pattern depends on the angle of inclination of the tube.

The discussion so far suggests that the flow pattern in two-phase flow, as well as being related to the physical properties of the phases, will be strongly

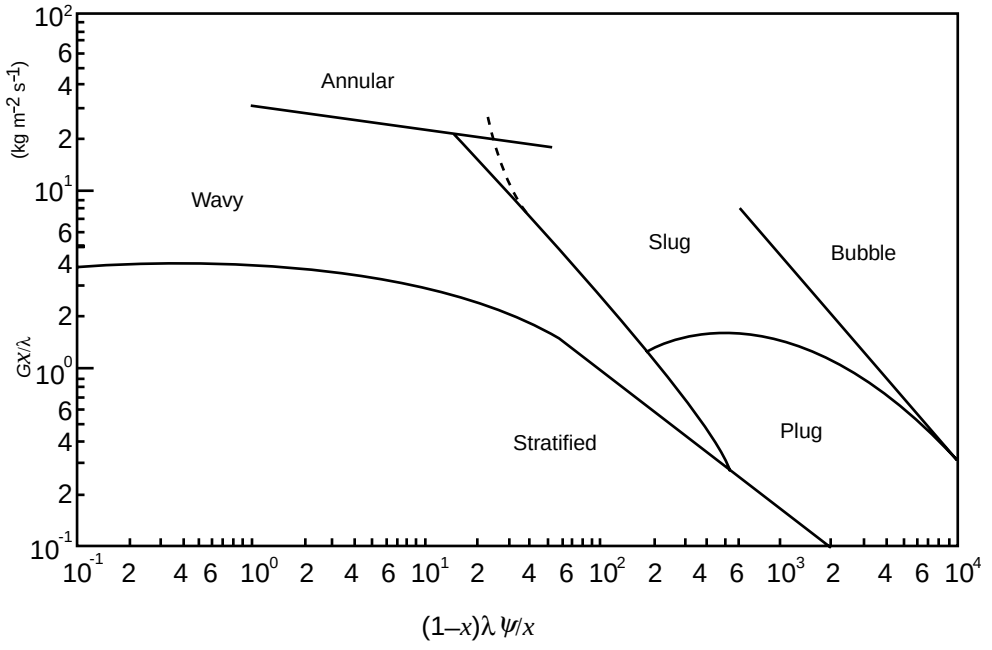

Fig. 12 Flow pattern map for horizontal two-phase flow. (From Ref.[6].)

influenced by the amounts of each of the phases present, and the velocity of the mixture through the channel. This has led to the use of empirical parameters to provide a ''chart'' for the determination of where the different flow patterns occur.

One of the earliest flow diagrams for horizontal flow was devised by Baker.[5] An example is given in Fig. 12 based on the work of Schicht from Butterworth and Hewitt.[6,7] The vertical axis is Gx/λ and the horizontal axis is $(1 - x)\lambda\psi/x$, where G is the total mass flow rate and x is the ''quality,'' i.e., the gas or vapor phase mass flow fraction:

$$\lambda = \left[\left[\frac{\rho_G}{\rho_A}\right]\left[\frac{\rho_L}{\rho_W}\right]\right]^{0.5} \tag{19}$$

$$\psi = \left[\frac{\sigma_W}{\sigma}\right]\left[\left[\frac{\mu_L}{\mu_W}\right]\left[\frac{\rho_W}{\rho_L}\right]^2\right]^{1/3} \tag{20}$$

where ρ is the density, σ is the surface tension, subscripts G and L refer to gas and liquid, respectively, and subscripts A and W refer to the corresponding values for air and water at atmospheric pressure.

A similar chart for vertical flow is given in Fig. 13, although the axes are simplified: the vertical and horizontal axes are $\rho_G v^2$ and $\rho_L v^2$, respectively, and ν_G and v_L are the superficial gas and liquid velocities, respectively.

Two-Phase Flow Pressure Gradients

The method that is usually adopted for the calculation of pressure drop in two-phase flow systems is based on empirical correlations, and involves putting parameters ϕ_G and $\phi_L$against the variable x as defined by the following equations:[4,9]

$$\varphi_{GorL} = \left[\frac{dp_F/dz}{dp_F/dz_{GorL}}\right]^{1/2} \tag{21}$$

and

$$x = \left[\frac{[dp_F/dz]_L}{[dp_F/dz]_G}\right]^{1/2} \tag{22}$$

where $[dp_F/dz]_G$ and $[dp_F/dz]_L$are the pressure gradients for the gas and the liquid phases, respectively, flowing alone in single-phase mode in the channel.

Four sets of data are obtained depending on whether the phases would be flowing under laminar or turbulent conditions.

Space limitations prevent an extensive review and discussion of two-phase flow but the reader is referred to Butterworth and Hewitt and Hewitt and Hall Taylor for further reading.[4,7]

SPECIALIST FLUID FLOW

The following provides a list of the operations that involve flow of fluids and require specialized individual

Jets, nozzles, and sprays
Plumes

CONCLUSIONS

The flow of fluids is fundamental to many processes, and a thorough knowledge of the behavior of fluids under flowing conditions is vital for the safe and economic operation of a process plant. Furthermore, to make a reliable plant design and an accurate assessment of the energy requirements that will be needed to move fluids around the plant when it is built, an engineer relies on the accurate prediction of fluid behavior in the various items of equipment that constitute the plant. The discussion in this section is aimed at providing an indication of the principles of fluid flow. The limitations of space, however, have of necessity curtailed that discussion to the fundamentals. The reader is directed to the many books that have been published on the topic; some of them are referred to in the text.

Fluid Transport in Porous Media

Michael C. Brooks
U.S. Environmental Protection Agency, Kerr Research Center, Ada, Oklahoma, U.S.A.

INTRODUCTION

Fluid transport through porous media is a relevant topic to many scientific and engineering fields. Soil scientists, civil engineers, hydrologists, and hydrogeologists are concerned with the transport of water, gases, and non-aqueous phase liquid (NAPL) contaminants through porous earth materials; petroleum engineers are concerned with the flow of water, gas, and oil through production reservoirs; chemical engineers use principles of fluid transport through porous media in the design and operation of chemical reactors, and material engineers design and manufacture a variety of porous materials. The topic in general requires an understanding of concepts from a number of disciplines, such as physics, chemistry, engineering, fluid mechanics, microbiology, and geology. Albeit a complex topic, the following four questions can provide a conceptual framework within which to understand the fundamentally important components:

- Which phases are present?
- How many phases are in motion?
- Do chemical species of interest partition between phases?
- Are the species of interest produced or consumed by reactive processes?

The first question is addressed in the second section through a discussion of porous media characteristics and the distribution of fluids in porous media. Fluid motion in porous media is discussed in the third section, and partitioning and reactive processes are discussed in the fourth section.

There is a wealth of literature available on transport in porous media; consequently, the goal herein is to provide the reader with a general overview of important topics relevant to the framework provided by the four general questions above. To limit the scope of this work, the topics herein are limited to those associated with isothermal flow in rigid porous media with unchanging pore structure.

POROUS MEDIA

A porous medium is simply a solid material (i.e., solid phase) through which a significant void volume extends. Typically, the term is used when the void size in the media is large relative to the fluid or gas molecules contained therein, yet small enough such that capillary forces are significant.[1] Examples include ceramic coasters on which drinking glasses are placed, activated carbon for water treatment, and aquifers used to supply drinking water. Fig. 1 lists six fundamental properties used to characterize porous media. Because porous media are often composed of solid particles, the particle-size distribution is one such fundamental characteristic of porous media, and other properties are often correlated to the particle size distribution. Another important characteristic of porous media is its porosity (η), which is defined as:

$$\eta = \frac{V_V}{V_S} \tag{1}$$

where V_V is the volume of voids [L^3] and V_S is the total sample volume [L^3]. For transport to occur, the voids must be interconnected. The term effective porosity (η_e) is used to describe the interconnected pore space, and is defined as the volume of interconnected pore volume divided by the total sample volume. The total sample volume is not arbitrary and must be of sufficient size to meet the requirements of a representative elementary volume (REV). This ensures the sample volume is large enough for a value representative of the bulk porous media properties, yet small enough for mathematical treatment on a continuum basis. Fig. 2 illustrates porosity as a function of sample volume to illustrate the concept. The REV concept is used often in the study of porous media because it is impractical to fully describe the actual pore space over most domain sizes of interest.

The voids within the porous media are occupied by gas and liquid. The terms used to describe the phase distribution in the pore space include saturation and fluid content. The saturation (S_α) is defined as the volume occupied by phase α divided by the pore volume, while the fluid content (θ_α) is defined as the volume of fluid α divided by the sample volume. The sum of all phase saturations is equal to 1, and the sum of all fluid contents is equal to the porosity.

The pore-size distribution of porous media is inherently important, as it is directly related to such characteristics as fluid flow and storage, and multiphase fluid distribution and displacement. The methods used to measure the pore-size distribution include image

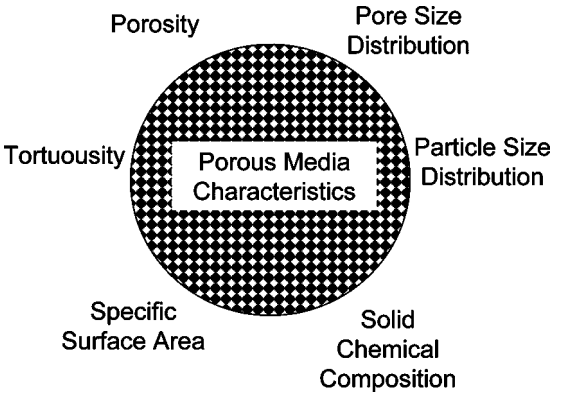

Fig. 1 Characteristic properties of porous media.

analysis techniques, geophysical techniques, and fluid displacement techniques.[2] The pore-size distribution directly affects the capillary pressure–saturation relationship. Capillary pressure–saturation curves can be measured by mercury intrusion or water drainage (or retention) methods. Both methods are based on the measurement of displaced fluid volume as a function of capillary pressure, and differ in that the former measurement is based on the intrusion of a nonwetting fluid (mercury) into the media, and the latter measurement is based on the drainage of a wetting fluid (typically water) from the media.

The terms wetting and nonwetting refer to the relative affinity of a fluid to the porous media, and are formally defined based on the contact angle; wetting fluids have contact angles less than 90° and nonwetting fluids have contact angles greater than 90° (Fig. 3). The capillary pressure is the pressure difference across the nonwetting–wetting fluid interface, and is defined by the Young–Laplace equation of capillarity:

$$P_c = P_{nw} - P_w = \sigma\left(\frac{1}{r_1} + \frac{1}{r_2}\right) \quad (2)$$

where P_c is capillary pressure [$ML^{-1}T^{-2}$], P_{nw} is the nonwetting fluid pressure [$ML^{-1}T^{-2}$], P_w is the wetting fluid pressure [$ML^{-1}T^{-2}$], σ is interfacial tension [MT^{-2}], and r_1[L] and r_2 [L] are the radii of curvature for the wetting–nonwetting interface.[3] Considering a pore space filled with a wetting fluid, it will remain saturated with the wetting fluid until changes in P_{nw} or P_w result in a capillary pressure that exceeds the pore space entry pressure (i.e., the capillary pressure based on interfacial tension and pore space geometry). At that point, the wetting fluid will be displaced by the nonwetting fluid. The inverse relationship between capillary pressure and radii of curvature in Eq. (2) indicates that the nonwetting phase will displace the wetting phase in the larger pores first.

Several analytical equations have been proposed to describe capillary pressure–saturation relationships in porous media, and Fig. 4 presents one of the equations commonly used, the van Genuchten model.[4] The water release curve shown is based on the data presented by Schroth et al. for 20/30 and 40/50 silica sand.[5] The saturation–capillary pressure curve can be viewed as a cumulative distribution of pore sizes,

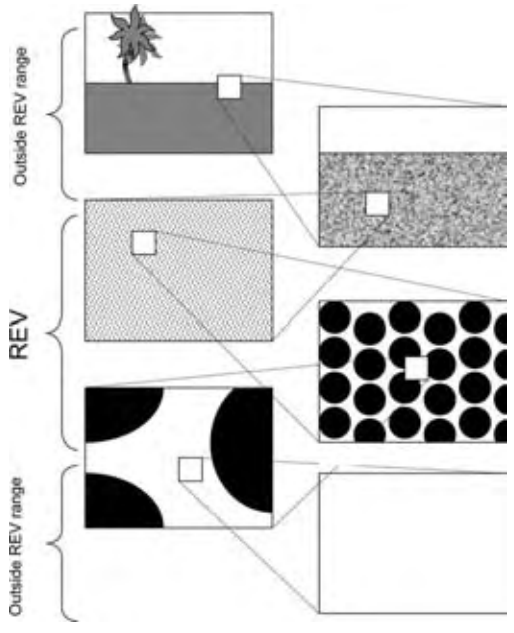

Fig. 2 Porosity as a function of sample volume; an illustration of the REV concept. If the sample volume (represented by the squares) becomes too large or too small, the porosity is no longer representative of the bulk porous media.

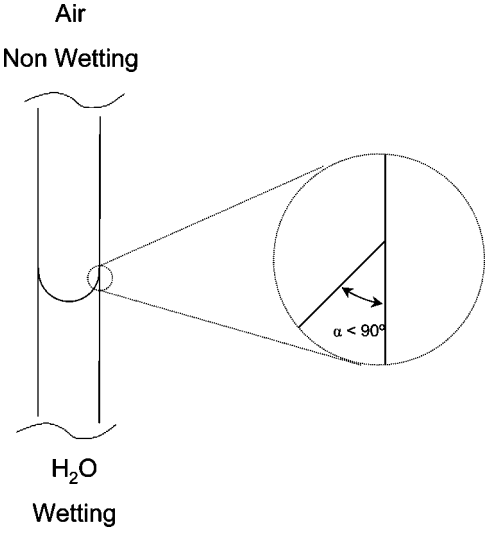

Fig. 3 Wetting vs. nonwetting fluids in porous media, illustrated by analogy to fluids in a capillary tube. Wetting fluids have contact angles less than 90°, and nonwetting fluids have contact angles greater than 90°.

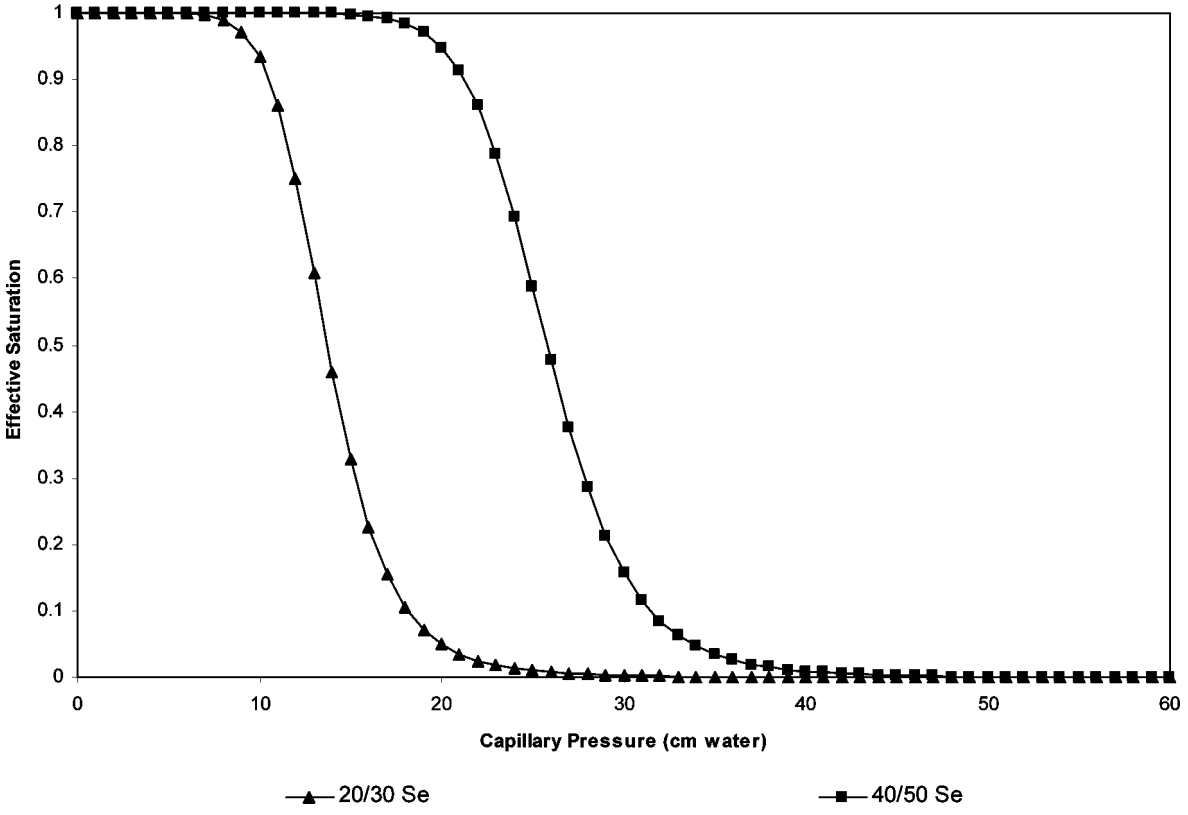

Fig. 4 Effective saturation (a normalized saturation value) as a function of capillary pressure, as described by the van Genuchten equation. The curves shown are based on data reported by Schroth et al. (From Refs.[4,5].)

and its derivative then represents the pore-size distribution.[6]

Other important characteristics of porous media include the specific surface area and the tortuosity factor. The specific surface area is defined as the surface area of the solid phase divided by the sample volume (and hence has units of L^{-1}), and is important to solid–fluid interactions (for example, this is an important parameter for activated carbon characterization). The tortuosity factor τ in porous media is defined as:

$$\tau = \left(\frac{l^*}{l}\right)^2 \tag{3}$$

where l^* [L] is the tortuous path length between two points traveled by a fluid particle, and l [L] is the straight line distance between the points.[2] Because of the tortuous path through porous media, τ is greater than unity. Finally, the chemical composition of the solid phase may also be important in fluid transport through porous media, and may affect such factors as the fluid's wetting nature (i.e., whether it acts as a wetting or nonwetting fluid), sorption of chemical species in the fluids, and reactions with chemical species in the fluids.

FLUID MOTION IN POROUS MEDIA

There are two transport processes associated with fluid motion through porous media: advection and dispersion. The former can be attributed to the bulk motion of the fluid, and the latter can be attributed, in general, to variations in concentration and velocity.

Advection

One of the most common equations for fluid flow through porous media is Darcy's law, which states that fluid flux in porous media is linearly proportional to the hydraulic gradient:

$$\mathbf{q} = \frac{Q}{A} = -K\frac{\mathrm{d}h}{\mathrm{d}x} \tag{4}$$

where $\mathbf{q}$ is the Darcy flux (the bold format indicates a vector) [LT^{-1}], Q is the volumetric flow rate [L^3T^{-1}], K is the hydraulic conductivity [LT^{-1}], A is the cross-sectional area [L^2], h is the hydraulic head [L], and x is the linear flow distance [L]. Darcy's law is generally valid when the Reynolds number (defined as $qd\rho/\mu$ where d is a characteristic length scale of the porous media [L], ρ is the fluid density [ML^{-3}], and μ is the

viscosity [$ML^{-1}T^{-1}$]) is less than 10.[7] The hydraulic head h is the sum of gravitational and pressure potentials, as velocity potentials are negligible under conditions applicable for Darcy's law:

$$h = z + \frac{P}{g\rho} \tag{5}$$

where z is height above a datum [L], P is pressure [$ML^{-1}T^{-2}$], ρ is density [ML^{-3}], and g is the gravitation constant [LT^{-2}]. The hydraulic conductivity K is a function of both the porous media and the fluid moving through it. The term hydraulic conductivity is used when the fluid is water. By convention, positive flow is in the direction of the negative hydraulic gradient, and hence a negative is included on the right-hand side of the equation.[4] Because a portion of the cross-sectional area A is occupied by solid material (i.e., $\{1 - \eta\}^* A$ is occupied by solid material), the fluid velocity through the pores is higher than the Darcy flux $\mathbf{q}$. This velocity is called the seepage velocity or pore water velocity, v [LT^{-1}], and is defined as $\mathbf{q}/\eta$. Although it was originally derived from an empirical basis, it has been shown that Darcy's law can be derived from momentum conservation principles, and is a special case of the Stokes equation when inertial effects can be neglected, e.g., Refs.[8,9]. Under these constraints, it is applicable to homogenous laminar liquid flow; within a rigid, immobile, and homogenous solid matrix, averaged over a sample volume of sufficient size such that viscous forces can be treated as a body force. A more general form of Darcy's law is as follows:

$$\mathbf{q} = -\frac{k k_r \rho g}{\mu} \frac{\partial \phi}{\partial x} \tag{6}$$

where k is the intrinsic permeability [L^2], k_r is the relative permeability [dimensionless], and ϕ is the potential.[10] In cases where density is pressure dependent, as possibly in gas flow, the hydraulic head is replaced by the more general potential term ϕ, given by:

$$\phi = z + \frac{1}{g} \int_{P_0}^{P} \frac{dp}{\rho(P)} \tag{7}$$

where P is pressure [$ML^{-1}T^{-2}$], P_0 is a reference pressure [$ML^{-1}T^{-2}$], and $\rho(p)$ is pressure-dependent density [ML^{-3}]. The conductivity K in Eq. (4) was replaced in Eq. (6) by separate terms for conductance as a function of the porous media (i.e., intrinsic permeability k) and fluid properties (i.e., ρ/μ). The relative permeability k_r accounts for variations in permeability when multiple fluids are present in the porous media and is a function of saturation. It is assumed in multiphase fluid applications of Darcy's law that the pressure distribution in one fluid does not impact the pressure distribution in the other phases.

It is worth mentioning that while Darcy's law is often used to describe gas and liquid flow under heterogenous conditions, its validity under extended conditions is not accepted without debate (e.g., Refs.[11,12]). Consideration should therefore be given to the particular conditions under investigation to ensure the applicability of Darcy's law to describe fluid flux.

Flow Equations

Darcy's law describes fluid flux in porous media, and must be combined with the continuity equation to develop flow equations. From the flow equations, the spatial and temporal pressure and velocity distributions can be estimated that are needed for the transport equations. The derivation of flow equations starts with the continuity equation, which states that the change in mass or volume within a control volume equals the net flux across the control volume boundary, plus sources and sinks within the control volume. For water within porous media, the continuity equation on a mass basis is:

$$\frac{\partial(S_W \rho_W \eta)}{\partial t} = -\nabla \cdot (\rho_W \mathbf{q}) \pm \phi \tag{8}$$

where S_W is the water saturation [dimensionless], ρ_W is the density of water [ML^{-3}], t is time [T], and ϕ is mass sources or sinks [MT^{-1}]. To solve Eq. (8), both sides must be expressed as a function of one variable, which is chosen to be pressure in most cases. To express the left-hand side of Eq. (8) in terms of pressure, the chain rule is used:

$$\frac{\partial(S_W \rho_W \eta)}{\partial t} = \left(\rho_W \eta \frac{\partial S_W}{\partial P} + S_W \eta \frac{\partial \rho_W}{\partial P} + S_W \rho_W \frac{\partial \eta}{\partial P}\right) \frac{\partial P}{\partial t} \tag{9}$$

It is from the three terms inside the parentheses on the right-hand side of Eq. (9) that the various storage terms used in flow equations are derived. Simplification of Eq. (9) depends on the nature of the particular flow problem (or an a priori assumption of flow behavior). For example, within confined aquifers (i.e., fully saturated), $\partial S_W/\partial P = 0$, and $S_W = 1$, and the terms within the parentheses on the right-hand side of Eq. (9) represent the specific storage of the confined aquifer.[7] Or, in partially saturated conditions, changes in water density and porosity are negligible compared to changes in saturation as a function of pressure,

and the latter represents the storage capacity for partially saturated systems. Darcy's law is used to express the right-hand side of Eq. (8) as a function of hydraulic head (and hence, pressure) to complete the flow equation.

As a final note to the flow equation, it should be evident that porous media properties can vary with location. In this case, the medium is considered heterogenous with respect to the property of interest (as opposed to homogenous media where the porous media property of interest does not vary with location). Likewise, the medium is characterized as either anisotropic or isotropic depending on whether the property is a function of direction or independent of direction, respectively. For example, if the vertical hydraulic conductivity is less than the horizontal conductivity (as is typically the case in aquifers because of sedimentation processes), the medium is considered to be anisotropic. Simplification of the flow equations will depend on the heterogeneity and the anisotropic nature of the porous media.

Multiphase Flow

Multiphase flow occurs when there are two immiscible fluids moving in the porous media, or when there are two miscible phases provided the viscosities are sufficiently different. As presented above, Darcy's law can be extended to describe multiphase flow. However, a wide range of flow patterns are possible because of the instabilities that may result as one fluid displaces another. For example, Tung and Dhir report observations of bubbly, slug, and annular two-phase flow patterns in two-phase flow experiments using air, water, and porous media composed of particles with diameters greater than or equal to 6 mm, while Lenormand, Touboul, and Zarcone reported viscous fingering (i.e., instabilities at the interface between the fluids) two-phase flow patterns using oil and air in micromodels with rectangular pores, 1 mm in depth by 0.1–0.6 mm in width.[13,14]

The major forces controlling multiphase flow patterns are capillary forces, viscous forces, and buoyancy forces.[15] These forces are often compared using three key dimensionless numbers: the ratio of the displaced to the invading fluid viscosities,

$$M = \frac{\mu_{\text{displaced}}}{\mu_{\text{invading}}} \tag{10}$$

the capillary number, which is the ratio of the viscous to the capillary forces,

$$Ca = \frac{(\nu\mu)_{\text{displaced}}}{\sigma} \tag{11}$$

and the Bond number, which is the ratio of buoyancy to capillary forces.

$$Bo = \frac{g\Delta\rho d^2}{\sigma} \tag{12}$$

For example, an unstable interface is observed when a more viscous fluid is displaced by a less viscous fluid in porous media (i.e., as M increases). However, capillary forces can offset the effects of viscosity differences, but as the speed of displacement increases (i.e., as Ca increases), instabilities are more likely. Likewise, as Bo increases, instabilities are more likely because of fluid density differences.

Dispersion

Advective transport alone does not account for all observed transport behavior. Transport observations in porous media exhibit characteristics indicative of a phenomenon beyond that described by advection only, such as breakthrough prior to and tailing after the advective front. This additional transport phenomenon is attributed to hydrodynamic dispersion, which is the sum of diffusive and mechanical dispersive processes. The former is attributed to concentration gradients, and the latter is attributed to variations in velocity at both micro and macro spatial scales.

Diffusive transport results from random molecular motion, which produces net molecular motion from areas of high concentration to low concentration. Fick's law states that diffusive flux is proportional to the concentration gradient, and for porous media applications, is expressed as:

$$\mathbf{J} = -\theta\tau D_{\text{mo}} \frac{\partial C}{\partial x} \tag{13}$$

where $\mathbf{J}$ is flux [$\text{ML}^{-2}\text{T}^{-1}$], D_{mo} is the molecular diffusion coefficient [L^2T^{-1}], C is concentration [ML^{-3}], and x is distance [L]. Under most conditions, the diffusion coefficient can be assumed to be a constant independent of concentration; however, there are conditions in which the diffusion coefficient is a function of concentration, as, for example, in the case of transport of high ionic strength solutions.[16] The diffusion coefficient for a chemical species in porous media is less than the diffusion coefficient for that species in an open fluid because of porous media tortuosity and partial saturation.[17] The diffusion coefficient in porous media is referred to as the effective diffusion coefficient (D_{eff}), and is taken as the product τD_{mo}.

In contrast to diffusion, mechanical dispersion is attributed to variations in advective velocities over a wide range of spatial scales. On the microscale, velocity

variations within pores result in a transport-mixing phenomenon; at an intermediate scale, velocity variations between pores result in a transport-mixing phenomenon; and on the macroscale, variations in porous media characteristics (such as permeability) result in a transport-mixing phenomenon. The magnitude of mechanical dispersion is consequently dependent on the scale of the system under consideration, and can vary by orders of magnitude between laboratory- and field-scale systems.

Mechanical dispersion is assumed to mathematically follow a Fickian diffusion formulation, i.e., the mechanical dispersive flux is assumed to be linearly proportional to the concentration gradient. As such the hydrodynamic dispersion is the sum of diffusive and mechanical dispersive terms, and the total dispersive flux is written as:

$$\mathbf{J}^{\mathrm{D}} = -\theta D_{\mathrm{H}} \frac{\partial C}{\partial x} \tag{14}$$

where D_{H} [$\mathrm{L}^2\mathrm{T}^{-1}$] is the sum of molecular diffusion and mechanical dispersion. A more detailed discussion of hydrodynamic dispersion can be found in Bear.[7]

Dispersive transport behavior in porous media is not always adequately described using the Fickian dispersive model as given by Eq. (14). Nonideal (i.e., non-Fickian) behavior can result from a number of factors, such as extensive heterogeneity in porous media properties and nonequilibrium partitioning processes. Other models have been proposed to relate the dispersive flux to the concentration field (e.g., Ref.[18]). Schumer et al. proposed an alternative formulation in which the dispersive flux is proportional to a fractional derivative of concentration:[19]

$$\mathbf{J}^{\mathrm{D}} = \eta_{\mathrm{e}} D_{\mathrm{H}} \Delta^n(C) \tag{15}$$

where $\Delta^n(C)$ is the nth ($0 < n \leq 1$) derivative of concentration, with n closer to 0 for a very heterogenous medium and equal to 1 for a homogenous medium. The resulting transport equation is reportedly better able to match transport behavior with large tailing phenomena (i.e., prolonged observations of concentration after the advective front).

Advective-Diffusion Equation

A complete derivation of the mass transport equation is presented in detail elsewhere, and an abbreviated derivation is outlined here for one-dimensional transport of a chemical species in porous media saturated with water (e.g., Ref. [9,20]). As with the flow equation, the transport equation begins with the mass conservation principle: the change in mass within a control volume is equal to the net mass flux across the boundary of the control volume, plus sources or sinks within the control volume. The total mass flux, $\mathbf{J}^{\mathrm{T}}$ [$\mathrm{ML}^{-2}\mathrm{T}^{-1}$], is equal to the sum of the advective and dispersive fluxes:

$$\mathbf{J}^{\mathrm{T}} = \mathbf{J}^{\mathrm{A}} + \mathbf{J}^{\mathrm{D}} = \mathbf{q}C - \theta D_{\mathrm{H}} \frac{\partial C}{\partial x} \tag{16}$$

where the negative sign preceding the dispersive flux term indicates positive flux in the direction of negative concentration gradient. In the limit as the finite control volume approaches zero:

$$\frac{\partial m}{\partial t} = \nabla \cdot \mathbf{J}^{\mathrm{T}} \pm \Phi \tag{17}$$

where m is the total mass per sample volume [ML^{-3}] of a species of interest, $\mathbf{J}^{\mathrm{T}}$ is the total mass flux [$\mathrm{ML}^{-2}\mathrm{T}^{-1}$], and Φ refers to mass sources or sinks [MT^{-1}]. The derivation can likewise be extended to three dimensions. The mass term m represents the total mass in the control volume, and accounts for the mass in all phases present. For the simple system under consideration, mass of the species may exist on the solid and in the water phase:

$$m = \rho_{\mathrm{b}} C_{\mathrm{S}} + \theta_{\mathrm{w}} C_{\mathrm{w}} \tag{18}$$

where ρ_{b} is the bulk soil density [ML^{-3}], C_{s} is the solid concentration [MM^{-1}], θ_{w} is the water content [$\mathrm{L}^3\mathrm{L}^{-3}$], and C_{w} [ML^{-3}] is the water concentration. To complete the transport equation, a relationship describing mass partitioning between the water and solid phase is needed. Assuming linear, reversible, and equilibrium partitioning (i.e., $C_{\mathrm{s}} = K_{\mathrm{d}} C_{\mathrm{w}}$), Eq. (18) becomes:

$$m = \left(1 + \frac{K_{\mathrm{d}} \rho_{\mathrm{b}}}{\theta_{\mathrm{w}}}\right) C_{\mathrm{w}} \tag{19}$$

and the transport equation can be written as follows:

$$RC = D \frac{\partial^2 C}{\partial x^2} - v \frac{\partial C}{\partial x} \tag{20}$$

where R is the retardation factor (i.e., $1 + K_{\mathrm{d}} \rho_{\mathrm{b}} / \theta_{\mathrm{w}}$).

Under complex conditions, numerical approximation techniques are required to solve the transport equation, and the solution to the advective-diffusion equation may have to be coupled to numerical solutions to the flow equations as well. However, analytical solutions can be obtained in simpler systems. The solution to the one-dimensional advective–dispersive transport equation with constant pore velocity, subject to the initial condition of $c(x, 0) = 0$ for $x \geq 0$, and the boundary conditions of $c(0, t) = c_0$ for $t \geq 0$,

and $c(\infty, t) = 0$ for $t \geq 0$, in nondimensional form is

$$c = \left(\frac{1}{2}\right)\left\{\text{erfc}\left[\sqrt{\frac{Pe}{4R\tau_{pv}}}(R - \tau_{pv})\right] + \exp(Pe)\text{erfc}\left[\sqrt{\frac{Pe}{4R\tau_{pv}}}(R + \tau_{pv})\right]\right\} \quad (21)$$

where c is the dimensionless concentration (C/C_0), τ_{pv} is the dimensionless pore volume ($\tau = vt/L$, t = time [T], and L = linear extent of the flow domain [L]), and Pe is the Peclet number [dimensionless].[21] Eq. (21) represents an analytical solution based on the step change in injected concentration (i.e., $c = 0$ for $t \leq t^*$, $c = c_0$ for $t > t^*$), and can be used to generate a solution based on a finite pulse, i.e., $c(0, 0 \leq t \leq t_p) = c_0$, $c(0, t > t_p) = 0$, where t_p is the pulse duration [T], by superposition.

The Peclet number (Pe) is defined as

$$Pe = \frac{vl}{D_H} \quad (22)$$

where v is velocity [L^2T^{-1}], l is a characteristic length of the system [L], and D is dispersion coefficient [LT^{-2}]; and is a nondimensional measure of the ratio of advective to dispersive transport processes. When velocity is sufficiently low, diffusion is the dominant process in hydrodynamic dispersion, but as velocity increases, mechanical dispersion becomes the dominant process. It is instructive to note the limiting cases of $Pe = 0$ and $Pe = \infty$. In the former case, diffusive processes dominate transport and the solution resembles a continuously stirred reactor tank. In the latter case, advective transport dominates, and the solution resembles a plug flow solution.

PHASE PARTITIONING AND REACTIVE PROCESSES

Phase partitioning is of course a very important transport process in porous media, and phase partitioning processes in porous media are summarized in Fig. 5. Numerous treatment processes are based on phase partitioning, such as liquid and gas treatment by activated carbon (sorption), or packed tower air stripping (volatilization). Conversely, partitioning plays a direct role in water resource contamination, as in the case of groundwater pollution resulting from leaky gasoline storage tanks (dissolution).

In the analysis presented in the previous section, the porous media were saturated with water, and partitioning was described using a linear equilibrium reversible relationship. Considering a more complex system, if the pore space is filled by three phases (water, gas, and an NAPL), then Eq. (18) becomes:

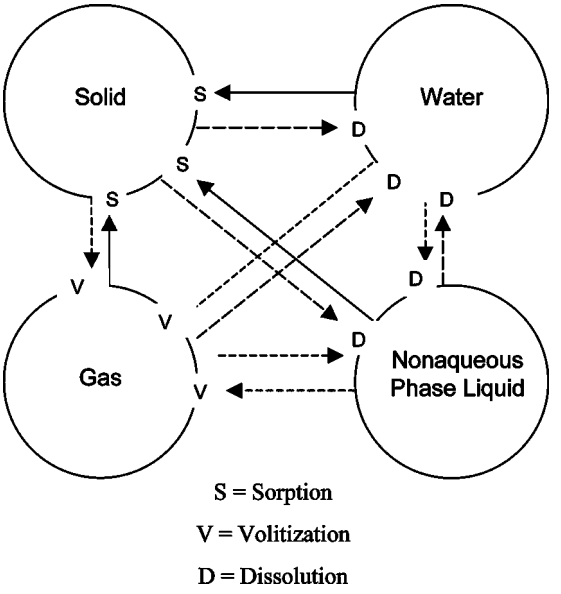

Fig. 5 Conceptual figure of partitioning in porous media.

$$m = C_w\theta_w + \rho_b C_s + \theta_g C_g + \theta_N C_N + a_{g/N}C_{g/N} + a_{N/w}C_{N/w} + a_{g/w}C_{g/w} \quad (23)$$

where the subscripts g, N, g/N, N/w, and g/w refer to gas, NAPL, gas/NAPL interface, NAPL/water interface, and gas/water interface, respectively. The partitioning represented by the last three terms accounts for chemical species that partition at fluid interfaces, such as surfactants for water–air or water–NAPL systems, or long-chain alcohols for water–air systems (e.g., Refs.[22–24]). To complete the equation, relationships describing mass partitioning must be used; assuming linear, reversible, and equilibrium partitioning, Eq. (23) becomes:

$$m = \left(1 + \frac{K_d\rho_b}{\theta_w} + \frac{H\theta_g}{\theta_w} + \frac{K_N\theta_N}{\theta_w} + \frac{\Gamma_1 a_{g/N}}{\theta_w} + \frac{\Gamma_2 a_{N/w}}{\theta_w} + \frac{\Gamma_3 a_{g/w}}{\theta_w}\right)C_w \quad (24)$$

where K_N is the NAPL-water partitioning coefficient, and Γ_1, Γ_2, and Γ_3 represent interfacial partitioning coefficients. Of course, other partitioning behavior is possible besides linear-reversible-equilibrium partitioning, and the following sections discuss phase partitioning in more detail.

Sorption

Chemical species may sorb onto the porous media from the liquid or gas phases, owing to one or more

chemical, electrostatic, or physical forces.[25] In general, chemicals that are hydrophobic in nature tend to sorb more strongly than hydrophilic chemicals. As presented in the section on fluid motion, sorption was assumed to be linear and reversible, and was assumed to be an equilibrium process. However, sorption may be nonlinear and irreversible, and may occur slow enough relative to transport to be a nonequilibrium process. Furthermore, sorption characteristic may vary with location or change with time.

Equilibrium sorption is most often described using a linear, Freundlich or Langmiur relationship. The Freundlich sorption isotherm is:

$$C_s = k_f C_w^{1/n} \tag{25}$$

where k_f is the partitioning coefficient $[(ML^{-3})^{-1/n}]$. When $n = 1$, the equation reduces to the linear partitioning equation:[25]

$$C_s = k_d C_w \tag{26}$$

where k_d is the distribution coefficient $[L^3M^{-1}]$. The Langmuir sorption equation is:

$$C_s = \frac{C_s^{Max} b C_w}{1 + bC_w} \tag{27}$$

where b is the Langmuir sorption constant, and C_s^{Max} is the maximum number of sorption sites.

If transport occurs much faster than sorption, sorption processes may not reach equilibrium conditions. Nonequilibrium sorption may result from physical causes such as intraparticle rate-limited diffusion, chemical causes such as rate-limiting reaction kinetics, or a combination of the two. One approach used to model rate-limited sorption is bi-continuum models consisting of one region where transport is described by the advection–dispersion equation with equilibrium sorption, and another region where transport is diffusion limited with equilibrium sorption, or another region where sorption is chemically rate limited.

Dissolution

Dissolution refers to the partitioning of chemical species between gas–liquid and liquid–liquid phases. Assuming local equilibrium partitioning, the maximum amount of a species that will dissolve into a liquid at a given temperature is given by its solubility. When local equilibrium is not achieved, a rate-limited mass transfer expression is used. For example, Miller, Poirzer-McNeill, and Mayer present a common rate-limited expression for dissolution:[26]

$$J = \kappa\left(C_{aq}^* - C_{aq}\right) \tag{28}$$

where J = mass flux across the interface $[MT^{-1}L^{-2}]$, κ = dissolution mass transfer coefficient $[LT^{-1}]$, and C_{aq}^* = equilibrium aqueous phase concentration $[ML^{-3}]$. The product of the mass transfer coefficient and the specific interfacial area is the mass transfer rate coefficient (i.e., $K_a = \kappa a$). Extensive research on the mass transfer coefficient and the mass transfer rate coefficient has been conducted in several fields of study, and results are often expressed by empirical relationships in the form of $Sh = f(\eta, S, Re, Sc, Pe)$, where Sh is the Sherwood number:

$$Sh = \frac{\kappa l}{D} \tag{29}$$

which represents the ratio of mass transfer rate to diffusion rate, and Sc is the Schmidt number:

$$Sc = \frac{\mu}{\rho D} \tag{30}$$

which represents the ratio of momentum to mass diffusion. Ramachandran and Chaudhari present summaries of empirical relations developed by researchers investigating κ, a, and K_a.[27] For the dissolution of NAPLs into groundwater, Miller, Poirzer-McNeill, and Mayer, Mercer and Cohen, and Powers et al. review factors affecting dissolution and summarize mass transfer coefficient correlations reported in the literature.[26,28,29]

Volatilization

If a gas phase is present, chemical species may volatilize from the liquid or solid phase, which is an important partitioning process in a variety of circumstances (e.g., transport in the unsaturated zone, or for treatment processes). The equilibrium vapor pressure can be used with the ideal gas law to estimate the mass in a given volume and temperature under equilibrium conditions. For solutions with more than one component, Raoult's law can be used to quantify the vapor pressure of each component. For dilute aqueous solutions, Henry's law describes the equilibrium relationship between dissolved chemicals and their vapor pressure:

$$P_i = H^* X_i \tag{31}$$

where P_i = vapor pressure of species $i[ML^{-1}T^{-2}]$, H = Henry's law constant for species $i[ML^{-1}T^{-2}]$, and X_i = mole fraction of the ith species in solution.

For nonequilibrium conditions, a rate-limited mass-transfer expression similar to Eq. (28) is typically assumed:

$$J = k\left(C_g^* - C_g\right) \tag{32}$$

where J is the mass flux across the gas–liquid interface [$MT^{-1}L^{-2}$], k is the mass transfer coefficient [LT^{-1}], C_g^* is the equilibrium gas concentration [ML^{-3}], and C_g is the bulk gas concentration [ML^{-3}].

Reactions

Abiotic and biotic reactions may occur that can produce or consume chemical species in porous media, and transport equations must therefore include descriptions of such processes for prediction accuracy. For example, microorganisms may use ethanol as a carbon source, and consume ethanol as it is transported through the porous system. Examples of other reactive processes include radioactive decay and abiotic degradation. Reactions of chemical species in porous media are often expressed using:

$$\frac{dC}{dt} = -kC^n \tag{33}$$

where k is a reaction constant, and n is the order of the reaction.[30] For a zero-order reaction:

$$C = -kt + C_0 \tag{34}$$

and for a first-order reaction:

$$C = C_0 e^{-kt} \tag{35}$$

For inclusion in the transport equation, the right-hand side of Eq. (33) would be used in place of Φ in Eq. (17).

CONCLUSIONS

A general overview was provided of porous media characteristics, fluid flow in porous media, advection and dispersion in porous media, and phase partitioning and reactive processes in porous media. Four questions were posed in the introduction, and it was suggested that the answers to those questions could be used to highlight the important features of a particular porous media transport problem. By the very nature of porous media, the answer to the first question (i.e., which phases are present?) will at least include a solid phase and one fluid phase, composed of either a liquid or a gas. If multiple phases are present in the void space, then the distribution of the liquid and gas in the pore space will be a function of capillary pressure. The second question (i.e., how many phases are in motion?) indicates the nature of the transport phenomenon. In the simplest case, no phases are in motion, and the only transport mechanism to consider in the static system is diffusion. If one or more phases are in motion, then advection and dispersion must also be considered for each phase in motion. The third question (i.e., do chemical species of interest partition between phases?) depends on the chemical properties of the transporting species and porous media. In the simplest case, the species of interest does not partition between phases. Or when partitioning does occur, the simplest case is partitioning described by reversible, linear equilibrium partitioning. Beyond that, a wide range of partitioning behavior can occur. And finally, the last question (i.e., are the species of interest produced or consumed by reactive processes?) addresses changes that may occur due to radioactive decay, microbiological activity, or abiotic reactions.

Fluidization

A.-H. Park
L.-S. Fan
Department of Chemical and Biomolecular Engineering, The Ohio State University, Columbus, Ohio, U.S.A.

INTRODUCTION

Fluidization refers to the state of solid particles in a suspended condition owing to the flow of fluid, gas, and/or liquid. Contact schemes of fluidized bed systems can be classified on the basis of the states of solid motion. For a batch-solids system, the fluid at a low velocity merely percolates through the voids between packed particles, while the particles remain motionless. The solids in this case are in the fixed bed state. With an increase in the fluid velocity, particles move apart and become suspended; the bed then enters the fluidization state. The fluidization characteristics vary, depending on whether gas, liquid, or gas-liquid is the fluidizing medium.

Fluidized beds generally possess the following properties that promote their use in reactor applications:

1. Capability of continuous operation and transport of solids in and out of the bed.
2. High heat transfer rates from bed to surface and from gas to particle leading to temperature uniformity in the bed.
3. High mass transfer rates from gas to particle.
4. Applicability over a wide range of particle properties and high solids mixing rates.
5. Simplicity in geometric configuration and suitability for large-scale operation.

Fluidized beds have been used extensively for physical operations (e.g., adsorption and heat exchanger), chemical synthesis (e.g., acrylonitrile synthesis and maleic anhydride synthesis), metallurgical and mineral processes (e.g., roasting of sulfide ores, resid hydrotreating, and reduction of iron oxide), and other applications, such as coal combustion and microorganism cultivation.

In what follows, the fundamental properties of two-phase fluidization are described. Unless otherwise noted, the properties refer to gas–solid fluidization. The books that can serve as general references for two-phase (gas–solid or liquid–solid) or three-phase (gas–liquid–solid) fluidization subjects are Refs.[1–9].

PARTICLE AND REGIME CLASSIFICATION

Classification of Fluidized Particles

Particles can be classified into four groups (i.e., Groups A, B, C, and D) as shown in Fig. 1, based on their fluidization behavior.[10] Group C comprises small particles ($d_p < 20\,\mu m$) that are cohesive. Group A particles, with a typical size range of 30–100 μm, are readily fluidized. No maximum stable bubble size exists for Group B particles. Group D comprises coarse particles ($d_p > 1\,mm$) that are commonly processed by spouting.

Fluidization Regime

Regime classification for dense- and lean-phase fluidization, in general, can be based on bubble or solid flow behavior. Dense-fluidization regimes include particulate fluidization, bubbling fluidization, and turbulent fluidization. In a broad sense, ''dense-phase fluidization'' also encompasses the slugging, spouting, and channeling conditions of operation. Lean-phase fluidization includes fast fluidization and dilute transport. The fundamental distinction between these regimes or conditions of operation is briefly described next. Fig. 2 illustrates various flow regimes.

Minimum fluidization and particulate fluidization

The state of fluidization begins at the point of minimum or incipient fluidization. At the minimum fluidization point, the pressure drop for a fixed bed and that for a fluidized bed are equivalent. This relationship is used as the basis for the formation of the predictive equation for the minimum fluidization velocity. The pressure drop in the fixed bed can be described by the Ergun equation. Under the minimum fluidization condition, the Ergun equation can be expressed as

$$\frac{\Delta p_b}{H_{mf}} = 150\frac{(1-\alpha_{mf})}{\alpha_{mf}^3}\frac{\mu U_{mf}}{\varphi^2 d_p^2} + 1.75\frac{(1-\alpha_{mf})}{\alpha_{mf}^3}\frac{\rho U_{mf}^2}{\varphi d_p} \quad (1)$$

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120006805

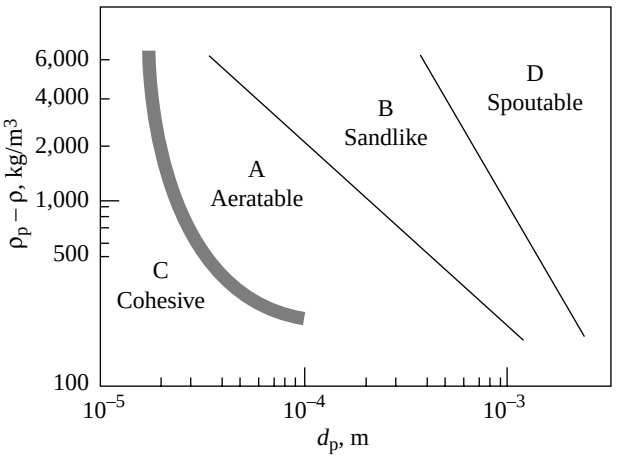

Fig. 1 Geldart's classification of fluidized particles. (From Ref.[10].)

In a fully fluidized bed, the pressure drop (cross-sectionally averaged) counterbalances the weight of the pseudocontinuum of the gas–solid mixture, which yields

$$-\frac{\mathrm{d}p_\mathrm{d}}{\mathrm{d}H} = (\rho_\mathrm{p} - \rho)(1 - \alpha)g \tag{2}$$

Under the minimum fluidization condition, Eq. (2) gives

$$\frac{\Delta p_\mathrm{b}}{H_\mathrm{mf}} = \frac{\Delta p_\mathrm{d}}{H_\mathrm{mf}} = (\rho_\mathrm{p} - \rho)(1 - \alpha_\mathrm{mf})g \tag{3}$$

Equating Eqs. (1) and (3) results in

$$\mathrm{Ar} = 150\frac{(1 - \alpha_\mathrm{mf})}{\alpha_\mathrm{mf}^3\varphi^2}\mathrm{Re}_\mathrm{pmf} + \frac{1.75}{\alpha_\mathrm{mf}^3\varphi}\mathrm{Re}_\mathrm{pmf}^2 \tag{4}$$

and

$$\mathrm{Re}_\mathrm{pmf} = \frac{\rho U_\mathrm{mf} d_\mathrm{p}}{\mu} \tag{5}$$

A semiempirical correlation based on Eq. (4) can be given by[11]

$$\mathrm{Re}_\mathrm{pmf} = \sqrt{(33.7)^2 + 0.0408\mathrm{Ar}} - 33.7 \tag{6}$$

The above analysis for minimum fluidization is applicable to both, the gas–solid and liquid–solid systems.

For a bed with Group A particles, bubbles do not form when the gas velocity reaches U_mf. The bed enters the particulate fluidization regime under this condition. This is also the regime under which liquid fluidization is operated. The operation under the particulate fluidization regime is characterized by a smooth bed expansion with an apparent uniform bed structure without bubbles for $U_\mathrm{mf} < U < U_\mathrm{mb}$, where U_mb is the superficial gas velocity at the minimum bubbling condition. In particulate fluidization, all the gas passes through the interstitial space between the fluidizing particles without forming bubbles. The bed appears grossly homogeneous. This regime exists only in a bed with Group A particles, under a narrow operating range of gas velocities. At high pressures or with gases of high density, the operating range of this regime expands.

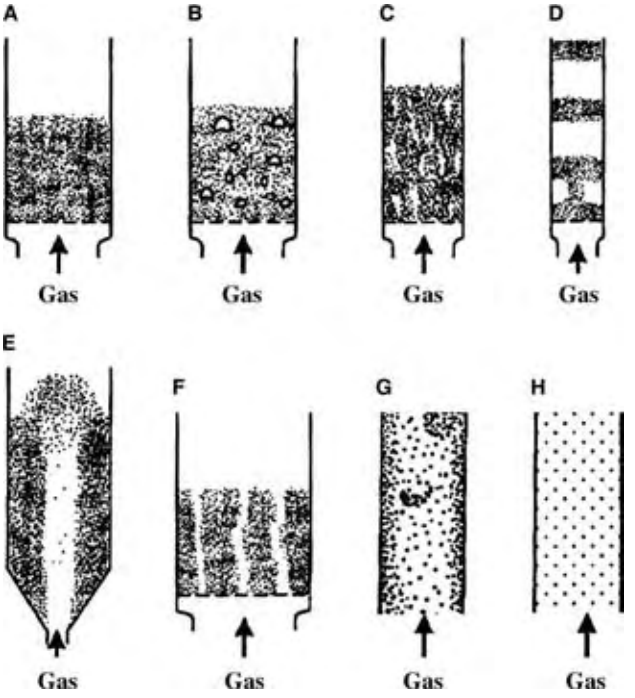

Fig. 2 Various flow regimes or patterns in dense-phase fluidization: (A) particulate fluidization; (B) bubbling fluidization; (C) turbulent fluidization; (D) slugging; (E) spouting; (F) channeling; (G) fast fluidization. (From Ref.[7].)

For liquid fluidization, the Richardson–Zaki equation[12] as given below can be used to describe the bed expansion:

$$\varepsilon = \left(\frac{U_\mathrm{l}}{U_i}\right)^{1/n} \tag{7}$$

where U_i is the extrapolated liquid velocity as the bed voidage approaches 1, and n is the Richardson–Zaki index (see Table 1 for estimation).

Bubbling fluidization

Bubbles are formed as a result of the inherent instability of gas–solid systems. The instability of a gas–solid fluidized bed is characterized by fast growth in local voidage in response to a system perturbation. Because

Table 1 Index for the Richardson–Zaki equation

$n = 4.65 + 20d_p/D_c$	$Re_t < 0.2$
$n = (4.4 + 18d_p/D_c)Re_t^{-0.03}$	$0.2 < Re_t < 1$
$n = (4.4 + 18d_p/D_c)Re_t^{-0.1}$	$1 < Re_t < 200$
$N = 4.4Re_t^{-0.1}$	$200 < Re_t < 500$
$N = 2.4$	$500 < Re_t$

$Re_t = U_t d_p \rho_l / \mu_l$.
(From Ref.[13].)

of the instability in the bed, the local voidage usually grows rapidly into a shape resembling a bubble.[13] Although it is not always true, the initiation of the instability is usually perceived to be the onset of bubbling, which marks the transition from particulate fluidization to bubbling fluidization. The theoretical expansion of the physical origin behind and prediction of the onset of the instability of gas–solid fluidized beds has been attempted (e.g., Refs.[14–16]). The efforts have been focused on the primary forces behind the stability among the interparticle contact forces, particle–fluid interaction forces, and particle–particle interaction via particle velocity fluctuation.

Most bubbles in bubbling fluidized beds are of spherical cap or ellipsoidal cap shape. Configurations of two basic types of bubbles, fast bubble (clouded bubble) and slow bubble (cloudless bubble), are schematically depicted in Fig. 3. The cloud is the region established by the gas, which circulates in a closed loop between the bubble and its surroundings. The cloud phase can be visualized with the aid of a color tracer gas bubble. The bubble wake shown in Fig. 3 plays an important role in solid movement or -mixing in the bed and the freeboard. A bubble wake in a single-phase fluid is defined as the streamline-enclosed region beneath the bubble base. In a gas–solid fluidized bed, the emulsion phase can be treated as a pseudosingle-phase fluid. Hence, a bubble wake is defined as the region enclosed by streamline of the pseudofluid behind the bubble base. In the bed, the wake rises with the bubble and thereby provides an essential means for global solid circulation and induced axial solids mixing.[17] In the freeboard, particles carried along the bubble wake are the primary origin of the particles there.

When gas enters the orifice of the distributor, it can initially form bubbles or jets. The formation of bubbles or jets depends on various parameters including types of particles, fluidization conditions around the orifice, orifice size, and the presence of internals in the bed. The initial bubble or jet is then transformed into a chain of bubbles. The jet is defined as an elongated void, which is appreciably larger than a bubble; it extends to some distance from the orifice into the inner bed. In general, bubbles tend to form in the presence of small particles, such as Group A particles; jets tend to form in the presence of large particles, such as Group D particles, when the emulsion phase is not sufficiently fluidized, or when internals are present and disrupt the solid flow to the orifice region.[18]

In bubbling fluidized beds under ambient pressure and low gas velocity conditions where the bubble size increases with the gas velocity, the bubble size may be estimated by various correlation equations, such as those developed by Mori and Wen,[19] Darton et al.,[20] and Cai et al.[21] There is a similarity in the rise behavior of a single bubble in gas–solid and liquid media. The rise velocity of a single spherical cap bubble in an infinite liquid medium can be described by the Davies and Taylor equation.[22] Experimental results indicate that the Davies and Taylor equation is valid for large bubbles with bubble Reynolds numbers greater than 40.[23] Whereas for bubbles in fluidized beds, the bubble Reynolds numbers are typically of the order of 10 or less. By analogy, the rise velocity of an isolated single spherical cap bubble in an infinite gas–solid medium can be expressed in terms of the volume bubble diameter by[1]

$$U_{b\infty} = 0.71\sqrt{g d_{b\infty}} \tag{8}$$

In a free bubbling bed, the average bubble-rise velocity U_{bb} can be described by[1]

$$U_{bb} = U - U_{mf} + 0.71\sqrt{g d_{bb}} \tag{9}$$

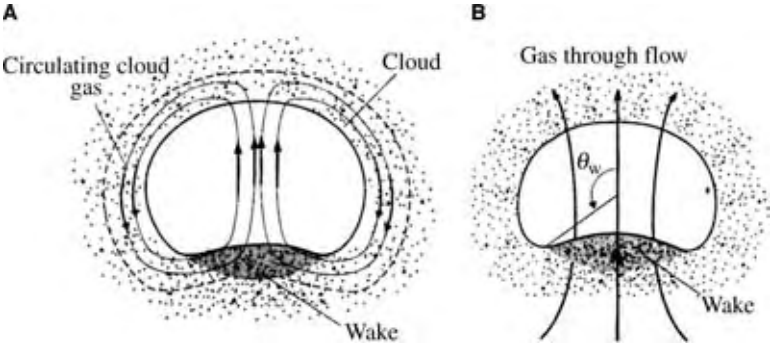

Fig. 3 Bubble configurations and gas flow patterns around a bubble in gas–solid fluidized beds: (A) fast bubble (clouded bubble) $U_b > U_{mf}/\alpha_{mf}$; (B) slow bubble (cloudless bubble) $U_b < U_{mf}/\alpha_{mf}$. (From Ref.[7].)

The distribution of gas flow in the fluidized bed is important for the analysis of the fundamental characteristics of transport properties in the bed. One common method to estimate the superficial gas flow division is based on the two-phase theory of fluidization, which considers the division of the superficial gas flow in the bed into two subflows—the bubble-phase and the emulsion-phase flow. According to the theory, the flow velocity can be generally expressed as

$$U = \alpha_b U_{bb} + U_{em} \quad (10)$$

where U_{em} and $\alpha_b U_{bb}$ are the superficial gas velocities for the emulsion-phase flow and for the bubble-phase flow, respectively. The variation of the relative magnitude of each flow depends on the gas velocity as well as on the gas and particle properties. A simple two-phase theory is to express U_{em} as U_{mf} and $\alpha_b U_{bb}$ as $(U - U_{mf})$. However, $U - U_{mf}$ may overestimate the actual bubble phase flow in a fluidized bed, as a result of two prevailing effects of the gas flow pattern: 1) significant emulsion-phase flow or invisible gas flow through the bubble, and 2) larger interstitial gas flow in the emulsion phase than U_{mf}.[24]

Turbulent fluidization

The turbulent regime is often regarded as the transition regime from bubbling fluidization to lean-phase fluidization. At relatively low gas velocities, bubbles are present in the turbulent regime, while at relatively high gas velocities in the turbulent regime, the clear boundary of bubbles disappears and the nonuniformity of solid concentration distribution yields distinct gas voids, which become less distinguishable as the gas velocity further increases toward lean-phase fluidization. The onset velocity of the transition to the turbulent regime is commonly defined, based on the variation of the amplitude of the pressure fluctuation with the gas velocity, as shown in Fig. 4, to be the gas velocity corresponding to the peak, U_c, whereas the leveling point, U_k, may be recognized as the onset of the turbulent regime proper.[25]

Entrainment and elutriation

The freeboard region in a fluidized bed accommodates particles that are being entrained from the dense bed. Entrainment refers to the ejection of particles from the dense bed into the freeboard by the fluidizing gas. Elutriation refers to the separation of fine particles from a mixture of particles, which occurs at all heights of the freeboard, and their ultimate removal from the freeboard. The terms entrainment and elutriation are sometimes used interchangeably. The carryover rate relates to the quantities of the particles leaving the freeboard. Coarse particles with a particle terminal velocity that is higher than the gas velocity eventually return to the dense bed, while the fine particles eventually exit from the freeboard. The freeboard height required in design consideration is usually higher than the transport disengagement height, defined as a height beyond which the solids holdup, solids entrainment, or carryover rate remains nearly constant.

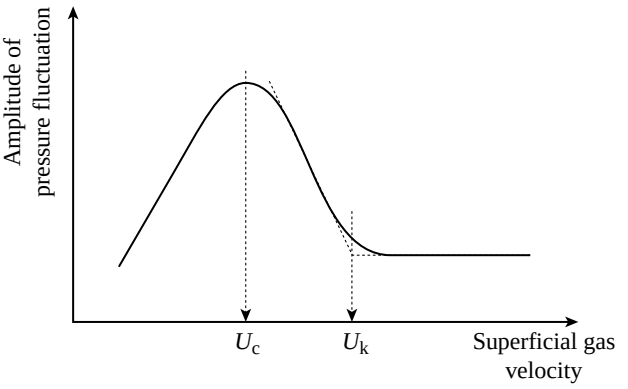

Fig. 4 Variation of pressure fluctuation with the gas velocity for dense-phase fluidized bed with FCC particles. (From Ref.[23].)

Slugging beds

When bubbles grow to sizes comparable to the bed diameter, slugging occurs. Slugging is most frequently encountered in small-diameter beds with large bed heights, especially when large/heavy particles are employed. There are requirements of a minimum slugging velocity and a minimum bed height for a slug flow to take place. The slugs may appear in different forms including the round-nosed slug, which occurs in systems of fine particles, the wall slug (also known as the half slug), which takes place in the beds with rough walls, and the square-nosed slug, which appears in coarse particle systems where the particle bridging effect is significant.

Spouted beds

In a spouted bed, gas enters the bed through a jet nozzle forming a spout. The surrounding annular region forms a downward-moving bed. Particles are entrained into the spout from the bottom and sidewall of the spout. A part of the gas seeps into the annular region through the spout wall, whereas the other part leaves the bed from the top of the spout. The particles carried into the spout disengage from the gas in a solid-disengagement fountain, just above the bed, and then return to the top of the annular region.[26] Group D particles are commonly used for the spouted bed operation.

Fast fluidization and dilute transport

The fast fluidization regime is characterized by the clustering phenomenon with a core-annular heterogeneous flow structure, whereas the dilute transport regime is characterized by a homogeneous flow structure. Lean-phase fluidization that encompasses these regimes is carried out in a circulating fluidized bed (CFB), where solid particles circulate between the riser and the downer. The fast fluidization regime is the principal regime under which the CFB is operated. The operating variables for a CFB system include both the gas flow rate and the solid circulation rate, whereas in a dense-phase fluidized bed system, only the gas flow rate is the operating variable. The solid circulation is established by a high velocity of gas flow.

The fast fluidization regime is represented by a dense region at the bottom of the riser and a dilute region above it. The inter-relationship of the fast fluidization regime with other fluidization regimes in dense-phase fluidization and with the dilute transport regime is reflected in the variations of the pressure drop per unit length of the riser, Δ_p/Δ_z, gas velocity, and solid circulation rate as given in Fig. 5.[27]

The transport velocity, U_{tr}, marks the lower limit of the gas velocity for fast fluidization operation. The transport velocity can be evaluated from the variations of the local pressure drop per unit length (Δ_p/Δ_z) with respect to the gas velocity and the solid circulation rate, J_p. An example of such a relationship is shown in Fig. 6. It is seen in the figure that, along the curve AB, the solid circulation rates are lower than that of the saturation carrying capacity of the flow. Particles with low particle terminal velocities are carried over from the riser. With an increasing solid circulation rate, more particles accumulate at the bottom. At point B in the curve, the solids fed into the riser are balanced by the saturated carrying capacity. A slight increase in the solid circulation rate yields a sharp increase in the pressure drop. This behavior reflects the collapse of the solid particles into a dense-phase fluidized bed and is noted as choking. When the gas velocity is equal to or higher than the

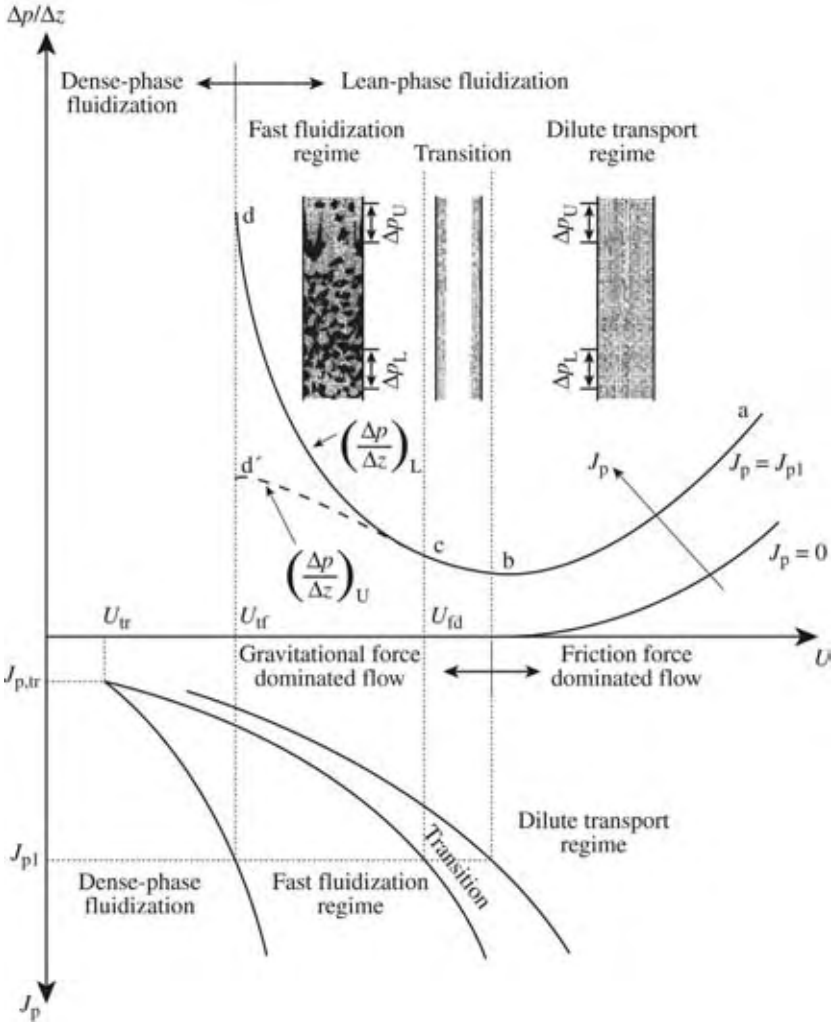

Fig. 5 Variation of pressure drop per unit riser length with solid circulation rate and gas velocity for various fluidization regimes. (From Ref.[27].)

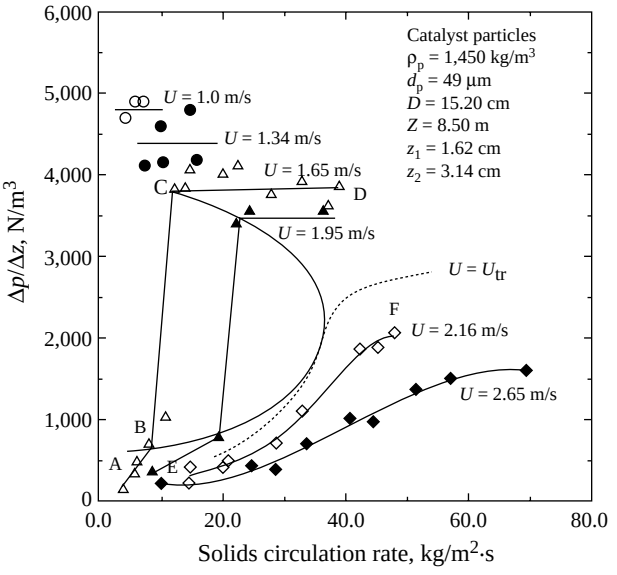

Fig. 6 Local pressure drop as a function of solid circulation rate at various gas velocities. (From Ref.[23].)

transport velocity (e.g., curve EF in Fig. 6), there is no longer a sharp increase in the slope of the J_p vs. (Δ_p/Δ_z) relationship. Thus, U_{tr} is characterized as the lowest gas velocity at which the discontinuity in the curve of J_p versus (Δ_p/Δ_z) disappears.[25] U_{tr} varies with gas and solid properties as correlated by Bi and Fan.[28]

OTHER SYSTEMS

Downer

In contrast to the riser, the downer involves downward flow of gas and solid in the gravitational direction at a high velocity. The downer is characterized by the absence of the minimum fluidization velocity, which allows a higher solid/gas loading ratio and a shorter flow development zone providing near plug flow conditions.[29] Thus, the downer has the benefits of uniform axial and radial gas–solid flow structures, thereby enhancing the reactant conversion for reactions in favor of the plug flow pattern.

Three-Phase Fluidized Bed

In gas–solid–liquid fluidization systems, the gas can be a continuous phase or discrete bubbles, while the liquid can be a continuous phase, a film or droplets, and the solids can be either in a continuous flow or a batch.[6]

A: Appendix A

Fig. 7 Basic classification of gas–liquid–solid fluidization systems. (From Ref.[6].)

The operational modes of the three-phase fluidized beds can be classified by the directions of the gas and liquid flows: cocurrent upward, cocurrent downward, countercurrent, or crosscurrent as shown in Fig. 7.[30]

The dispersed (or homogeneous) bubble and coalesced bubble (or churn-turbulent) flow regimes are the most common in operating the three-phase fluidized bed systems.[9] In the dispersed bubble flow regime, the bubbles with a fairly uniform size distribution rise without significant bubble coalescence. The vortical-spiral flow condition occurs in the coalesced bubble flow regime at lower gas velocities and marks a transition between the dispersed bubble regime and the churn-turbulent flow.[31] As the gas velocity further increases, the turbulent flow condition is developed, as large bubbles are generated by intensive bubble coalescence. The addition of fine particles leads to larger bubble sizes, and thus accelerates the transition.[32]

High-pressure and high-temperature operation of three-phase fluidized beds is commonly encountered in most industrial applications of commercial interest.[9] The flow characteristics of reactors at high pressure and temperature are distinctly different from those in ambient conditions. For example, elevated pressure leads to higher gas holdup and smaller bubble size in the system and, thus, dramatically affects the transport phenomena, including heat and mass transfer, and phase mixing. The effect of the operating pressure on the regime transition has been examined by many researchers in bubble columns,[32–40] in three-phase fluidized beds,[41] and in slurry bubble columns.[42]

The effects of pressure and temperature on fluid dynamics and transport properties are mainly due to variations in bubble characteristics, such as bubble size and bubble size distribution, and changes in the physical properties of fluid phases. The bubble size and distribution in the bed are closely associated with the initial bubble size, bubble coalescence rates, and bubble breakup rates. Under high-pressure conditions, bubble coalescence is suppressed and bubble breakup is enhanced, yielding smaller bubble sizes and narrower bubble size distributions. Thus, the flow regime transition is delayed in high-pressure bubble columns and slurry bubble columns.[42] Increasing temperature also delays the regime transition. In the coal liquefaction reactors, a gas holdup as high as 0.50 with the bubble size that may be as small as 0.7 mm was reported.[33]

For three-phase fluidization systems, two distinct phenomena pertaining to macroscopic hydrodynamic behavior—bed contraction and moving packed bed flow—are noted below.

Bed contraction phenomenon

Three-phase fluidized beds using small particles display unique bed expansion characteristics. Upon the initial introduction of the gas into the liquid–solid fluidized bed, contraction, instead of expansion, of the bed occurs.[43] An increasing gas flow rate causes further contraction up to a critical gas flow rate beyond which the bed expands.[44,45] A quantitative elucidation of the bed contraction phenomenon was reported by Stewart and Davidson[46] and El-Temtamy and Epstein.[47] Basically, bed contraction is caused by the behavior of the bubble wake, which entraps liquid and particles and, therefore, is associated with large bubble systems. The entrainment of the liquid and particles by the bubble wake reduces the effective amount of liquid in the bed used to fluidize the remaining particles. The bed contraction phenomenon has been extensively studied under ambient fluidization conditions and has also been observed at high pressure.[48]

On the basis of the generalized wake model of Bhatia and Epstein,[49] a criterion for the bed contraction was developed.[49,50] In the generalized wake model, the three-phase fluidized bed is assumed to consist of three regions, the gas bubble region, the wake region, and the liquid–solid fluidized region. Bed contraction will occur when the following criterion is satisfied, $\psi < 0$ where

$$\Psi = \left(\frac{n}{n-1} + k\right)\frac{U_l}{\varepsilon_l} + \frac{xk\left(U_g/\varepsilon_g\right)}{n-1} - \left[(1+k)U_l + \frac{k}{n-1}\left(\frac{U_g}{\varepsilon_g} - \frac{U_l}{\varepsilon_l}\right)\right] + xk\left(U_l - \frac{U_l}{\varepsilon_l}\right)\left(\frac{n}{n-1}\right) \quad (11)$$

Here, n is the Richardson–Zaki index, k is the ratio of wake size to bubble size, and x is the ratio of solid concentration in the wake region to that in the liquid–solid fluidized region.

Moving packed bed phenomenon

The moving packed bed flow is characterized by the motion of solids in a piston flow in a three-phase fluidized bed. Moving packed bed flow, which usually occurs during the start-up, depends not only on the gas and liquid velocities, but also on how they are introduced into the bed. Moving packed bed flow is caused by the surface phenomena involving fine bubbles attached onto particles and subsequent formation of a fine bubble blanket under the packed solids; a liquid flow would move the entire bed upward. Thus, this phenomenon is associated with the small bubble system. The moving packed bed flow phenomenon in a three-phase fluidized bed is a known, anomalous event in the resid hydrotreating industry. This was observed in the 1960s, in the bench and pilot units, during the development and commercialization of the

resid hydrotreating process.[51] The reactor was typically operated at pressures between 5.5 and 21 MPa and temperatures between 300°C and 425°C. In the early 1970s, moving packed bed flow was observed in a commercial three-phase fluidized bed reactor. The occurrence of a moving packed bed in a three-phase fluidized bed could simply be circumvented by utilizing a start-up procedure that involves degassing the bed first and then introducing liquid flow to expand the bed prior to commencing the gas flow. Commercial operators of three-phase fluidized bed reactors have long recognized and undertaken a proper start-up procedure of this nature since observing this anomalous event. As small bubbles can also be generated under ambient conditions using surfactants in an air–water system, the moving packed bed flow phenomenon was reported in open literature first by Saberian-Broudjenni et al.[52] and later by Bavarian and Fan[53,54] in small columns with small bubbles generated in the same manner.

COMPUTATIONAL FLUID DYNAMICS

The discrete phases including particles, bubbles, and droplets in multiphase fluidization systems can be simulated numerically using the Eulerian continuum, and Lagrangian and direct simulation for solid particles, or the front tracking method for deformable surfaces, such as bubbles and droplets. In the continuum method, the individual phases are treated as pseudocontinuous fluids, each being governed by conservation laws expressed in terms of the volume per unit time or ensemble-averaged properties.[55–60] Numerical simulations using the continuum method have been extensively conducted for gas–solid,[61–64] gas–liquid,[65–68] and gas–liquid–solid flows.[68–71]

There are two main approaches for the numerical simulation of the gas–solid flow:[72] 1) Eulerian framework for the gas phase and Lagrangian framework for the dispersed phase (E–L) and 2) Eulerian framework for all phases (E–E). In the E–L approach, trajectories of dispersed phase particles are calculated by solving Newton's second law of motion for each dispersed particle, and the motion of the continuous phase (gas phase) is modeled using an Eulerian framework with the coupling of the particle–gas interaction force. This approach is also referred to as the distinct element method or discrete particle method when applied to a granular system.[73] The fluid forces acting upon particles would include the drag force, lift force, virtual mass force, and Basset history force.[74] Moreover, particle–wall and particle–particle collision models (such as hard sphere model, soft sphere model, or Monte Carlo techniques) are commonly employed for this approach. In the E–E approach, the particle cloud is treated as a continuum.[69] Local mean variables are utilized instead of point variables to describe the motions of both phases on the basis of the local average technique of Anderson and Jackson.[55] This approach is more suitable for modeling the dense multiphase system with a significant volume fraction for the dispersed phase (>10%).

Because the effects of turbulence on particle motion are significant for most gas–solid fluidization systems, the numerical modeling of the carrier flow turbulence and motion of particles dispersed in a turbulent flow have been the subjects of extensive research. Direct numerical simulation (DNS) resolves the smallest scale structures (Komolgorov length scale) and can provide detailed point information for the flow field. No empirical closure models are needed in the DNS scheme. Large Eddy simulation (LES) involves both direct simulation and the Reynolds-averaging method. For the LES, large-scale motions are resolved rigorously, and the small-scale (sub-grid) motion is assumed to be homogeneous and independent of flow geometry.

On computation of gas–liquid bubble columns and gas–liquid–solid fluidized beds, numerical simulations provide a useful description of the hydrodynamics of bubble flows in liquids.[67,70,75–78] In the E–E method, both the continuous liquid phase and the dispersed bubble phase are treated as interpenetrating continua, occupying the same space based on the concept of volume averaging, with different velocities and volume fractions for each phases. In the E–L method,[75,77] on the other hand, liquid is treated as a continuous phase as described in the Eulerian mode, and bubbles are treated as a dispersed phase as tracked in the Lagrangian mode. Both the E–E and the E–L methods have proven to be more effective in modeling the gas–liquid flow in the homogeneous regime than in the heterogeneous regime.

More recently, the level-set technique has been developed for computing interfacial motion in two or three dimensions.[79] It is especially effective in simulating large topological changes such as bubble breaking and merging.

CONCLUSIONS

The fluidized bed systems have been utilized extensively in many physical, chemical, petrochemical, electrochemical, and biochemical processes. Successful applications of the fluidization systems lie in a comprehensive understanding of hydrodynamics, heat and mass transfer properties, and mixing. Various nonintrusive measurement techniques, such as electric capacitance tomography and radioactive particle tracking technique, are available to advance the fundamental understanding of the microscopic and macroscopic phenomena of fluidization. Till date, the

design of the fluidized beds, however, still relies heavily on empirical relationships and engineering models. The computational fluid dynamics approach to fluidized bed simulation has gained considerable attention in recent years. However, many challenges remain, such as the formulation of closure relationships on turbulence. Fluidization of nanoparticles (<100 nm) is an area of appreciable fundamental and applied interest for future research and development efforts.

NOMENCLATURE

Ar	Archimedes number
d_{bb}	Averaged volume diameter of bubble in the bed
$d_{b\infty}$	Volume diameter of an isolated bubble
d_p	Particle diameter
g	Gravitational acceleration
H	Vertical distance from gas distributor
H_{mf}	Bed height at minimum fluidization
p_d	Dynamic pressure
Re_{pmf}	Particle Reynolds number at minimum fluidization velocity
U	Superficial gas velocity
U_{bb}	Average bubble-rise velocity in the whole bed
U_{mf}	Superficial gas velocity at the minimum fluidization
α	Bed voidage
α_b	Volume fraction of the bed occupied by bubbles
α_{mf}	Bed voidage at minimum fluidization
ϵ	Bed voidage
Δp_b	Pressure drop across the bed
μ	Dynamic viscosity
ρ	Density of fluid
ρ_p	Density of particle
ϕ	Sphericity of particles

INTRODUCTION

This entry covers key features of fluidized bed reactors for catalytic and noncatalytic reactions involving solid particles and one or more fluids, most commonly a gas, and also liquids and gas–liquid mixtures. Fluidized beds find wide application in several industries—chemical processes, petrochemicals, polymers, mineral processing, pharmaceuticals, and food processing—because of their unique features that are advantageous in a number of applications. Enough background is provided for the reader to understand the major advantages and disadvantages of fluidized bed reactors, the most important design challenges and considerations, and the principal applications. Emphasis is placed on gas–solid-fluidized beds, but liquid–solid and gas–liquid–solid (three-phase) fluid bed reactors are also treated in brief. For more extensive coverage, the reader should consult standard reference works on fluidization.[1–6]

KEY FEATURES OF GAS–SOLID-FLUIDIZED BED REACTORS

The advantages of gas–solid-fluidized bed reactors relative to packed bed reactors are:

- Greatly improved bed-to-wall and bed-to-immersed-surface heat transfer
- Reduced axial and lateral temperature gradients, minimizing the probability of hot spots, catalyst sintering, and unwanted side reactions
- Ability to add or remove particles continuously or intermittently, without shutting down the process
- Reduced pressure drops (The pressure drop across the bed, once fluidized, essentially remains equal to only that required to support the weight of the bed.)
- Smaller catalyst particles, leading to improved catalyst effectiveness factors
- Ability to introduce (usually as a spray) modest quantities of liquid reactants that vaporize before reacting or yield solid products upon reaction inside the bed.

Fluidized beds, however, have some important disadvantages relative to packed (fixed or moving) bed reactors:

- Substantial axial gas mixing, causing much larger deviations from plug flow than for packed bed reactors, thereby adversely affecting conversions and selectivities
- For reactions where the particles themselves react, substantial particle mixing, greatly broadening solid residence time distributions relative to moving beds
- Particle attrition because of particles colliding with each other and with fixed surfaces
- Wear on immersed tubes and other interior surfaces because of the particle impingement
- Entrainment of particles, causing loss of catalyst and/or solid product, contributing to air pollution and requiring gas–solid separation equipment
- Increased risk because of complex hydrodynamics and difficulties in characterizing and predicting reactor performance

Gas–solid contacting and axial dispersion of both gas and particles depend on the particle properties, operating conditions, column geometry, and scale, all of which affect the motion of gas and solids, commonly referred to as hydrodynamics. For extensive coverage of hydrodynamics[2–6] may be consulted. Here we summarize the key features that affect the performance of gas–solid-fluidized beds as chemical reactors.

Overall Configuration: Common configurations for fluidized bed reactors are shown in Fig. 1. Bubbling beds and turbulent beds [Fig. 1(a)] usually operate at excess superficial gas velocities ($U - U_{mf}$) of $<0.25\,m/s$ and between ~ 0.3 and $1.2\,m/s$, respectively,

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007772

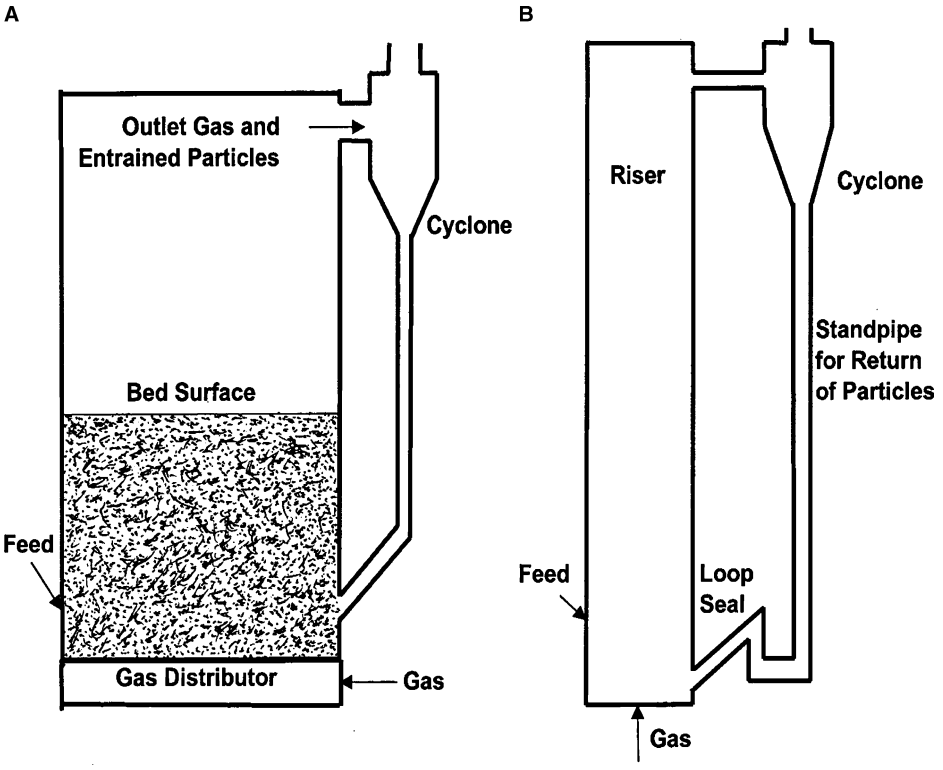

Fig. 1 Typical equipment configurations for: (A) dense (bubbling, slugging or turbulent) fluidized bed reactors; (B) circulating fluidized bed reactors. Heat transfer surfaces or baffles that might be present in (A) or (B) are not shown.

whereas circulating beds (Fig. 1B) generally feature superficial gas velocities of 2–12 m/s.

Particle Properties: Particles should be free-flowing (not sticky and with rounded shapes), ideally within either group A or group B of the powder classification scheme of Geldart.[7] Catalyst particles primarily belong to group A (mean diameter 50–100 μm), whereas particles that react in the bed fall into group B or D (mean diameter 200–2000 μm). Particle size distributions should be reasonably broad, e.g., covering a range from 10 to 200 μm. Particle densities should, however, be as uniform as possible. The particles must be able to withstand frequent collisions without breaking. Ideally, they should also not be subject to major electrostatic charging effects.

Operating Pressure and Temperature: Fluidized beds generally operate more smoothly with increasing absolute pressure, so that elevated pressures do not present a problem from a fluidization point of view. Many fluidized bed reactors also operate at high temperatures. The effects of temperature differ from system to system, probably because temperature affects particle properties (e.g., surface hardness and stickiness) in addition to causing well-characterized changes in gas properties. The effects of pressure and temperature have been reviewed by Yates.[8]

Gas Distributor: The gas distributor plate at the bottom of the reactor must introduce gas uniformly, prevent hole-plugging or weeping of solids, promote good gas–solid contacting, and support the weight of the bed when it is defluidized. During steady state operation, it is usually important to ensure that the pressure drop across the distributor is at least 30% of that across the bed itself. Gas introduction points should not be more than 0.3 m apart. Many different distributor geometries are found in industry, including tuyères, bubble caps, pipe grids with orifices oriented obliquely downward, and multiorifice plates (see Ref.[9] for more details).

Internals: Fluidized bed reactors commonly contain heat transfer surfaces, and baffles are sometimes added to improve gas–solid contacting and/or to reduce axial dispersion. Surfaces should, whenever possible, be horizontal or vertical, not inclined at other angles. The minimum gap between adjacent surfaces should be at least 20–30 mean particle diameters and several times the maximum particle dimension to prevent bridging and defluidization. Internal surfaces are subjected to buffeting, buoyancy forces, and impingement of particles, causing wear and/or particle attrition. These issues need to be considered in the design process. To prevent fouling and build-up of stagnant solids on top of the surfaces, flat surfaces should be inclined at 60° or more to the horizontal.

Particle Feeding: Many fluidized bed reactors require that particles be fed continuously or intermittently. Pneumatic feeding and screw feeders are most common. Because lateral mixing is much less than axial mixing in fluidized beds, it may be essential to introduce solids at a number of different positions

around the periphery of the reactor to minimize horizontal gradients. Lock hoppers may be needed if the reactor operates at elevated pressures. Preventing backflow of gases from the reactor may be essential for reasons of safety.

Entrainment: Most fluidized bed reactors employ one or more cyclone, either inside the freeboard region at the top of the vessel or located externally, to capture entrained solids that are then returned continuously to the base of the fluidized bed via a standpipe and a mechanical (e.g., slide) valve or aerated nonmechanical valve (see Ref.[10] for details of solid return systems). A ''flapper'' gate, acting as a check valve, is commonly employed to prevent backflow of gas up the standpipe. While cyclones are by far the most popular, other gas–solid separators like impingement separators, electrostatic precipitators, filters, and scrubbers are sometimes provided, especially as second- or third stage separators.

Flow Regime: Fluidized beds may operate in several different distinct flow regimes—bubbling, slug flow, turbulent, fast-fluidization, or dense suspension upflow. In principle, they may operate in any of these flow regimes. In practice, however, slug flow is seldom experienced in commercial reactors because of their large diameter and limited H/D, although slugging is common in laboratory and pilot-scale fluid bed reactors. Industrial reactors used for solid-catalyzed reactions seldom operate in the bubbling regime because the interphase mass transfer resistance would then severely limit gas–solid contacting. However, bubbling is often relevant for the larger particles found in gas–solid reactions. Catalytic reactors most often operate in the turbulent or dense suspension upflow regime, because of favorable gas–solid contacting combined with limited gas axial mixing, whereas the turbulent and the fast-fluidization regimes are common for gas–solid reactions.

FLUIDIZED BED CATALYTIC REACTOR PROCESSES

The advantages of fluidized bed reactor technology, discussed earlier, have led to several commercial fluidized bed catalytic processes. The key ones are surveyed here.

Fluid Catalytic Cracking

Fluid catalytic cracking (FCC) represents the major industrial application of fluidized bed technology. As of 1997, there were over 350 units operating worldwide, processing more than 16 million barrels of feed per day.[11] For a summary of typical FCC process conditions, see Ref.[11].

The process is operated as a circulating fluidized bed, with fine catalyst particles continuously circulated between the riser, where the cracking reactions occur and catalyst is deactivated because of coke deposition, and the regenerator, where the coke on the catalyst particles is combusted. Matsen[12] reported the slip factor in FCC risers to be approximately 2, which is consistent with radial segregation of the catalyst, leading to radial variations in gasoline yield.[13,14] Data[15] indicate that the catalyst particles travel upward at the wall of the riser because of the high gas velocity and solid flux. This results in reduced gas backmixing, thereby minimizing overcracking of gasoline.

In early FCC process designs, the regenerator was operated as a bubbling or a turbulent fluidized bed combustor. Mobil and UOP developed riser regenerators in the 1970s.[11] The riser regenerator is advantageous in operations in which there is no external CO recovery boiler. With today's trend of processing heavier and more variable feedstocks in FCC units, the preference is to operate in a partial combustion mode in the regenerator, in which case riser regenerators are of little benefit. Most modern FCC systems use a turbulent fluidized bed regenerator.

Partial Oxidation Reactions

This class of reactions, carried out in fluidized beds, involves parallel and series reactions, with reaction intermediates being the desired products. Industrial examples include partial oxidation of *n*-butane to maleic anhydride and *o*-xylene to phthalic anhydride. The vigorous solid mixing of fluidized beds is valuable for these reactions because they are highly exothermic. However, gas backmixing must be minimized to avoid extended gas residence times that lead to the formation of products of total combustion (i.e., CO_2 and H_2O). For this reason, fluidized bed catalytic partial oxidation reactors are operated in the higher velocity regimes of turbulent and fast-fluidization.

Most fluidized bed partial oxidation processes are operated in the turbulent flow regime of fluidization. However, DuPont operated a circulating fluidized bed catalytic reactor process for maleic anhydride production in Spain,[16] featuring regeneration of the catalyst (by oxidation) on the downcomer side of the circulating system.

Fischer–Tropsch Synthesis

Fischer–Tropsch reactions convert synthesis gas into hydrocarbons. The fluidized bed process for this reaction, known as the Synthol process, was developed

by Sasol of South Africa to produce synthetic gasoline from coal. Duvenhage and Shingles[17] describe the development of the Sasol reactor technology from pilot studies in the 1940s to today's commercial operation. Sasol 1A and 1B circulating fluidized bed reactors started up in 1955 and were fraught with problems: the planned run length of 340 days was in actuality more like 40 days. Many of the problems were resolved over 20 years,[17] and two additional trains of larger circulating fluidized bed reactors were commissioned uneventfully in the early 1980s. In the late 1980s, Sasol began pilot studies that led to the installation of two large turbulent fluidized bed reactors in 1995 and 1999. Among the advantages of this design are lower installed and operating costs associated with smaller vessels, reduced bed pressure drops, and lower catalyst usage.[17] The Sasol reactors rely on immersed heat exchangers to remove the heat of reaction. Plugging and cutting of the tube sheet coolers in the risers of the Sasol 1A and 1B reactors proved to be a problem.[17] The tube sheets were eventually replaced with cooling coils because of the tendency for tube sheet coolers to plug with solids.[18]

Oxychlorination of Ethylene

Vinyl chloride monomer, the basic building block of polyvinylchloride (PVC), is commercially manufactured by dehydrochlorination of 1,2-dichloroethane. The modern process for producing 1,2-dichloroethane involves oxychlorination of ethylene in a fluidized bed catalytic reactor:

$$C_2H_4 + 2HCl + \frac{1}{2}O_2 \rightarrow Cl_2C_2H_4 + H_2O \quad (1)$$

This is a highly exothermic reaction that takes place in the gas phase in the presence of a $CuCl_2$ catalyst. Small amounts of alkali and rare-earth metals in the catalyst inhibit by-product formation. The reactor is operated at 220–240°C and 2–4 bar. Immersed heat exchangers again remove the excess exothermic heat of reaction.

Propylene Ammoxidation

Ammoxidation refers to the catalytic oxidation of a feedstock with ammonia. When propylene is the feedstock, acrylonitrile is produced. Most of the world's acrylonitrile is based on the Sohio (now BP) process in which stoichiometric amounts of propylene and ammonia are reacted with a slight excess of air in a fluidized bed operated in the turbulent fluidization flow regime. The reactor temperature and pressure are 450°C and 1.5 bar, respectively. The reaction usually takes place over a bismuth molybdenum oxide catalyst; other metal oxides (iron–antimony, uranium–antimony, and tellurium–molybdenum) have also been used. The catalyst contains iron compounds that increase selectivity to acrylonitrile. The exothermic heat of reaction is removed by immersed heat exchangers in which boiler feed water is circulated and high-pressure steam is produced.

Polymerization

The gas-phase polymerization of ethylene to produce linear low-density polyethylene (LLDPE) is often carried out in fluidized bed reactors. The Unipol process technology is licensed worldwide by Union Carbide. It can also be used to make high-density polyethylene (HDPE). In the early years, ethylene was fed to the reactor with a 1-butene comonomer. The process was later modified to introduce higher α-olefins such as 1-hexene, yielding stronger LLDPE. The LLDPE resin is produced with Ziegler catalysts in large fluidized bed reactors (~5 m tall and 3–4 m in diameter) operated at pressures of 15–25 bar and temperatures of 70–90°C. Unipol reactors employ flared sections at the top to promote gas–solid disengagement. The monomer/comonomer mixture, together with nitrogen and hydrogen, is fed to the reactor in which the solid resin is vigorously fluidized. The gaseous feed reacts and condenses on the solid product. Particles continue to grow; large resin particles sink to the bottom of the reactor and are continuously withdrawn. The heat of polymerization is removed by immersed heat transfer surfaces. Per pass conversion is only ~2%. The unconverted gaseous feed exiting the top of the reactor is compressed, cooled, and recycled. In the condensing mode of operation, the recycled gas mixture is cooled below its dew point so that a portion of the recycled olefins enters the reactor in the liquid phase. The liquid droplets rapidly evaporate, helping to remove the heat of polymerization. This strategy increases the rate of production from fluidized bed polymerization reactors.

Catalytic Reforming

Catalytic reforming is the key refinery process for converting low-octane paraffinic hydrocarbons in the gasoline range (i.e., naphtha) to high-octane naphthenes and aromatics. The noble metal catalysts and promoters (e.g., platinum and rhenium) deactivate because of coke deposition and must be regenerated. The first generation catalytic reforming technology developed in the 1950s employed fixed bed reactors operated at pressures of 30 bar or more. The rate of coke formation is reduced at high pressure, facilitating longer run times before the reactors are shut down for

regeneration (after ~6 months). However, reformate yield and octane number are adversely affected by high pressure. Continuous catalytic reforming (CCR) technology, featuring four reactors in series, has been developed to overcome this problem. The reforming catalyst forms a slowly moving bed that descends through each reactor. In the UOP stacked design, the catalyst is transferred between reactors because of gravity. In the IFP design, the reactors are side by side, and the catalyst leaving the bottom of one reactor enters a lift-pot from which it is transported to the top of the next reactor. From the lift-pot at the base of the fourth reactor, the deactivated catalyst is sent back to the regenerator, located upstream of the first reactor. Modern CCRs operate at ~5 bar, substantially increasing the reformate yield and octane number. The CCR process is similar to the FCC process in that the catalyst is continuously circulated. However, the solid circulation flux is much lower in the CCR process. Furthermore, the regenerators of FCC units provide combustion environments to remove coke from the catalyst. Combustion also occurs in the CCR regenerator, but oxygenation and chlorination take place to restore the acidity of the bifunctional catalyst.

GAS–SOLID REACTIONS

This section concerns noncatalytic gas–solid reactions:

$$\mathrm{A\,(gas)} + \mathrm{B\,(solid)} \rightarrow \mathrm{products\,(gas\ and/or\ solid)} \quad (2)$$

Table 1 describes the nature of gases and solids depending on the reaction. These reactions include combustion, gasification, pyrolysis, calcination, and roasting. Some specific information is also provided for these types of reaction. Many noncatalytic gas–solid reactions use coal, biomass, and municipal solid wastes as feedstock. Table 2 summarizes their chemical compositions. These compositions differ in many ways, including the organic/inorganic content and chemical and physical properties.[19] The most important noncatalytic gas–solid reactions using fluidized bed technology are discussed here.

Combustion

Fluidized bed steam generators burning solid fuels have operated in the energy industry since 1980. This technology penetrated the energy market surprisingly quickly. Outstanding features of fluidized bed steam generators are high fuel flexibility, integrated emission control, flexibility in meeting the operating requirements of various industries, and a proven record of reliability. Fuel flexibility has become an important criterion in selecting boiler technology for new utility power plants: the type and the grade of fuels also affect the solid handling provisions, energy recovery, emissions control, and solid waste handling.[20] For example, the 200 MW_e Tonghae thermal power plant CFB boiler (2 units) began commercial operation in 1998–1999 by firing low-quality Korean anthracite for electrical power generation.

Although combustion efficiency is a function of many variables (the most important being combustion

Table 1 Main characteristics of fluidized bed combustion, gasification, pyrolysis, calcination, and roasting

Reaction type	A	B	Main products	Other products	Temperature range (°C)	Solid residence time (sec)
Combustion	Air	Coal, MSW, or biomass	CO_2, H_2O, ash	SO_x, NO_x	850–930	3–500
Gasification	Air, oxygen, or steam	Biomass, MSW, or coal	CO, H_2, CH_4, char	Tar, SO_x, NO_x	650–850	1–600
Pyrolysis or fast pyrolysis	Recycle gases with or without air	Biomass, hydrocarbons	Liquid fuel (bio-oil), H_2O, char, coke	Lower molecular weight hydrocarbons	450–550	0.5–500
Calcination	Air	Limestone, dolomite, alumina, phosphates, etc.	Oxides	SO_x, NO_x	600–800	1–60
Roasting	Air or oxygen-enriched air	Sulfide ores	Oxides	SO_2	600–1000	30–120

Table 2 Physical, chemical, and fuel properties of biomass, coal, and municipal solid waste

Property	Biomass	Coal	MSW
Fuel density (kg/m^3)	~500–800	~1300–1500	~700–800
Mean particle size (mm)	~3	~0.1–3	~3–5
C content (wt.% of dry fuel)	42–54	65–85	25–30
O content (wt.% of dry fuel)	35–45	2–15	20–25
S content (wt.% of dry fuel)	Max. 0.5	0.5–7.5	Max. 0.25
SiO_2 content (wt.% of ash)	23–49	40–60	10–40
K_2O content (wt.% of ash)	4–48	2–6	1.5–9
Al_2O_3 content (wt.% of ash)	2.4–9.5	15–25	2–10
Fe_2O_3 content (wt.% of ash)	1.5–8.5	8–18	2–6
Ignition temperature (°C)	418–426	490–595	400–450
Friability	Low	High	Medium
Dry heating value (MJ/kg)	14–21	23–28	10–13[a]

[a]Dry heating value could be as low as 3 MJ/kg for developing countries.

temperature, excess air, residence time, feed size, cyclone separation efficiency, and mixing of gas and solids), carbon burnout efficiency is high (usually 99% or more) in fluidized bed combustion (FBC) systems. Many comprehensive FBC simulation models are available in the literature.[21] One of them has the advantage of being integrated with Aspen Plus, an advanced computer based simulation package for process engineering that is able to simulate a variety of processes ranging from single unit operations to complex multiunit processes.[21]

Several clean coal municipal waste or biomass technologies [bubbling fluidized bed (BFB) and circulating fluidized bed (CFB)] at atmospheric or at higher pressure, typically 6–15 bar) have been developed that reduce pollutant emissions.[22] Limestone is employed as a sorbent to capture sulfur in the bed, where it undergoes calcination followed by sulfation. The Ca to S molar feed ratio must typically be 2 to 3 for 90–95% retention of sulfur (SO_2 emission of ~200 mg/MJ). Unfortunately, the limestone utilization is normally low, typically 30–40%. NO_x emissions are low for FBC boilers relative to those of conventional pulverized coal boilers because of lower operating temperatures (typically 830–880°C). Compared with BFB combustors (135–1800 mg/MJ), CFB combustors tend to have lower NO_x levels (135–180 mg/MJ) because of air staging. Due to the catalytic effect of SO_2 and limestone, N_2O emissions show a maximum for a bed temperature of ~800°C. Ultralow emissions of NO_x (45 mg/MJ) can be obtained by combining FBC, and selective noncatalytic reduction with ammonia or selective catalytic reduction (over Pt, Au or V_2O_5) is commonly used. However, achieving ultralow NO_x emissions may compromise sulfur oxide reduction and/or carbon utilization. Compared with BFB combustors, CFBs also produce less CO (~40 mg/MJ) because of the more intensive gas turbulence and better mixing, although lateral solid mixing remains an issue. Before discharge to the atmosphere, the flue gas is passed through a baghouse to remove most of the entrained dust. Particulate emissions from FB combustors are, on average, ~10 mg/MJ. Cofiring biomass and coal, compared with firing coal alone, helps reduce both NO_x and SO_2 and also fuel costs, minimize waste, and reduce soil and water pollution, depending upon the chemical composition of the biomass.[22]

Frequent operational problems have been encountered in biomass combustors. One common issue is agglomeration of bed material. Biomass ash is often relatively rich in alkali and alkaline-earth metals, causing it to melt at relatively low temperatures. Fouling of the heat exchangers may cause additional problems.

Several countries have introduced stringent emission limits (0.1 ng-TE/Nm^3) for chlorinated dioxins and furans emitted from combustion sources, in particular solid waste incinerators, because of concerns over their adverse health effects. Technologies for reducing their formation and emission in incineration processes have been studied extensively and can be applied in modern incineration plants.[23] Activated carbon injection and fabric filtration are currently practiced in many installations. However, to minimize capital cost, a more fundamental approach is needed to control and limit formation of these pollutants in incineration processes, e.g., involving the postcombustion zone, the combustion chamber, and waste feeding.[23]

Gasification

Gasification is the conversion of coal, municipal solid waste (MSW), or biomass to a gaseous fuel by heating in the presence of oxygen and/or steam. The resulting

fuel gas is more versatile than the original solid reactant. For example, it could be used to power gas engines and gas turbines, or as a chemical feedstock to produce liquid fuels. Air-blown processes produce low-calorific-value gases with a typical higher heating value (HHV) of 4–7 MJ/m^3, while oxygen- and steam-blown processes result in gases with an HHV of 10–18 MJ/m^3.[24] The reactions in the gasifier include partial oxidation and complete oxidation of the carbon content, steam–carbon reaction, Boudouard reaction, shift reaction, and methane formation.[25] A number of reactor configurations have been used including BFBs and CFBs.

Lurgi's atmospheric CFB technology, originally developed for alumina calcination, was later adapted to coal combustion. It has since been applied to biomass gasification. Recently, a consortium of Japanese utilities announced the construction of a commercial-scale 250 MW (1700 t/d) integrated gasification combined cycle (IGCC) plant at Nakoso, Japan, based on two stages. In the first (combustion) stage, the high temperature simplifies separation of liquid slag from the gas. In the second (reduction), only coal is introduced, in the absence of additional oxidant. The temperature drop over the reductor stage is 700°C, with a reactor outlet temperature of ~1000°C.[25] Many fluidized bed gasification processes have been and are being developed, but none incorporates a heat carrier in such a way that the tars are combusted and char reacts with the gasifying agent to produce synthesis or fuel gas. Such a system could produce pure syngas, with the gas free of tars and carbon conversion virtually complete.[26]

The major operational difficulty is gas cleaning, which is still the major bottleneck, limiting the use of biomass for electricity generation. The gas formed contains a number of impurities: particulates (ash and char), tar, and nitrogen, sulfur, and alkali compounds. The tar, consisting of high molecular weight compounds that typically condense at temperatures below 450°C, can cause blockages and corrosion, while also reducing overall efficiency. Moreover, impurities (such as methane) can affect the end usage of syngas.

As a first approximation, a nonstoichiometric equilibrium model based on direct minimization of Gibbs free energy may be applied to predict gasifier performance, although experimental data deviate somewhat from model predictions.[24] Extensive research is being carried out to develop a process to produce a low-tar or tar-free gas. To reach these goals, two strategies are applied: improvement of the gasification technologies (updraft gasifier and cocurrent moving bed gasifier with throat[26]) and development of tar-removal processes. Since the mid-1980s, interest has grown with respect to catalytic biomass gasification.[27] The catalysts may be divided into two groups depending on the position of the catalyst reactor relative to the gasifier. In the first, the catalyst is added directly to the biomass prior to gasification. These catalysts consist of cheap disposable materials, e.g., dolomite ($MgCO_3 \cdot CaCO_3$), calcite (CaO), or magnesite (MgO), which reduce tar content. The second group of catalysts is placed in a secondary reactor downstream from the gasifier. Commercially available and relatively inexpensive, nickel reforming catalyst is highly effective at removing hydrocarbons and adjusting the gas composition to syngas quality. It is most active and has a longer lifetime when operated at 780°C in a fluidized bed.[27]

Pyrolysis

Pyrolysis is a moderate temperature (~500°C) process in which biomass, coal, or MSW is decomposed in the absence of an oxidizing agent at very high heating rates and vapor residence times typically less than 1 sec.[28] The product is collected as a liquid (bio-oil) and a solid char after rapid cooling. For fast pyrolysis, BFBs and CFBs have been used extensively. They are designed and operated to maximize the liquid fraction at up to 75 wt.% on a dry feed basis. The bio-oil can be stored and transported. Its typical higher heating value is ~18 MJ/kg, and its chemical composition differs significantly from that of petroleum-derived oils. Several fast pyrolysis technologies have reached near-commercial status. Six CFB plants have been constructed by Ensyn Technologies, the largest with nominal capacities of 50 t/day. DynaMotive demonstrated a BFB process at 10 t/day of biomass and is scaling up the plant to 110 t/day.[28] Bio-oil has been successfully burned in boilers and furnaces, although some problems have been reported with char levels which can block filters and atomizers. Other problems have also been encountered—the alkaline nature of the ash in turbines, the high viscosity of the bio-oil product (40–100 cP at 40°C), water content with possible phase separation, and corrosion from its low pH (pH 2–3). Comparison of three routes from biomass to electricity—combustion, gasification, and fast pyrolysis—based on cost and performance indicates that fast pyrolysis is expensive up to 5 MW_e. However, competition will be fierce as electricity production costs vary only slightly among these options.[29]

Upgrading bio-oil (oxygen content typically 35–40 wt.%) to quality transport liquid fuel requires full deoxygenation, e.g., by hydrotreating or catalytic vapor cracking over zeolite catalysts. Neither of these processes appears to be economically viable. The hydrotreating process is realized at high pressure and high temperature with sulfided CoMo or NiMo catalysts supported on alumina.

Very few chemicals produced from the fractionation of the bio-oil are already available. The most promising

are glycoaldehyde as a meat-browning agent and levoglucosan, which has potential in the synthesis of antibiotics and flavor compounds. Some phenols were even found in coal pyrolysis, which may produce high value specialty chemicals. Specialty chemicals generally require further work to develop reliable low-cost separation procedures.

Fluid coking is a thermal cracking process developed by Exxon (now ExxonMobil) in which heavy residual hydrocarbons, heavy oils, or bitumen derived from oil sands are upgraded in fluidized bed reactors at high temperatures and moderate pressures. The hydrocarbon to be upgraded is fed as a liquid. The lower-molecular-weight product is withdrawn at the top, while heavy ''coke'' coats the particles. The coke particles are then extracted near the bottom, after being passed through a stripper in which steam removes liquid hydrocarbon from the surfaces of the particles. The coke particles are circulated to a combustion chamber where the exothermic heat of reaction heats the coke particles, some of which are then recirculated to the fluid coker to provide the heat needed by the endothermic thermal pyrolysis reactions.

Calcination

An early fluid bed calciner for limestone and dolomite, built by England Lime Company in 1949, was 4 m in diameter, 14 m tall, and operated at 1000°C. As the reactions are highly endothermic and both the gas and solid exit at high temperature, several attempts were made to save energy, including multistaging and combining a calciner with suspension preheating.[4]

In the late 1960s, Lurgi adopted the CFB for calcination of alumina trihydrate. Design studies have shown that CFBs can be applied for capacities as high as ~1000 t/day. A high degree of automation, economy of space, and a simplified process flowsheet are important design criteria.

Apatitic rock phosphates (a poor-quality phosphate) are commonly calcined in fluidized beds (with one, two, or even three stages) to remove impurities (carbonates, water, and organic matter) and to increase phosphorus concentration. The hydrocarbon content (up to 5%) of this phosphate provides most of the heat needed for calcination. Increasing the process temperature improves the upgrading of the ore, but decreases the agronomic effectiveness in direct application to soils. This operation has a maximum temperature of ~900°C.[30]

Roasting

Roasting is often used in the metallurgical industry to convert mineral sulfides into oxides or other compounds such as sulfates suitable for further treatment and recovery of metals. Oxides and sulfates are readily dissolved in leach solutions, while sulfides only dissolve with great difficulty. In these pyrometallurgical processes, sulfide ores as fine particles (100–500 μm) are normally roasted to oxides in fluidized beds at 600–1000°C. The residence time of the solids is around a minute, and short circuiting of solids must be avoided. Fluidized bed roasters are widely used, especially for zinc sulfide ores, which account for >80% of all zinc production. As the reactions are exothermic, the temperature is kept constant by direct (water addition) or indirect (immersed cooling tubes) heat exchangers. In the late 1950s, Dorr-Oliver designed the first fluidized bed roaster producing SO_2 from pyrite, zinc blend, and sulfide ores. The roaster was 5.5 m in diameter and 7.6 m high; it operated at 700°C and superficial gas velocities of 0.45–0.5 m/s.

Pyrometallurgical processes operating at high temperatures are usually associated with expensive emissions control, as dioxins, chloride compounds, and mercury can be generated. Competitive technologies include hydrometallurgical operations. In such processes, pressure reactors (autoclaves) are gaining acceptance for the leaching of ores and concentrates, and in the recovery of metals from leach solutions. To continue to be attractive, pyrometallurgy faces two major challenges: reducing environmental emissions and increasing the capacity of existing plants. Although many plants attempt to increase the roasting capacity by applying an oxygen-enriched roasting condition, optimization of the concentrate flow and the process hydrodynamics is an alternative way to improve capacity, versatility, and stability. Improvements in mass/heat transfer in conventional fluidized beds have led to numerous innovative reactor configurations. One example is the toroidal fluidized bed developed by Torftech for sulfide ore roasting. This roaster has a fixed annular gas distributor consisting of angled blades, which force the particles into a toroidal motion that enhances heat/mass transfer, even at low gas velocities.[31]

Other Processes

Ultrapure silicon and iron ore reduction

Silicon of exceptional purity for semiconductor and photovoltaic industries is obtained from metallurgical-grade silicon or liquid silicon tetrachloride. At least four of six steps involve fluidized beds. In Osaka Titanium's process, step 1 (obtaining $SiHCl_3$ from Si and HCl) takes place at 300°C, whereas in the Union Carbide process, $SiHCl_3$ is obtained by hydrogenating gaseous $SiCl_4$ over $CuCl_2$ catalyst at 500°C. Other

noncatalytic gas–solid hydrogenation reactions are also carried out in fluidized beds. For example, Bethelem Steel developed the H-Iron process. Alan Wood Steel, Kawasaki Iron and Steel, and others have developed processes that produce iron by reducing fine iron oxides in a single stage at ~700°C. Other processes for iron ore reduction with hydrogen include the Stelling process to form cementite and the Armco or Exxon process with multistage reactors.[4]

Chlorination and fluorination of metal oxides

These reactions are in some cases the only way to obtain highly purified metals such as titanium and U-235. The chloride process, in which $TiCl_4$ is produced from titaniferous feedstocks, chlorinated in the presence of solid carbon at 950–1150°C in a BFB, is of significant importance in producing titanium metal and TiO_2 pigments. A recent techno-economic study identified the potential of a CFB reactor for the chlorination of fine slag, which can be obtained at lower cost than standard chloride-grade slag.[32]

Nano- and ultrafine particles

Several fluid bed processes are under development for production and encapsulation of nanoparticles, for example, WC-Co composites, bioceramics (i.e., calcium phosphate hydroxyapapite), carbon encapsulation of iron magnetic nanoparticles, and carbon nanotubes. These nano- or ultrafine powders have broad industrial and pharmaceutical applications. Production processes usually include solution preparation (sol–gel), drying, calcination, and sintering. The last three steps may be realized in a fluidized bed, but fluidization of nano- and ultrafine powders is very difficult because of strong interparticle forces.

LIQUID–SOLID REACTIONS IN FLUIDIZED BEDS

Liquid-fluidized beds predate gas-fluidized beds, but they have considerably fewer applications because of a smaller number of advantages. Most applications are physical,[33] with bioreactors being the sole significant reactor application. Much of the recent attention has focused on aerobic wastewater treatment and fermentation processes, e.g., with methane as the organic substrate (see Refs.[34,35] for more details). In these processes, microbial cells are attached to the surface of inert particles (e.g., sand or activated carbon) as a biofilm, or trapped within the pores or interior of particles, causing the particle size and/or density to vary with time. Loaded particles therefore have different fluidization characteristics, and this difference can be used to separate product from fresh particles to recover the biomass.

Advantages of liquid fluidization include lack of plugging, reduced pressure drops, good heat and mass transfer, favorable surface area, and ability to readily separate excess biomass. The fluidization may be upward, or downward (referred to as ''inverse fluidization'') when the particles have a lower density than the liquid. Tapering may be used to reduce entrainment. Various configurations, including circulating beds,[36] are possible.

GAS–LIQUID–SOLID (THREE-PHASE) CHEMICAL PROCESSES IN FLUIDIZED BEDS

In gas–liquid–solid (three-phase) fluidized beds, solid particles are simultaneously contacted with both gas and liquid. The gas and liquid may flow cocurrently upward, or the liquid may descend, while the gas rises. The liquid usually forms the continuous phase in which the solid particles and gas bubbles are dispersed. The bubbles are larger when the particles are smaller, and bed contraction can occur when gas is introduced into a liquid-fluidized bed of fine particles. Higher pressures lead to smaller bubbles and increased gas hold-ups.

Advantages of three-phase fluidized beds over trickle beds and other fixed bed systems are temperature uniformity, high heat transfer, ability to add and remove catalyst particles continuously, and limited mass transfer resistances (both external to the particles and bubbles, because of turbulence and limited bubble size, and inside the particles owing to relatively small particle diameters). Disadvantages include substantial axial dispersion (of gas, liquid, and particles), causing substantial deviations from plug flow, and lack of predictability because of the complex hydrodynamics. There are two major applications of gas–liquid–solid-fluidized beds: biochemical processes and hydrocarbon processing.

Biochemical Processes

Three-phase fluidized beds can be used as bioreactors for aerobic biochemical processes, including both fermentation processes and wastewater treatment. The gas phase is air, required for biological growth, while the solid particles provide immobilized surfaces on or in which cell growth can occur. The aqueous liquid phase provides the culture medium needed for the growth and maintenance of the cells. Air may be introduced separately from the liquid, or be premixed with the aqueous medium. The liquid medium may exhibit non-Newtonian rheology. A disadvantage of three-phase

fluidization for some processes, e.g., those involving mammalian cells, is that fluidization results in significant shear stresses, which may disrupt or damage the cells. Extensive background information, literature references, and a summary of recent advances in understanding three-phase hydrodynamics are provided by Fan[34,37] and Wright and Raper.[38] Various geometries are possible, for example, tapered columns, draft tubes, and external circulation.[34]

Wastewater treatment is relatively simple in that the sole purpose is the degradation of all the organic species present in the liquid to remove both biological oxygen demand (BOD) and chemical oxygen demand (COD). Three-phase fluidization is also of interest for bioremediation of contaminated soils. Production of alcohols by fermentation (e.g., ethanol from glucose) has been practiced commercially. Other fermentation processes have been examined for production of enzymes, acetic acid, stem cells, monoclonal antibodies, antibiotics, and other pharmaceutical products.

Hydrocarbon Processing

A number of energy-related processes have been developed employing three-phase fluidization. Early examples were in coal liquefaction and hydrogenation. In the 1960s and 1970s, there was significant activity to develop three-phase fluidization processes, including the H-Oil, H-Coal, and LC-Fining processes. The latter remains in commercial operation, and practical aspects have been described in the literature.[34,39] The reactor in this case is called an ''ebullated bed.'' Hydrogen gas is bubbled through a heavy hydrocarbon liquid (e.g., a residue, heavy oil, or bitumen) at elevated temperature ($>400^{\circ}C$) and pressure ($>10\,MPa$) in the presence of solid catalyst particles. Complex reactions including thermal cracking, hydrocracking, and hydrodesulfurization occur, leading to an upgraded product with a higher H/C ratio. Fresh catalyst is added periodically to maintain the overall activity level. Efforts to resolve practical problems in a large industrial unit have been described by McKnight et al.[39] A more recent development is the liquid-phase methanol synthesis process where syngas is reacted to produce methanol in a catalyst-inert oil slurry.

FLUIDIZED BED REACTOR MODELING

Considerable effort has been expended to devise models for fluidized bed reactors. These models differ greatly in complexity. It is important to adopt a model with the optimum degree of sophistication, complex enough to capture the mechanistic elements affecting the principal aspects of concern, but not so complex that they contain features whose inclusion is not justified in view of the uses to which the model will be put.

Models that are entirely empirical are seldom of much value for fluidized bed reactors, given the hydrodynamic complexity and the large number of variables. The simplest mechanistic models treat the reactor as simple single-phase vessels (well-mixed or plug flow) and have little relation to reality. Two-phase models were developed beginning in the 1950s and 1960s, with bubbling beds primarily in mind. In such models, reviewed in a number of studies (e.g., in Refs.[1,4,40]), the bed is divided into two parallel one-dimensional paths, one of high voidage (e.g., to represent the bubble phase) and the other of much lower voidage (representing the dense phase). Mole balances are then written for each phase, incorporating interphase mass transfer between the phases, as well as terms to account for the reaction(s). The predicted performance is then dependent on the interphase transfer, as well as the fraction of solids, total volume of each phase, gas flow assigned to each phase, and chemical kinetics. Such models are widely used and have been quite successful for steady state fluidized bed gas-phase solid-catalyzed reactions.

The two-phase models have been extended to gas–solid reactions (e.g., in Refs.[1,4,40]), requiring that the mole balances also account for reaction of the solid phase and that the stoichiometry of the reaction be satisfied. Population balances may then be added to account for changes in particle size distribution. Single-particle reaction models (e.g., shrinking core model) may also be needed to account for changes in particle properties resulting from the reaction(s). Two-phase models have also been extended to other flow regimes—slugging beds (e.g., in Ref.[41]), turbulent beds (e.g., in Ref.[42]), and fast fluidization.[5] They also form the basis of a more generic probabilistic approach,[43] which covers the bubbling, turbulent, and fast-fluidization flow regimes.

In recent years, there has been considerable effort to develop computational fluid dynamic (CFD) models to predict the hydrodynamics and performance of fluidized beds. While this approach will no doubt yield valuable tools in the future, CFD models are not yet at the point where they can be used with confidence for design and scale-up of fluidized bed processes.

CONCLUSIONS

Few fluidized bed reactors in practice operate in the bubbling regime.[18] The trend is toward higher gas velocities. Numerous potential applications of circulating fluidized bed technology as a catalytic reactor have been listed.[44] Improved understanding of the flow inside fluidized beds is reducing the risk associated with scale-up and leading to new processes.

A promising area involves integration of product separation with reaction by using fluidized bed membrane reactors, where semipermeable membranes, immersed in the bed, allow selective withdrawal of products like hydrogen, or distributed introduction of reactants like oxygen. Continuous product removal can overcome reaction equilibrium limitations of industrially important reactions such as steam methane reforming.[45] Controlled addition of oxygen through membranes can also enhance selectivity to desired products and reduce the risk of explosions in catalytic partial oxidation reactions.[46]

Other areas for future development captured in this entry are nanoparticle processes, the development and validation of CFD, and other advanced reactor models for fluidized beds. In addition, incremental improvements in fluidized bed processes will be made, helping to ensure that fluidized beds continue to gain ground as reactors in many industries.

INTRODUCTION

Fluorescence provides a good noncontact thermometry technique in hostile environments such as those found at high temperatures. Phosphors are typically rare earth-doped ceramics that emit light when excited. The intensity, rise time, decay time, and wavelength shift of this emitted light can be temperature dependent. When thermographic phosphors are applied to a surface, with an excitation source and a method to characterize the emission provided, it is possible to determine the surface temperature. One of the simpler methods to apply these coating is through the use of temperature sensitive paints (TSPs). These TSPs are created by mixing phosphor with a binder material to form a sprayable coating, which can be easily and economically applied to a large area. Ideally, these phosphor paints need to survive at the limit of the existing decay time data, or 1700°C. The survivability of phosphor paint depends on the physical characteristics of the binder. The goal of this research is to discover binders that will allow phosphor paints to survive at high temperatures. Suitable binders will allow the construction of noncontact measurement devices useful in environments that are not suited for more common thermocouple or infrared devices. For a phosphor paint to be useful at a selected temperature, it must fluoresce when excited and have a measurable decay time.

BACKGROUND

Phosphors are fine powders that are doped with trace elements that give off visible light when suitably excited. Many of these phosphors have a ceramic base and can survive and function at high temperatures such as those present during combustion. When phosphor is applied as a thin coating, it quickly equilibrates to the ambient environment and can be used to measure the surface temperature.

The basic physics of thermographic phosphors is well established, and researchers at Oak Ridge National Laboratory (ORNL) have demonstrated several useful applications.[1–14] The thermometry method relies on measuring the rate of decay of the fluorescence yield as a function of temperature. Having calibrated the phosphor over the desired temperature range, a small surface deposit is excited with a pulsed light source. The resulting fluorescent decay (typically in less than 1 ms) time is measured to calculate the temperature of the substrate. In many instances, (e.g., in a continuous steel galvanneal process) a simple puff of powder onto the surface provides an adequate fluorescent signal.[1,2]

Often temperature measurements are made using thermocouples or optical pyrometry. However, in situations where rapid motion or reciprocating equipment is present at high temperatures, it is best to use other techniques. For many phosphors, the prompt fluorescence decay time (τ) varies as a function of temperature and is defined by:

$$I = I_0 \exp\left(-\frac{t}{\tau}\right) \quad (1)$$

where I is the fluorescence light intensity (arbitrary units), I_0 the initial fluorescence light intensity

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120008045

(arbitrary units), t the time since cessation of excitation source (s), and τ the prompt fluorescence decay time (s).[1,2]

The time needed to reduce the light intensity to e^{-1} (36.8%) of its original value is defined as the prompt fluorescence decay time. An example of this quantity for several thermographic phosphors is shown in Fig. 1. Notice the fluorescence decay time decreases by four orders of magnitude when the temperature increases from 600 to 1100°C.

This entry gives an overview into research to find binder and phosphor combinations that can emit fluorescence and remain mechanically viable at temperatures as large as 1700°C. Emphasis will be placed on developing procedures and techniques for the application and the pretreatment of candidate binder and phosphor combinations.

HISTORY

In May 2001, a research program was initiated to evaluate temperature sensitive paints (TSPs) that could be used in high temperature thermometry applications. This three-year program was funded by the NASA John H. Glenn Research Center in Cleveland, Ohio. A research team lead by ORNL was assembled to locate binder and phosphor combinations that can emit fluorescence and maintain structural integrity at high temperatures. The ultimate goal for this research was to locate TSPs that could be used to measure the heat flux and temperature present inside a common turbine or rocket engine. The phosphors in question are typically rare earth compounds that emit copious

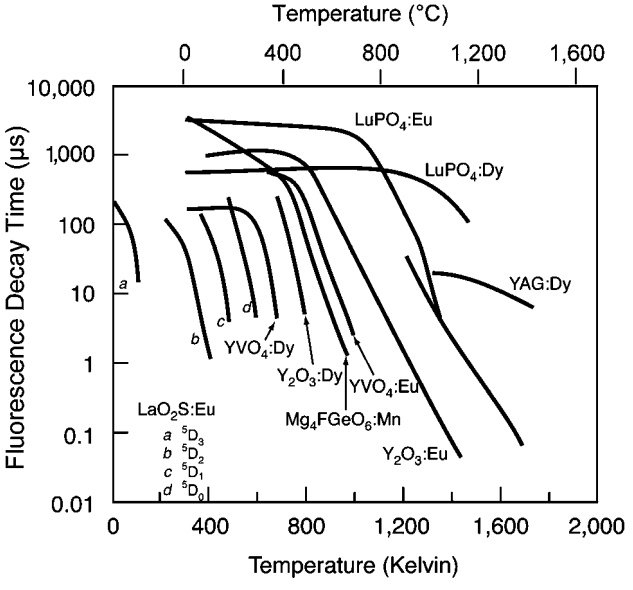

Fig. 1 Prompt fluorescence decay time for a selection of phosphors.

fluorescence and have grain sizes of less than 10 μm. Binders used for this purpose must: 1) be easy to apply with an airbrush; 2) set to a temperature resistant inorganic finish; and 3) have minimal reaction to the phosphor material.

During the first year of the program, research was completed to determine if heat flux could be measured using a phosphor coating. From the second to the fourth year, research was completed to find phosphor and binder combinations that can emit light and remain mechanically viable at high temperatures.

HEAT FLUX MEASUREMENTS

Measurement of prompt fluorescence decay time can be correlated with temperature to determine the amount of heat flux present in the sample environment. In the simplest sense, heat flux is proportional to the temperature difference on both sides of a homogeneous slab. By measuring these temperatures, it is a simple matter to determine the heat flux across any gradient. To measure the heat flux passing through a selected region, it will be necessary to simultaneously excite the phosphor on both surfaces of the material slab. The best excitation source for this task is the pulsed laser, since it emits a desired wavelength of coherent light with a large power density. Lasers should have sufficient power to excite the phosphor paint through the thickness of the gauge material.

This initial effort was designed to determine if fluorescence from two candidate phosphors could be detected through several single crystal and polycrystalline yttrium stabilized zirconia (YSZ) samples. YSZ samples in this research are divided into crystal and polycrystalline forms. The YSZ compound is a combination of approximately 90% zirconium oxide (ZrO_2) and 10% yttrium oxide (Y_2O_3). The single crystal YSZ samples have a density of 5.8 g/cm^3 with a lattice constant of 0.541 nm. The polycrystalline YSZ samples have a density of 6.6 g/cm^3 with thickness of 0.11, 0.16, and 0.20 mm. A thin layer of graphite was applied to one side of each polycrystalline YSZ sample to add strength. After application of the phosphor paint, each polycrystalline sample was heated to 800°C for 8 hr to remove the graphite. This heating cycle also cured the water-based phosphor paint. Detailed information on this research can be found in Refs.[6–8].

Yttrium aluminum garnet ($Y_3Al_5O_{12}$–YAG) doped with europium (Eu) and cerium (Ce) was used as the active phosphors for this research. The YAG : Eu phosphor glows bright orange when irradiated with a standard ultraviolet light. Emission peaks at wavelengths of 592, 610, 631, 697, and 710 nm are clearly visible in the YAG : Eu spectrum. Conversely, YAG : Ce glows bright green when irradiated with

ultraviolet radiation. The fluorescence emission is centered at 510 nm with a full width at half maximum of about 150 nm.

A mixture of 50% HPC® and 50% LK® (by volume) was used as a binder for each phosphor paint. Both the HPC and LK binders are manufactured by Zyp Coatings, Inc., Oak Ridge, Tennessee. When cured, HPC is not reactive and is composed of magnesium aluminum silicate. Engineers at Zyp indicate that HPC will withstand temperatures of about 1400°C. HPC is water based and has a shelf life of 12 months. The LK binder is not reactive and is composed 75% SiO_2, 20% K_2O, and 5% Li_2O. Engineers at Zyp indicate that LK will withstand temperatures of about 1100°C if additional fillers are added to the mix. LK is also water based and has a shelf life of 12 months. The selected HPC and LK paint is a good combination for this research. By itself, HPC is thick and difficult to spray. Conversely, LK by itself cannot be used safely above 1000°C. The selected combination is easy to spray and provides consistent results to temperatures in excess of 1000°C.

The sample matrix used in this research can be found in Table 1. Both the single crystal (set I) and polycrystalline (set II) samples were coated with a paint containing about 20% YAG : Eu by volume. The set III polycrystalline samples were coated with a paint containing approximately 20% YAG : Ce by volume. Fluor pigments and the HPC/LK binder was well mixed before application. Paint was applied to the each YSZ sample using a standard airbrush. Each sample was kept warm on a hotplate during the spraying process to help evaporate the water from the binder. Paint uniformity was checked using an ultraviolet lamp. The paint thickness for this research was estimated to be approximately 0.025 mm (1 mil). At the conclusion of the spraying process, samples were heated to 800°C to set the binder.

Opposite halves of each YSZ crystal piece were coated with YAG : Eu paint mixture. This procedure was accomplished to allow the YAG : Eu to be excited through the thickness of the YSZ. The number of edges visible on the painted phosphor surface can identify the polycrystalline samples. A simple cardboard and tape mask was used during the spraying process to make a straight edge on the YSZ surface. When illuminated with an ultraviolet lamp, both sets of samples clearly show two, one, and zero edges. These edges correspond to YSZ thicknesses of 0.20, 0.16, and 0.11 mm respectively. The surface of the painted YAG : Eu samples was bright white. However, the surface of the painted YAG : Ce samples was light green. The surface of the unpainted YSZ was light beige in color.

A PerkinElmer LS-50B spectrophotometer was used to determine if fluorescence emission could be imaged through two different thicknesses of YSZ. Painted crystal samples were imaged using an excitation light source with wavelengths of 355, 405, and 532 nm. Emission lines from YAG : Eu have the highest intensity for the 405 nm excitation source. All the YAG : Eu emission peaks are clearly visible using the 405 nm excitation source. The same YAG : Eu emission peaks are also faintly observed using the 355 nm excitation source. No peaks were observed using the 532 nm excitation source.

The goal for this analysis was to measure the prompt fluorescence decay time for each polycrystalline YSZ thickness. Results from this analysis are shown in Table 2. Visible fluorescence was observed through all three YSZ thicknesses at each of the tested laser wavelengths. It was not possible to measure the prompt fluorescence decay time for YAG : Eu because the reduction of light intensity did not follow a simple exponential curve. This phenomenon is most likely caused by electrical noise, stray light, or the absorption and re-emission of fluorescence from the YSZ.

The average prompt fluorescence decay time for YAG : Ce was measured to be 62.7 ± 2.9 ns. The accepted value for YAG : Ce of 65 ns falls within the uncertainty of these measurements.[15] It should be noted that the prompt fluorescence decay time for YAG : Ce was measured through several thicknesses of YSZ.

Table 1 YSZ and phosphor sample test matrix

Set	YSZ sample	Sample identifier	YSZ thickness (mm)	Phosphor	Phosphor ratio (vol.%)
I	Single crystal	One	1.00	YAG : Eu	20
		Two	0.25		
II	Polycrystalline	Zero	0.11	YAG : Eu	20
		One	0.16		
		Two	0.20		
III	Polycrystalline	Zero	0.11	YAG : Ce	20
		One	0.16		
		Two	0.20		

Table 2 Polycrystalline YSZ results

Phosphor paint	Excitation laser wavelength (nm)	YSZ thickness (mm)	Observed fluorescence (YSZ side)	Measured fluorescence decay time (τ)
YAG : Eu	405	0.11	Very faint	None
		0.16	Very faint	None
		0.20	Very faint	None
	532	0.20	Strong	Not valid
YAG : Ce	355	0.11	Faint	57.5 ± 0.2 ns
		0.16	Faint	None
		0.20	Faint	None
	532	0.16	Strong	63.1 ± 0.2 ns
		0.20	Strong	67.5 ± 0.3 ns

ZYP COATINGS SURVIVABILITY RESEARCH

Three binders, HPC, LK, and ZAP®, from Zyp Coatings, Inc., Oak Ridge, Tennessee, were used during the second year of the program. Each of these three binders was designed for use in high temperature applications and are available in the commercial market. Three other binders were tried during the initial stages of this research. None of these other binders were found to be viable above 1200°C and were dropped from future trials. Detailed information on this research can be found in Refs.[9–12].

When cured, the ZAP binder coating is composed of 53.5% P_2O_5 and 46.5% Al_2O_3. The maximum recommended use temperature for this formulation is 1800°C. It is water and alcohol based with a shelf life of 12 months. The sprayed coating dries at room temperature in 15–20 min after application. ZAP is a hard coating that can be used in any atmosphere. Heating to 900°C for 60 min cures the ZAP binder without organic ash.

A selection of rare earth compounds is used for the phosphor powders in this research: yttrium oxide doped with europium (Y_2O_3 : Eu), and YAG doped with dysprosium (YAG : Dy), thulium (YAG : Tm), and europium (YAG : Eu). The dopant concentrations are typically a few percent by mass. A selected binder and phosphor powder are mixed together to create a strong and durable paint. A maximum of 50% phosphor powder by volume was added to each mixture. Paint mixtures were sprayed on a clean 25 mm × 25 mm (1 in. × 1 in.) ceramic card and cured based on specific binder instructions. Paint uniformity was checked using black light inspection during application. All samples were inspected after the cure cycle before being exposed to the high temperature environment for 1 hr. After curing and before thermal cycling, a PerkinElmer LS-50B spectrophotometer was used to determine the baseline fluorescence spectrum for each paint sample. After each thermal cycle the paint sample was reanalyzed using the LS50-B.

Results from these measurements can be found in Table 3. Each paint combination was exposed to the high temperature listed in Table 3 for 1 hr and then slowly cooled. The heating rate was kept small to minimize effects because of the difference in expansion coefficient between the paint and the ceramic substrate.

Results shown in Table 3 show that most of the HPC/LK bound samples survived heating to 1400°C. Most of the paints were removed from the surface of the ceramic at 1500°C. These data also shows that paint consisting of a 100% ZAP binder and 30% YAG : Dy powder by volume is intact and emits fluorescence after heating to 1500°C. This paint surface did look bumpy or mottled after heating. The other ZAP paints were also intact, but with reduced fluorescence. In fact, the 100% ZAP and 30% by volume YAG : Dy paint was also found to emit fluorescence after heating to 1600°C.

COTRONICS COATINGS SURVIVABILITY RESEARCH

During the third and final year of the NASA-Glenn research, several Resbond® ceramic binders manufactured by Cotronics Corporation of Brooklyn, New York, were evaluated using a powdered Y_2O_3 : Eu phosphor. The main fluorescence emission from Y_2O_3 : Eu occurs at a wavelength of 611 nm. Selected material and preparation properties for the tested Resbond binders are given in Table 4. The Cotronics series of ceramic binders includes six different formulations. Of these, only the four varieties listed in Table 4 were tested. During initial research, Cotronics Resbond 795 did not adhere to the surface. Since the other two binders have similar

Table 3 Binder and phosphor paint survivability results

	Paint			Phosphor emission				
Binder (composition)	Fraction(vol.%)	Phosphor	Emission lines (nm)	1200°C	1300°C	1400°C	1500°C	Comments
100% HPC	20	Y_2O_3 : Eu	611			Yes	Yes	Paint mostly gone after heating to 1500°C
100% HPC	10	Y_2O_3 : Eu	611			Yes	Yes	Paint mostly gone after heating to 1500°C

properties, it was considered more productive to focus on the three remaining binders. Detailed information concerning this research can be found in Refs.[13,14].

SAMPLE PREPARATION

To create the TSPs, phosphor powder is mixed with ceramic binder. The compositions for paint samples used in this research are shown in Table 5. Typically, the phosphor powder accounts for 20 vol.% of the paint mixture. In some cases, 10 vol.% of a second powder such as magnesium oxide (MgO_2) is added displacing the binder. This addition is an attempt to increase the thermal conductivity. The paint preparation procedure began by measuring the powdered solids in a graduated capped vial. Individual tubes were vibrated to insure proper volume measurement.

Table 4 Properties for selected Cotronics Resbond ceramic binders

Resbond composition	791 Silicate glass	792 Silicate glass	793 Silica oxide	795 Alumina oxide

791	35	Y_2O_3 : Eu	20	35	10
	40			40	0
	70			0	10
	80			0	0
792	70	Y_2O_3 : Eu	20	0	10
	80			0	0
793	80	Y_2O_3 : Eu	10	0	10
			20	0	0

Liquids were then added in predetermined amounts. After all the components were added to the cylinder, they were mixed by vigorously by shaking the capped vial. The mixture was applied to the surface of a cleaned alumina substrate using a commercial air-brush. The TSPs were allowed to cure according to the manufacturer's specifications as shown in Table 6. In the case of Resbond 791, water was added to thin the mixture to make it easier to apply using the air-brush. However, the undiluted Resbond 791 paints were applied using a brush, since spraying was difficult and it did not give the desired uniform coating.

EXPERIMENTAL METHOD

To determine the survivability for a TSP, samples were thermally cycled in a Thermoline 46200 high-temperature furnace. The furnace controls were set to raise the temperature to some predetermined value. The sample was then allowed to remain at this high temperature for 1 hr or more, followed by cooling to ambient room conditions. To quantify the fluorescence efficiency of phosphor suspended in the TSP, a Perkin Elmer LS-50B spectrophotometer was used to measure the emission spectrum of the sample after each thermal cycle. For each TSP mixture, two samples were made. The first sample was heated through the curing cycle and used as a control. The second was thermally cycled by heating to a set temperature and allowing it to cool back to room temperature. After the sample cooled, the emission spectrum was measured. Fig. 2 shows the variation in the emission spectrum for a Resbond 793 and Y_2O_3 : Eu-based TSP after thermal cycling at several different temperatures. It is quite obvious that fluorescence intensity for the 611 nm emission line decreases as a function of temperature. In fact, the 611 nm fluorescence emission is reduced to the background level after thermal cycling at 1600°C. The TSP fluorescence spectrum shown in Fig. 2 contained 80% Resbond 793 and 20% Y_2O_3 : Eu by volume. After thermal cycling, TSP samples were analyzed under a ultraviolet light to qualitatively estimate the intensity of the remaining 611 nm fluorescence from Y_2O_3 : Eu.

QUALITATIVE RESULTS

Qualitative results for the Resbond binder and Y_2O_3 : Eu TSP samples are shown in Table 6. Notice that all of the tested TSP samples showed some fluorescence after thermal cycling to 1300°C. Fluorescence was also observed for all but one TSP sample at 1400°C. Only three TSPs made with Resbond 792 and 793 showed significant fluorescence at 1500°C. Finally, fluorescence was observed after exposure to 1600°C for one TSP containing 20% Y_2O_3 : Eu and 80% Resbond 793 by volume. These results are consistent with

Table 6 Qualitative results for the Resbond binder and Y_2O_3 : Eu TSP samples

earlier TSP research completed during the second year of the NASA-Glenn program.[9–12] As a group, it appears that TSPs made with Zyp binders were better able to withstand slightly higher temperatures compared to the ones made using any of the three tested Cotronics Resbond formulations. However, selected Zyp and Cotronics based TSPs were both able to survive to 1500°C.

QUANTITATIVE RESULTS

A quantitative determination of fluorescence intensity as a function of cycling temperature is more complex. It was decided to use a ratio of 0.2 (20%) of the maximum emission intensity as the criteria to determine the viability of fluorescence for a given TSP sample. If the fluorescence emission is small, it will be difficult to measure the decay time and obtain a corresponding surface temperature. There will come a point in intensity where a phosphor system cannot be used to measure temperature. The decision ratio of 0.2 was completely arbitrary and was based on the observation that the apparent fluorescence measurement uncertainty was about ±10% (intensity fraction of 0.1), which was two times the measured error for the 611 nm line for Y_2O_3 : Eu.

For each tested TSP, the spectral fluorescence intensity was measured using a PerkinElmer LS-50B spectrophotometer and an ultraviolet excitation source. In each case, the fluorescence was normalized to the Y_2O_3 : Eu maximum emission line at 611 nm. Samples were held at temperature for 1 hr, unless otherwise indicated.

Resbond 791

The evaluation of the Resbond 791 binder was complicated by its large viscosity. This required modifying the application procedure by either applying the paint with a standard bristle brush, increasing the supply pressure to the airbrush, or by thinning the binder. Since the other evaluated Resbond binders had smaller viscosities, it was felt that applying the thick paint with a brush and thinning of binder would provide a more equitable comparison. As such, the Resbond 791 binder was thinned in a one-to-one ratio with water, which aided in the application of the paint. Quantitative results for the Resbond 791 binder TSP are shown in Fig. 3.

Tests were performed using brushed-on paints. These coatings were thicker than the airbrushed coatings, but appeared to have the same maximum cycling temperature. The plot on the left side of Fig. 3 (labeled A) shows the normalized fluorescence emission (611 nm) for the brushed-on Resbond 791 paint vs. cycling temperature. The brushed-on TSP maintained a normalized peak emission greater than 0.2 to cycling temperatures up to 1600°C. The emission intensity decreased consistently from 1300 to 1500°C.

The plot on the right side of Fig. 3 (labeled B) shows the normalized fluorescence emission (611 nm) for the airbrushed (diluted) Resbond 791 paint vs. cycling temperature. The normalized emission spectra for the diluted sample was similar to that measured for the brushed-on TSP. It is interesting to note that the intensity of the brushed-on samples decreases slightly faster than the diluted TSPs, which could be partially caused

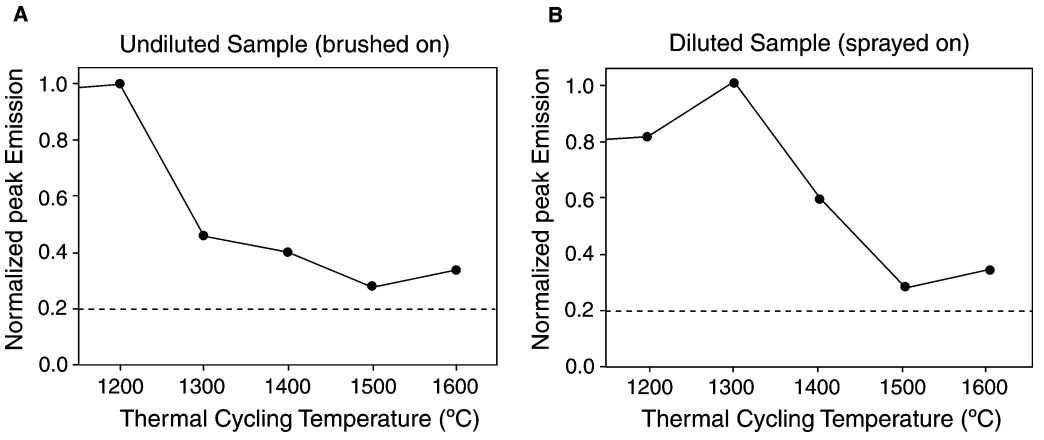

Fig. 3 Normalized emission for brushed-on and sprayed on Resbond 791 TSPs as a function of cycling temperature.

by differences in application method. The undiluted samples were brushed-on to the substrate surface, which typically does not provide even a coating. The uneven thickness could cause uneven heating and enhance flaking of the TSP.

Resbond 792

For all tested cases, the Resbond 792 TSPs falls below the 0.2 intensity criteria after the first thermal cycle (1100°C). Visual inspection of the samples in ultraviolet light indicates that there was a significant drop in emission intensity after 1100°C. These inspections also showed discernable fluorescence emission to 1300°C and limited fluorescence up to 1500°C. The dramatic drop in fluorescence intensity would tend to indicate that the Resbond 792 is not suitable for high-temperature TSP applications.

Resbond 793

Quantitative results for the Resbond 793 binder TSP are shown in Fig. 4. The Resbond 793 TSP maintained a normalized peak emission greater than 0.2 to cycling temperatures up to 1500°C. The corresponding 611 nm normalized peak emission decreased uniformly from 1200 to 1600°C. Visual inspection of the samples indicates that the coating remains relatively bright to 1400°C. At 1500°C, the coating is still bright, but starts to flake away from the surface. By 1600°C, almost all of the coating has flaked off of the surface, but the remaining portion was still discernable. Resbond 793

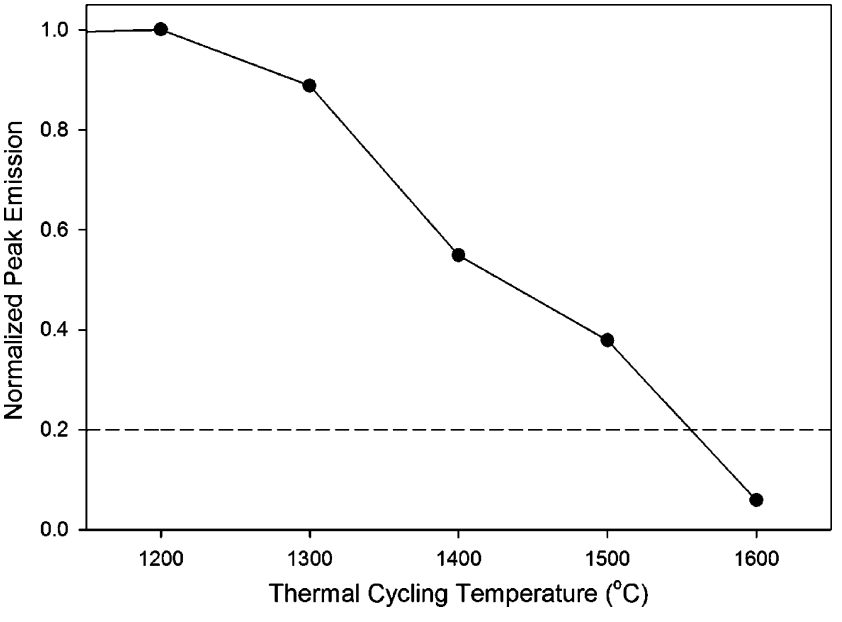

Fig. 4 Normalized emission for Resbond 793 TSP as a function of cycling temperature.

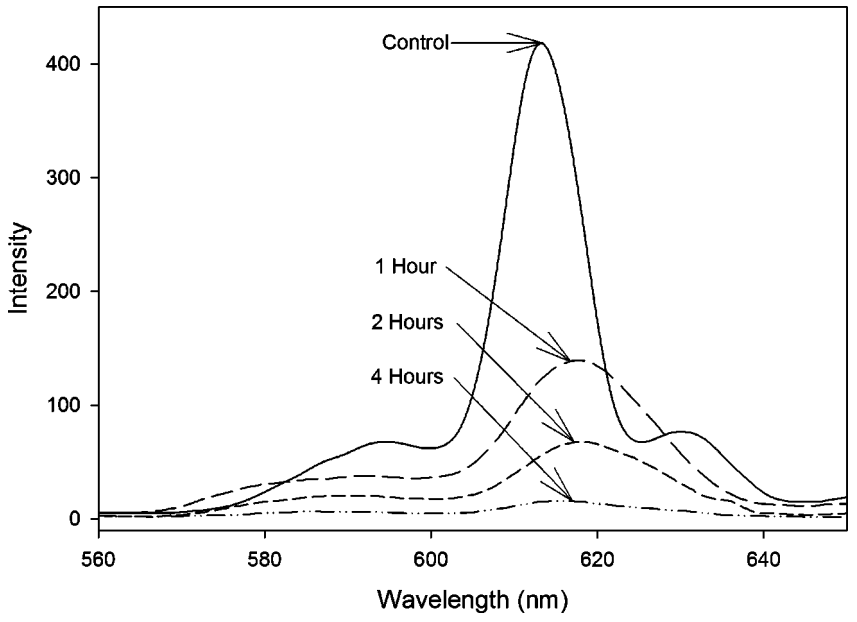

Fig. 5 Changes in fluorescence intensity for a Resbond 793 and Y_2O_3 : Eu TSP as a function of thermal exposure time.

has a low viscosity, which makes it easy to spray, and has the highest temperature survivability of any of the tested Cotronics binders. It appears to be the best of the tested materials for use in a TSP.

Temperature Exposure Time Dependence

The exposure time was originally selected because the anticipated test length was only a few seconds. It was felt that an hour of temperature exposure would well exceed the lifetime of any experimental test series. This exposure time was selected to make this work consistent with earlier research.[6–12] To date, no research had been completed comparing the effects of exposure time at temperature to the magnitude of fluorescence emission. It was decided to complete a series of tests with a single binder to determine the relationship between temperature exposure time and normalized emission intensity for a Y_2O_3 : Eu and Resbond 793 TSP.

To complete these tests, four new samples were prepared and cured as described in earlier sections. The first sample was held in reserve as the post cure control. The remaining samples were heated to 1400°C for 1, 2, and 4 hr. The 1400°C temperature was selected because nearly half of the room temperature fluorescence was emitted for this TSP in the previous test series. A separate sample was used in each duration test. The resulting emission spectra (ultraviolet excitation) for Y_2O_3 : Eu in a Resbond 793 binder with varied thermal cycling duration are shown in Fig. 5. After a 1-hr exposure, there is a noticeable decrease in fluorescence intensity. In fact, the decrease in intensity in the first hour of the test is surprising, as the previous results showed a 40% decrease, while this test had a nearly 70% decrease from the control. After 2 hr, there is further decrease in intensity to greater than 80% of the control, which indicates that the coating is marginal after 2 hr of exposure to 1400°C. After 4 hr, almost all the fluorescence is gone.

CONCLUSIONS

Recent research has shown that phosphor-based TSPs could be used for high temperature thermometry applications. Fluorescence from YAG : Eu and YAG : Ce could be detected through several thin YSZ samples. The average prompt fluorescence decay time for YAG : Ce was measured to be 62.7 $\pm$ 2.9 ns, which is close to the accepted value of 65 ns. This result can be used directly to develop an operational high temperature heat flux gauge.

Results also indicate that a 100% ZAP binder (Zyp Coatings) and 30% YAG : Dy (by volume) TSP will emit useful fluorescence to 1600°C. Other phosphors using the ZAP binder were found to be viable to 1500°C with reduced quantities of light emission. The Y_2O_3 : Eu phosphor and HPC/LK binder paint combinations were found to emit fluorescence to 1400°C. All of the tested Cotronics Resbond-based TSPs showed some fluorescence after thermal cycling to 1300°C. Fluorescence was also observed for all but one TSP sample at 1400°C. Only three TSPs made with Resbond 792 and 793 showed significant fluorescence at 1500°C. Fluorescence was observed at 1600°C for one TSP containing Resbond 793. In addition, Resbond 793 appears to have the best TSP characteristics of

the Cotronics binders, and it is one of the few binders that survives above 1500°C.

The temperature exposure time was found to be an important consideration for designing a TSP. After 2 hr of exposure at 1400°C, the fluorescence intensity decreases by 80%, which indicates the coating is of marginal use as a TSP. It appears that TSPs made with Zyp binders were better able to withstand slightly higher temperatures as compared to the ones made using any of the three tested Cotronics Resbond formulations. However, selected Zyp and cotronics based TSPs were both able to survive to 1500°C. Additional research is needed to further quantify these results.

Fluoropolymers

Sina Ebnesajjad
DuPont Fluoroproducts, Chestnut Run Plaza, Wilmington, Delaware, U.S.A.

INTRODUCTION

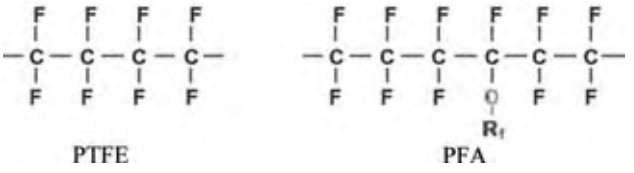
In this entry, fluoropolymer means a polymer that consists of partially or fully fluorinated olefinic monomers, such as vinylidene fluoride (CH_2=CF_2) and tetrafluoroethylene (CF_2=CF_2). Commercial fluoropolymers include homopolymers and copolymers. Homopolymers contain 99 wt.% or more one monomer and 1 wt.% or less of another monomer according to the convention by American Society for Testing Materials. Copolymers contain 1 wt.% or more of one or more comonomers. The major commercial fluoropolymers are based on tetrafluoroethylene, vinylidene fluoride, and to a lesser extent chlorotrifluoroethylene. Examples of comonomers include perfluoromethyl vinyl ether (PMVE), perfluoroethyl vinyl ether (PEVE), perfluoropropyl vinyl ether (PPVE), hexafluoropropylene (HFP), chlorotrifluoroethylene (CTFE), and perfluorobutyl ethylene (PFBE).

Fluoropolymers discussed include polytetrafluoroethylene (PTFE), perfluoroalkoxy polymer (PFA), fluorinated ethylene–propylene polymer (FEP), ethylene–tetrafluoroethylene copolymer (ETFE), ethylene–chlorotrifluoroethylene copolymer (ECTFE), polychlorotrifluoroethylene (PCTFE), polyvinylidene fluoride (PVDF), and polyvinyl fluoride (PVF).

In this entry, the classification, preparation, properties, fabrication, safety considerations, and economics of fluoropolymers are discussed. Monomer synthesis and properties have also been discussed. Increasing the fluorine content of a polymer increases chemical and solvent resistance, flame resistance, and photostability, improves electrical properties, such as dielectric constant, lowers coefficient of friction, raises melting point, increases thermal stability, and weakens mechanical properties.

FLUOROPOLYMER CLASSIFICATION

The era of fluoropolymers began with the serendipitous discovery of PTFE by Roy Plunkett of DuPont Company[1] while conducting research to find new refrigerants. A number of fluoroplastics have been developed since the discovery of PTFE. They are divided into two classes of perfluorinated and partially fluorinated polymers. Perfluorinated fluoropolymers are homopolymers and copolymers of tetrafluoroethylene (TFE). Some of the comonomers may contain a small amount of elements other than C or F. For example, PFA is a copolymer of TFE and perfluoroalkyl vinyl ether that contains oxygen. R_f is a perfluoroalkyl group of C_1 to C_4.



Partially fluorinated fluoropolymers contain hydrogen (H) or other atoms such as chlorine, in addition to fluorine and carbon. The most significant are homopolymers and copolymers of vinylidene fluoride (VDF). There are also copolymers and homopolymers of CTFE, although some have elastomeric properties. Other significant fluoroplastics include ETFE and PVF.

POLYMER DEVELOPMENT

Because of its high viscosity (10^{10}–10^{12} poise at 380°C), PTFE cannot be fabricated by melt-processing techniques. Melt-processible fluoropolymers have been developed by copolymerization of TFE, and FEP, a copolymer of TFE and HFP, has a lower maximum continuous use temperature than PTFE (200°C vs. 260°C) because of the deterioration of mechanical properties. Whereas, PFA, a copolymer of TFE with PPVE or PEVE, offers thermal stability, melt-processibility, and a maximum continuous use temperature of 260°C. Both FEP and PFA are considered perfluoropolymers.

Copolymers of ethylene with tetrafluoroethylene (ETFE) and chlorotrifluoroethylene (ECTFE) are mechanically stronger than perfluoropolymers, with some reduction in their chemical resistance and continuous use temperature and an increase in the coefficient of friction.

Amorphous copolymers of TFE are soluble in special halogenated solvents and can be applied to surfaces as a polymer solution to form thin coatings. The dried coating is as resistant to almost as many chemicals as PTFE is.[2]

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007773

MONOMER SYNTHESIS

Synthesis of Tetrafluoroethylene

The first reliable and complete description of synthesis was published in 1933 by Ruff and Bretschneider[3] in which they demonstrated the preparation of TFE (CF_2=CF_2, CAS number *116-14-3*) from the decomposition of tetrafluoromethane in an electric arc. Then TFE was obtained by bromination and separation of the dibromide (CF_2Br–CF_2Br) from the other reaction products. Dehalogenation with zinc was the next step for obtaining pure TFE. Commercially significant techniques for TFE preparation list Fluorspar (CaF_2), hydrofluoric acid, and chloroform as the starting ingredients,[4–11] as shown in the reaction sequence in Fig. 1.

Among other compounds produced are hexafluoropropylene and a small amount of highly toxic perfluoroisobutylene.

Sherratt[12] has provided a description of the preparation of TFE. The overall yield of TFE production depends on the pyrolysis reaction. The products of pyrolysis are cooled, scrubbed with a dilute basic solution to remove HCl, and dried. The resulting gas is compressed and distilled to recover the unreacted $CHClF_2$ and to recover high purity TFE. Polymerization of tetrafluoroethylene to a high molecular weight requires extreme purity, hence the removal of all traces of telogenic hydrogen or chlorine-bearing impurities. Tetrafluoroethylene can autopolymerize if it is not inhibited with terpenes, such as α-pinene, Terpene B, and D-limonene.[13]

HF preparation:

$$CaF_2 + H_2SO_4 \rightarrow 2HF + CaSO_4$$

Chloroform preparation:

$$CH_4 + 3Cl_2 \rightarrow CHCl_3 + 3HCl$$

Chlorodifluoromethane preparation:

$$CHC1_3 + 2HF \rightarrow CHClF_2 + 2HCl$$
(SbF_3 catalyst)

TFE synthesis:

$$2CHC1F_2 \rightarrow CF_2{=}CF_2 + 2HCl$$
(pyrolysis)

Fig. 1 Synthesis reactions of tetrafluoroethylene. (Courtesy of William Andrew Publishing, Inc.)

Synthesis of Hexafluoropropylene

Hexafluoropropylene (CF_3CF=CF_2, CAS number *116-15-4*) was first prepared by Downing et al.[14] by pyrolysis. The full synthesis and identification of HFP was conducted by Henne and Woalkes.[15] A six-step reaction scheme starting with the fluorination of 1,2,3-trichloropropane led to 1,2-dichlorohexafluoropropane, which was dehalogenated with zinc in boiling ethanol to yield hexafluoropropylene.

Synthesis of Perfluoroalkylvinylethers

Perfluoroalkylvinylethers, such as perfluoropropylvinylether (CF_2=CF–O–C_3F_7, CAS number *1623-05-8*) are synthesized according to the steps shown in Fig. 2. There are also electrochemical processes for the production of perfluoro-2-alkoxy-propionyl fluoride.[16]

Synthesis of Chlorotrifluoroethylene

This monomer is fairly simple to manufacture compared with the perfluorinated monomers.[17,18] The commercial process for the synthesis of CTFE (CF_2=$CClF$, 79-38-9) begins with 1,1,2-trichloro-1,2,2-trifluoroethane (TCTFE). It is dechlorinated by pyrolysis at 500–600°C in vapor phase. An alternative method for the preparation of TCTFE is catalytic dechlorination:

$$CCl_3-CCl_3 + HF \rightarrow CCl_2F-CClF_2 + 2HCl$$
(catalyst $SbCl_xF_y$)

$$CCl_2F-CClF_2 + Zn \rightarrow CFCl=CF_2 + ZnCl_2$$
(at 50–100°C in methanol)

The reaction products are put through a number of purification and distillation steps to remove the gaseous and liquid contaminants. Chlorotrifluoroethylene is further purified by the removal of methyl chloride, dimethyl ether, and water by passing the gas stream through sulfuric acid. Water and hydrochloric acid are removed by passing the CTFE through an alumina column before condensing it into a liquid.

Synthesis of Vinylidene Fluoride

There are numerous ways to prepare VDF (CF_2=CH_2, CAS number *75-38-7*). Two methods, including the popular commercial technique for VDF production, are described. Conversion of 1,1,1-trifluoroethane[19] begins by passing this gas through a platinum-lined Inconel tube, which is heated to 1200°C. Contact time is about 0.01 sec. The exit gases are passed through a sodium fluoride bed to remove the hydrofluoric

1. Hexafluoropropylene is converted hexafluoropropylene epoxy (HFPO) reacting HFP with oxygen under pressure in the presence of an inert diluent at 50-250°C or with an oxidizer such as hydrogen peroxide in a basic solution:[43,44]

$$CF_3CF{=}CF_2 + H_2O_2 \rightarrow CF_2{-}CF{-}CF_2 + H_2O \quad \text{(Basic Solution)}$$

HFPO

2. HFPO is reacted with a perfluorinated acylfluoride to produce perfluoro-2-alkoxy-propionyl fluoride:

$$CF_2{-}CF{-}CF_2 + R_f{-}C{=}O \rightarrow R_fCF_2OCF{-}C{=}O$$

Perfluoro-2-alkoxy-propionyl fluoride

3. Perfluoro 2-alkoxy-propionyl fluoride is reacted with the oxygen containing salt of an alkali or alkaline earth metal at an elevated temperature which depends on the type of salt. Examples of the salts include sodium carbonate, lithium carbonate, and sodium tetraborate:[45]

$$R_fCF_2OCF{-}C{=}O + Na_2CO_3 \rightarrow R_fCF_2OCF{=}CF_2 + 2CO_2 + 2NaF$$

Fig. 2 Synthesis of perfluoroalkylvinylethers. (From Ref.[16].)

acid and are then collected in a liquid nitrogen trap. Vinylidene fluoride is separated by low temperature distillation. Unreacted trifluoroethane is removed at −47.5°C and is recycled.

The commercial method begins with hydrofluorination of acetylene followed by chlorination,[20] by hydrofluorination of trichloroethane,[21] or by hydrofluorination of vinylidene chloride.[22] In each case, the final product, 1-chloro-1,1-difluoroethane, is stripped of a molecule of hydrochloric acid to yield vinylidene fluoride.

Synthesis of Vinyl Fluoride

Vinyl fluoride[23,24] was first prepared by the reaction of 1,1-difluoro-2-bromoethane [*359-07-9*] with zinc. Most approaches to vinyl fluoride synthesis involve reactions of acetylene [*74-86-2*] with hydrogen fluoride (HF) either directly or utilizing catalysts. Other routes involve ethylene [*74-85-1*] and HF, pyrolysis of 1,1-difluoroethane [*624-72-6*] and fluorochloroethanes, reaction of 1,1-difluoroethane with acetylene, and halogen exchange of vinyl chloride [*75-01-4*] with HF.[25–27]

MONOMER PROPERTIES

Properties of Tetrafluoropropylene

Tetrafluoroethylene is a colorless, odorless, tasteless, and nontoxic gas, which boils at −76.3°C and melts at −142.5°C. Critical temperature and pressure of tetrafluoroethylene are 33.3°C and 3.92 MPa. It is stored as a liquid; vapor pressure at −20°C is 1 MPa. Its heat of formation is reported to be −151.9 kcal/mol. Polymerization of tetrafluoroethylene is highly exothermic and generates 41.12 kcal/mol heat. The extent of which can be compared to the heats of polymerization of vinyl chloride and styrene, 23–26 and 16.7 kcal/mol, respectively.[28]

Safe storage of TFE requires its oxygen content to be less than 20 ppm. Temperature and pressure should be controlled during its storage. Increasing the temperature, particularly at high pressures, can initiate deflagration in the absence of air (TFE degrades into carbon tetrafluoride). In the presence of air or oxygen, TFE forms explosive mixtures in the molar percentage range of 14–43%. Detonation of a mixture of tetrafluoroethylene and oxygen can increase the maximum pressure to 100 times the initial pressure.

Properties of Hexafluoropropylene

Hexafluoropropylene is a colorless, odorless, tasteless, and relatively low toxicity gas, which boils at −29.4°C and freezes at −156.2°C. In a 4-hr exposure, a concentration of 3000 ppm corresponded to LC50 in rats.[29] Critical temperature and pressure of hexafluoropropylene are 85°C and 3254 MPa. Unlike tetrafluoroethylene, HFP is extremely stable with respect to autopolymerization and may be stored in liquid state without the addition of telogen.

Hexafluoropropylene is thermally stable up to 400–500°C. At about 600°C under vacuum, HFP decomposes and produces octafluoro-2-butene ($CF_3CF{=}CFCF_3$) and octafluoroisobutylene.[30]

Properties of Perfluoroalkylvinylethers

Perfluoroalkylvinylethers (PAVE) form an important class of monomers in that they are comonomers of choice for the ''modification'' of the properties of homofluoropolymers in addition to their broad use in the structure of copolymers of TFE. The advantage of PAVE as modifiers over hexafluoropropylene is their remarkable thermal stability. A commercially significant example is PPVE. It is an odorless and colorless liquid at room temperature. It is extremely flammable and burns with a colorless flame. It is less toxic than hexafluoropropylene.[16]

Properties of Chlorotrifluoroethylene

Chlorotrifluoroethylene is a colorless gas at room temperature and pressure. It is fairly toxic with an LC50 (rat), 4 hr of 4000 ppm.[31] It has a critical temperature and pressure of 105.8°C and 4.03 MPa. Oxygen and liquid CTFE react and form peroxides at fairly low temperatures. A number of oxygenated products are generated by the oxidation of chlorotrifluoroethylene, such as chlorodifluoroacetyl fluoride.[32] The same reaction can occur photochemically in the vapor phase. Chlorotrifluoroethylene oxide is a by-product of this reaction. The peroxides act as initiators for the polymerization of CTFE, which can occur violently.

Properties of Vinylidene Fluoride

Vinylidene fluoride (VDF), $CH_2{=}CF_2$, is flammable and is a gas at room temperature. It is colorless and almost odorless and boils at −84°C. Vinylidene fluoride can form explosive mixtures with air. Polymerization of this gas is highly exothermic and takes place above its critical temperature and pressure.[33]

Properties of Vinyl Fluoride

Vinyl fluoride (VF) [*75-02-5*] (fluoroethene) is a colorless gas at ambient conditions.[23] Vinyl fluoride is flammable in air between the limits of 2.6 and 22 vol.%. Minimum ignition temperature for VF and air mixtures is 400°C. Adding a trace amount (<0.2%) of terpenes is effective to prevent spontaneous polymerization of vinyl fluoride. Inhibited vinyl fluoride has been classified as a flammable gas by the U.S. Department of Transportation.

POLYMERIZATION AND FINISHING

Polytetrafluoroethylene [*9002-84-0*]

PTFE is produced[28,34] by free-radical polymerization mechanism in an aqueous media via addition polymerization of tetrafluoroethylene in a batch process. The initiator for the polymerization is usually a water-soluble peroxide, such as ammonium persulfate or disuccinic peroxide. A redox catalyst is used for low temperature polymerization. PTFE is produced by *suspension* (or *slurry*) *polymerization* without a surfactant to obtain granular resins or with a perfluorinated surfactant (*emulsion polymerization*) to produce fine powder and dispersion products. Polymerization temperature and pressure usually range from 0 to 100°C and 0.7 to 3.5 MPa.

Granular PTFE is produced by polymerizing tetrafluoroethylene alone or by using trace amounts of comonomers. A peroxide initiator, little or no surfactant, and other additives may be present in the aqueous polymerization medium that is vigorously stirred and sometimes buffered by an alkaline solution. Most of the polymer is formed in the gas phase in the shape of stringy and irregularly shaped particles. The particles are comminuted to different sizes, depending on the powder properties required by the fabrication process. For example, a smoother surface part requires smaller particle size while good flow is improved by larger particle size.

Fine powder PTFE is produced by polymerization of TFE in an aqueous medium in the presence of an initiator and surfactant. The polymerization does follow a conventional emulsion mechanism but some of the principles which apply. The stability of the dispersion during the polymerization, to avoid premature coagulation, is balanced against the need to break the emulsion to recover the PTFE. Low shear rate agitation is maintained during the polymerization using surfactant levels below the critical micelle concentration. The rate of polymerization and particle shape and size are affected by the concentration of the surfactant. Majority of the particles is generated in the early part of polymerization and grows as the cycle proceeds. Molecular weight and composition of within the particle can be controlled using the polymerization ingredients and conditions.

The same polymerization process makes aqueous dispersions of PTFE as fine powder. The dispersion is concentrated and stabilized using a variety of ionic and nonionic surfactants. Several concentration methods have been reported including electrodecantation, evaporation and thermal concentration. Chemical additives to match them with the fabrication process or part property requirements can modify the final PTFE dispersion.

Filled compounds of PTFE are produced from all three forms of using fillers, such as glass fiber, graphite, metal powder, carbon fiber, and others.[34]

Perfluoroalkoxy Polymer [*26655-00-5*]

PFA is a copolymer of TFE and a perfluoroalkyl vinyl ether, such as perfluoropropyl vinyl ether PPVE. Copolymerization of perfluoroalkylvinyl ethers with tetrafluoroethylene can be done in a halogenated solvent,[35] in an aqueous phase[36] sometimes containing some halogenated solvent usually in the absence of a surfactant.[37] Terpolymers of this class contain other monomers like hexafluoropropylene HFP.

Commercially, PFA is polymerized by free-radical polymerization mechanism usually in an aqueous media via addition polymerization of TFE and perfluoropropyl vinyl ether. The initiator for the polymerization is usually water-soluble peroxide, such as ammonium persulfate. Chain transfer agents such methanol, acetone and others are used to control the molecular weight of the resin. Generally, the polymerization regime resembles that used to produce PTFE by emulsion polymerization. Polymerization temperature and pressure usually range from 15 to 95°C and 0.5 to 3.5 MPa.

End groups are stabilized by treating the PFA with methanol, ammonia, amines and elemental fluorine that produces CF_3 end groups.[38–42] The polymer is recovered, dried and melt-extruded into cubes for melt fabrications processes. PFA is also available in bead (as polymerized), dispersion and fine powders forms.

Fluorinated Ethylene–Propylene Copolymer [*25067-11-2*]

FEP is a random copolymer of TFE and HFP, which can be polymerized, in an aqueous or a nonaqueous media.[37] Terpolymers of this class contain other monomers, such as perfluoroalkyl vinyl ether (e.g., PPVE) to improve stress crack resistance.

Commercially, it is polymerized by free-radical polymerization mechanism, usually in an aqueous (or nonaqueous) media via addition polymerization of TFE and hexafluoropropylene. The initiator for the polymerization is usually water-soluble peroxide, such as potassium persulfate. Chain transfer agents could be used to control the molecular weight of the resin. In general, the polymerization regime and conditions resemble those used to produce PTFE by emulsion polymerization. For melt fabrication processes, FEP is recovered, dried, and melt-extruded into cubes. It is also available in dispersion form.

Ethylene-co-tetrafluoroethylene Polymers [*68258-85-5*]

This plastic is a partially fluorinated straight-chain polymer with a very high molecular weight.[37] It is produced by free-radical polymerization mechanism in a solvent or a hybrid (a solvent/aqueous mixture) media, using an organic peroxide initiator. Copolymerization of tetrafluoroethylene and ethylene ($CH_2{=}CH_2$, molecular weight 28, CAS number *74-85-1*) proceeds by an addition mechanism.

Copolymers of tetrafluoroethylene and ethylene are highly crystalline and fragile at elevated temperatures and are modified by a third monomer. Production of ETFE terpolymers having improved high temperature mechanical (especially tensile) properties has been demonstrated.[43] They comprise of 40–60 mol% ethylene, 40–60 mol% tetrafluoroethylene, and a small amount of a polymerizable vinyl termonomer, such as perfluoroisobutylene, perfluoropropyl vinyl ether, and hexafluoropropylene.

Ethylene-co-chlorotrifluoroethylene Polymers [*25101-45-5*]

Ethylene and chlorotrifluoroethylene have been polymerized[18] in aqueous and solvent mediums using organic peroxides and oxygen-activated triethylboron. Typically, polymerization is done at 60–120°C and at a pressure of 5 MPa or higher. The polymerization reaction can also be initiated by radiation, such as by gamma rays. The most effective catalyst is tri-*n*-butylboron which produces an ECTFE with an alternating 1 : 1 ethylene : TFE ratio. To control the molecular weight of the resin, chain transfer agents, such as chlorinated compounds, alcohols, and ketones were required.

Polychlorotrifluoroethylene [*9002-83-9*]

Bulk, suspension, and emulsion techniques are used to polymerize CTFE .[44] Bulk polymerization takes place using halogenated acyl peroxide catalysts or UV and gamma rays. Suspension polymerization is carried out in aqueous medium using inorganic or organic peroxide catalysts. Emulsion polymerization yields a polymer with a normal molecular weight distribution and a molecular weight–melt viscosity relationship, similar to that of bulk polymerized polymer. Inorganic peroxy catalysts initiate the reaction in the presence of halogenated alkyl acid salt surfactants. Emulsion polymerization produces the most thermally stable PCTFE.

Polyvinylidene Fluoride [*24937-79-9*]

The first successful aqueous polymerization of vinylidene fluoride was reported in 1948[45], using a peroxide initiator in water at 50–150°C and 30 MPa. No surfactants or suspending agents were present in the polymerization recipe. Polyvinylidene fluoride has been polymerized by a number of methods including emulsion, suspension, solution, and bulk. Later, copolymers of vinylidene fluoride with ethylene and halogenated ethylene monomers were also produced.[46] In 1960, a manufacturing process was developed and PVDF was first introduced to the market. Reaction temperature ranges from 10 to 150°C at a pressure of 1 MPa or higher. Similar to that of TFE, emulsion polymerization of vinylidene fluoride requires a stable fluorinated surfactant and an initiator, such as peroxide or persulfate. Suspension polymerization is conducted in an aqueous medium sometimes in the presence of a colloidal dipsersant like a hydroxy cellulose. Solution polymerization of VDF is conducted in solvents using free-radical initiators. PVDF is commercially produced by aqueous emulsion or suspension process.

Polyvinyl Fluoride [*24981-14-4*]

Vinyl fluoride undergoes free-radical polymerization.[23,24] The first polymerization involved heating a saturated solution of VF in toluene at 67°C under 600 MPa for 16 hr. A wide variety of initiators and polymerization conditions have been explored. Examples of bulk and solution polymerizations exist; however, aqueous suspension or emulsion method is generally preferred. Copolymers of VF and a wide variety of other monomers have been prepared. More recently, interpolymers of VF have been reported with tetrafluoroethylene and other highly fluorinated monomers, such as hexafluoropropylene, perfluorobutylethylene, and perfluoroethylvinylether.

STRUCTURE–PROPERTY RELATIONSHIP

A way to understand the impact of fluorine is to explore the differences between linear polyethylene (PE) and PTFE.[37] There are important differences between the properties of PE and PTFE:

1. PTFE has one of the lowest surface energies in polymers.
2. It is the most chemically resistant polymer.
3. It is one of the most thermally stable polymers.
4. Its melting point and specific gravity are more than double those of PE.

The differences between PTFE and PE are attributable to the differences of C–F and C–H bonds. The differences in the electronic properties and sizes of F and H lead to the following observations:

1. Fluorine is the most electronegative of all elements (4 Paulings).
2. It has unshared electron pairs.
3. It is more easily converted to F^-.
4. Bond strength of C–F is higher than that of C–H.
5. It is larger than hydrogen.

The electronegativity of carbon at 2.5 Paulings is somewhat higher than that of hydrogen (2.1 Paulings) and lower than that of fluorine. Consequently, the polarity of the C–F bond is opposite to that of the C–H bond, and the C–F bond is more highly polarized. In the C–F bond, the fluorine end of the bond is negatively charged when compared with the C–H bond in which the carbon end is negatively charged.

The difference in the bond polarity of C–H and C–F affects the relative stability of the conformations of the two polymer chains. Crystallization of polyethylene takes place in a planar and trans conformation. At extremely high pressure, PTFE can be forced into such a conformation.[47] Below 19°C, PTFE crystallizes as a helix with 0.169 nm per repeat distance; it takes 13 carbon atoms for a 180° turn to be completed. Above 19°C, the repeat distance increases to 0.195 nm, which means that 15 carbon atoms are required for a 180° turn. At above 19°C, the chains are capable of angular displacement, which increases above 30°C until reaching a melting point (327°C).

The substitution of F for H in the C–H bond substantially increases the bond strength from 99.5 kcal/mol for the C–H bond to 116 kcal/mol for the C–F bond. Consequently, thermal stability and chemical resistance of PTFE are higher than those of PE because more energy is required to break the C–F bond. The polarity and the strength of the C–F bond render F atom abstraction mechanism for branching difficult. In contrast, highly branched polyethylene (>8 branches per 100 carbon atoms) can be synthesized. Branching mechanism as a tool to adjust crystallinity is not practical for PTFE. Instead, comonomers with pendent groups have to be polymerized with TFE.

Crystallinity of never-melted PTFE is in the range of 92–98%,[28] consistent with an unbranched chain structure; while FEP, a copolymer of tetrafluoroethylene and hexafluoropropylene, has an as-polymerized crystallinity of 40–50%. In FEP, the pendent CF_3 group is bonded to a tertiary carbon that is less thermally stable than primary and secondary carbon atoms. Degradation curves (Fig. 3) indicate degradation onset temperatures of 300°C for FEP (0.02% weight loss) and 425°C for PTFE (0.03% weight loss).

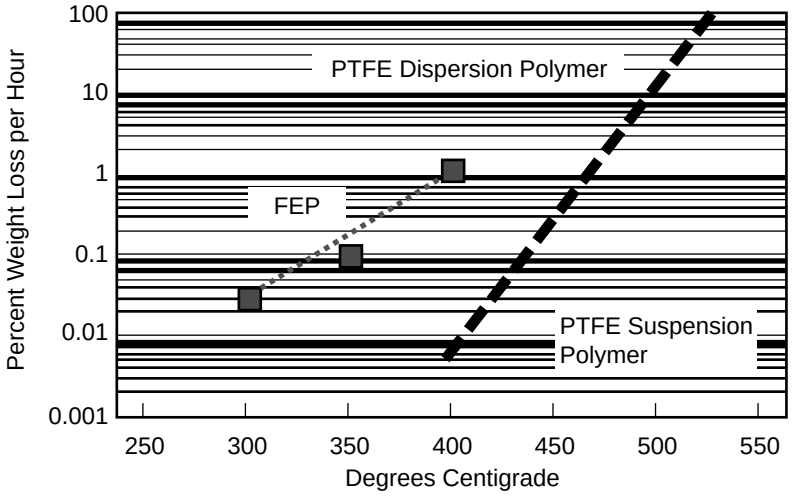


Fig. 3 A comparison of thermal degradation of FEP and PTFE in air. (From Ref.[48].) *(View this art in color at www.dekker.com.)*

POLYMER PROPERTIES

PTFE

It has excellent properties, such as chemical inertness, heat resistance (both high and low), electrical insulation properties, low coefficient of friction (static 0.08 and dynamic 0.01), and nonstick property over a wide temperature range (−260 to + 260°C). It has a density in the range of 2.1–2.3 g/cm^3 and melt viscosity in the range of 1–10 GPa sec.[28] Molecular weight of PTFE cannot be measured by standard methods. Instead, an indirect approach is used to judge molecular weight. Standard specific gravity (SSG) is the specific gravity of a chip prepared according to a standardized procedure. The underlying principle is that lower molecular weight PTFE crystallizes more extensively, thus, yielding higher SSG values.[49]

PTFE that has not been previously melted has a crystallinity of 92–98%, indicating a linear and nonbranched molecular structure. Upon reaching 342°C, it melts, changing from a chalky white color into a transparent amorphous gel. The second melting point of PTFE is 327°C because it never re-crystallizes to the same extent as prior to its first melting.

First order and second order transitions have been reported for PTFE. The transitions that are close to room temperature are of practical interest because of the impact on processing of the material. Below 19°C, the crystalline system of PTFE is a nearly perfect triclinic. Above 19°C, the unit cell changes to hexagonal. In the range of 19–30°C, the chain segments become increasingly disorderly and the preferred crystallographic direction disappears, resulting in a large expansion in the specific volume of PTFE (1.8%),[50] which must be considered in measuring the dimensions of articles made from this plastics.

Polytetrafluoroethylene is by far the most chemically resistant polymer among thermoplastics. The exceptions include molten alkali metals, gaseous fluorine at high temperatures and pressures, and few organic halogenated compounds, such as chlorine trifluoride (ClF_3) and oxygen difluoride (OF_2). A few other chemicals have been reported to attack PTFE at or near its upper service temperature, and PTFE reacts with 80% sodium or potassium hydroxide and some strong Lewis bases including metal hydrides.

Mechanical properties of PTFE are generally inferior to that of engineering plastics at the room temperature. Compounding with fillers has been the strategy to overcome this shortage. In the normally used temperature range, PTFE has useful mechanical properties.

Also, PTFE has excellent electrical properties, such as high insulation resistance, low dielectric constant (2.1), and low dissipation factor. Dielectric constant and dissipation factor remain virtually unchanged in the range of −40 to 250°C and 5 Hz to 10 GHz. Dielectric breakdown strength (short term) is 47 kV/mm for a 0.25 mm thick film (ASTM D149). Dielectric breakdown strength is enhanced with decrease in voids in PTFE, which is affected by the fabrication process. In air, PTFE is attacked by radiation and degradation, beginning at a dose of 0.02 Mrad.

PFA

These polymers are fully fluorinated and melt-processible.[51] They have chemical resistance and thermal stability comparable to those of PTFE. Specific gravity of PFA resins is in the range of 2.12–2.17. It has an upper continuous use temperature of 260°C.

Crystallinity and specific gravity of PFA parts decrease when the cooling rate of the molten polymer

is increased. The lowest crystallinity obtained by quenching molten PFA in ice was 48% (specific gravity 2.123).

Similar to that of PTFE, the molecular weight of PFA cannot be measured by conventional techniques. An indirect factor called melt flow rate (MFR), also called melt flow index (MFI), is used, which is defined as the amount of polymer melt that would flow through a capillary rheometer at a given temperature under a defined load (usually, grams in 10 min). It is inversely proportional to viscosity; viscosity is directly proportional to molecular weight of the polymer.

In contrast to the two transition temperatures for PTFE at 19 and 30°C, PFA exhibits one first order transition at −5°C. It has three second-order transitions at −100, −30 and 90°C.[18] It has excellent electrical properties , such as high insulation resistance, low dielectric constant (2.1), and low dissipation factor. Dielectric constant and dissipation factor remain virtually unchanged in the range of –40 to 250°C and 10^2 to 2.4×10^{10} Hz. Dielectric breakdown strength (short term) is 80 kV/mm for a 0.25 mm thick film (ASTM D149). Chemical properties of PFA are similar to those of PTFE. In air, PFA is attacked by radiation and degradation, beginning at a somewhat higher dose than that of PTFE.

FEP

Fluorinated ethylene–propylene copolymers are fully fluorinated and melt-processible.[52] They have excellent chemical resistance and thermal stability. Specific gravity of FEP resins is in the range of 2.13–2.15. It has an upper continuous use temperature of 200°C.

Similar to that of PTFE, molecular weight of FEP cannot be measured by conventional techniques. As in the case of PFA, MFR is used to characterize the molecular weight of FEP. Molecular weight distribution is determined by measuring the dynamic moduli of the polymer melt, using rheological analyses. Crystallinity of virgin (unmelted) FEP is 65–75%. It exhibits a single first order transition that is its melting point. Relaxation temperature of FEP increases with hexafluoropropylene content of the copolymer. It has a dielectric transition at −150°C which is unaffected by the monomer composition or crystallinity (specific gravity). Chemical properties of FEP are similar to those of PTFE and PFA. In air, FEP is attacked by radiation and its degradation begins at a dose of 0.2 Mrad (10 times higher than that of PTFE).

PCTFE

It is a semicrystalline polymer[44] with a helical polymer chain and a pseudohexagonal crystal. Crystal growth is spherulitic and consists of folded chains. The large size of chlorine constrains recrystallization after melting during the processing. This resin has good properties at cryogenic temperatures, though it is inferior to all fluoropolymers except PVDF.

In addition, PCTFE has exceptional barrier properties and superb chemical resistance. It is attacked by a number of organic solvents. It has low thermal stability and degrades upon reaching its melting point, requiring special care during processing.

ETFE

Equimolar ETFE and PVDF are isomers, but the former has a higher melting point and a lower dielectric loss than the latter. It crystallizes into unit cells believed to be orthorhombic or monoclinic.[53] The molecular conformation of ETFE is an extended zigzag. This polymer dissolves in some boiling esters at above 230°C, thus allowing the determination of molecular weight (weight-average) by light scattering. It has several transitions, alpha relaxation at 110°C (shifts to 135°C at higher crystallinity), beta at −25°C, and gamma relaxation at –120°C.

Terpolymers of ETFE have good mechanical properties including tensile and cut-through resistance and lower creep than perfluoropolymers. It is more resistant to radiation than perfluoropolymers (modestly affected up to 20 Mrad) and can be cross-linked by radiation, such as electron beam. Cross-linking is used to strengthen cut-through resistance of ETFE wire insulation. It has a dielectric constant of 2.6–3.4 and a dissipation factor of 0.0006–0.010 as frequency increases from 10^2 to 10^{10} Hz. Terpolymers of ETFE are resistant to stress cracking and chemical attack by most compounds. Strong oxidizing acids, concentrated boiling sulfonic acids, organic bases (amines), and any chemical that affects PTFE, PFA, and FEP attack ETFE.

ECTFE

It is semicrystalline (50–60%) and melts at 240°C (commercial grade).[44] It has an alpha relaxation at 140°C, a beta at 90°C, and gamma relaxation at −65°C. Conformation of ECTFE is an extended zigzag in which ethylene and CTFE alternate. The unit cell of ECTFE's crystal is hexagonal.

As in the case of ETFE, ECTFE terpolymers (same termonomers) have better mechanical, abrasion, and radiation resistance than those of PTFE and other perfluoropolymers. Dielectric constant of ECTFE is 2.5–2.6, and it is independent of temperature and frequency. Dissipation factor is 0.02 and much larger than ETFE's. ECTFE is resistant to most chemicals except for hot polar and chlorinated solvents. It does

not stress crack dissolve in any solvents. It has better barrier properties to SO_2, Cl_2, HCl, and water than FEP and PVDF.

PVDF

Polyvinylidene fluoride is a semicrystalline polymer (35–70% crystallinity) with an extended zigzag chain.[33] Head-to-tail addition of VDF dominates, but there are head-to-head or tail-to-tail defects that affect crystallinity and properties of PVDF. It has a number of transitions, and its density alters for each polymorph state. There are four known states, named as α, β, γ, and δ, and a proposed state. The most common phase is α-PVDF, which exhibits transitions at −70°C (γ), −38°C (β), 50°C (α″), and 100°C (α′).

It resists most organic and inorganic chemicals including chlorinated solvents. Strong bases, amines, esters, and ketones attack this resin. The impact ranges from swelling to complete dissolution in these solvents, depending on the conditions. It exhibits compatibility with a number of polymers. Commercially useful blends with acrylics and methacrylics have been developed. Just as ETFE, PVDF readily cross-links as a result of exposure to radiation. Radiation (gamma rays) has modest effect on the mechanical properties of PVDF.

PVF

Poly(vinyl fluoride) is a semicrystalline polymer with a planar, zigzag conformation.[23,24] The degree of crystallinity can vary significantly from 20–60% and is a function of defect structures. Commercial PVF is atactic, contains approximately 12% head-to-head linkages, and displays a peak melting point of about 190°C (52,53,62,63). Poly(vinyl flouride) displays several transitions below the melting temperature. Lower T_g occurs at −15 to −20°C and upper T_g is in the 40–50°C range. Two other transitions at −80 and 150°C have been reported.

Below about 100°C, PVF has low solubility in all solvents. Polymers with greater solubility have been prepared using 0.1% 2-propanol polymerization modifier and were characterized in *N*,*N*-dimethylformamide solution containing 0.1 N LiBr. M_n ranged from 76,000 to 234,000 (osmometry), and M_s ranged from 143,000 to 654,000 (sedimentation velocity). High molecular weight PVF is reported to degrade in an inert atmosphere, with concurrent HF loss and backbone cleavage occurring at about 450°C. In air, HF loss occurs at about 350°C, followed by backbone cleavage around 450°C.

It is transparent to radiation in the UV, visible, and near IR regions, transmitting 90% of the radiation from 350 to 2500 nm. It becomes embrittled upon exposure to electron-beam radiation of 1000 Mrad, but resists breakdown at lower doses. It retains its strength at 32 Mrad, while polytetrafluoroethylene is degraded at 0.2 Mrad. The self ignition temperature of PVF film is 390°C. The limiting oxygen index (LOI) for PVF is 22.6%. Hydrogen fluoride and a mixture of aromatic and aliphatic hydrocarbons are generated from the thermal degradation of PVF.

FABRICATION TECHNIQUES

With the exception of two fluoropolymers, PVF and PTFE, the rest of the resins described in this entry can be processed by standard melt-processing techniques, such as injection, transfer and blow molding, extrusion, and rotational molding. Process equipment for fluoropolymers must be made from corrosion resistant alloys because of the corrosive compound that may be produced when fluoropolymers are heated above their melting points. Higher melt viscosity of these resins may require more powder and higher pressure rating equipment.

Metal powder processing techniques in which a preform is molded and ''sintered'' are used to process PTFE. Compression molding may also be used to fabricate PTFE parts. Its dispersions are applied by similar techniques to other coatings. Paste extrusion in which PTFE is blended with a hydrocarbon, prior to molding a preform, is used to continuously fabricate PTFE into tubes, tapes, and wire insulation. The hydrocarbon is vaporized before the parts are sintered. PVF is dispersed in a polar latent solvent such as dimethyl acetamide and is melt-extruded as a plastisol, followed by solvent removal by drying.

APPLICATIONS

Properties of fluoropolymers that have led to applications include chemical resistance, thermal stability, cryogenic properties, low coefficient of friction, low surface energy, low dielectric constant, high volume and surface resistivity, and flame resistance. Fluoropolymers are used as liners (process surface) because of their resistance to chemical attack. They provide durable, low maintenance and economical alternatives to exotic metals for use at high temperatures without introducing impurities. Electrical properties make fluoropolymers highly valuable in electronic and electrical applications as insulation, e.g., FEP in data communications.

Mechanical properties of fluoropolymers are beneficial in low-friction bearings and seals that resist attack by hydrocarbons and other fluids in automotive and

office equipment. In food processing, the Food and Drug Administration approved grades are fabrication material for equipment. In houseware, fluoropolymers are applied as nonstick coatings for cookware and appliance surfaces. Medical articles, such as surgical patches and cardiovascular grafts rely on the long-term stability of fluoropolymers, as well as on their low surface energy and chemical resistance.

For airports, stadiums, and other structures, glass fiber fabric coated with PTFE is fabricated into roofing and enclosures, where it provides excellent resistance to weathering, including exposure to UV rays in sunlight, flame resistance for safety, and low surface energy for soil resistance and easy cleaning.

SAFETY

Fluoropolymers are chemically stable and inert or relatively unreactive. Reactivity, generally, decreases as fluorine content of the polymer increases. Fluorine induces more stability than chlorine. Fluoropolymers can produce toxic products if overheated. Precautions should be taken to exhaust any degradation fragments produced during the processing and fabrication of parts from fluoropolymers.

This family of plastics has low toxicity and almost no toxicological activity. No fluoropolymers have been known to cause skin sensitivity and irritation in humans. It has been shown that PVF does not cause any skin reaction in human beings.[1] Excessive human exposure to fluoropolymer dust resulted in no toxic effects, although urinary fluoride content increased.[2]

ECONOMY

Fluoropolymers are more costly to produce than polyolefins and many other plastics because of the capital costs and the cost of fluorine. Polymerization and finishing of these resins require processing of highly flammable hazardous materials, thus, mandating the use of expensive construction material and elaborate equipment. In early 2004, the cost ranges from US$6 per kg for mechanical grade PTFE to US$70 per kg for specialty grade PFA. Soluble perfluoropolymers cost $10–20 per gram and are only used in high value applications.

CONCLUSIONS

Commercial fluoropolymers are based on tetrafluoroethylene, vinylidene fluoride, and, to a lesser extent, chlorotrifluoroethylene. Examples of comonomers include perfluoromethyl vinyl ether, perfluoroethyl vinyl ether, perfluoropropyl vinyl ether, hexafluoropropylene, chlorotrifluoroethylene, and perfluorobutyl ethylene. The general consequences of substitution of fluorine for hydrogen in a polymer include increased chemical and solvent resistance, enhanced electrical properties, such as lower dielectric constant, lower coefficient of friction, higher melting point, increased photostability and thermal stability, improved flame resistance, and weakened mechanical properties. The ultimate properties are achieved when a polymer is entirely fluorinated.

Fouling of Heat Exchangers

T. Reg. Bott
School of Engineering, Chemical Engineering, University of Birmingham, Birmingham, U.K.

INTRODUCTION

During the course of operation of heat exchangers, which is usually 24 hr per day and 365 days per year, their heat transfer surfaces generally become dirty. This is generally known as fouling. The possible origins of the unwanted deposit are numerous, and almost any fluid being processed can give rise to deposit formation, depending on operating conditions. The presence of a deposit causes an added resistance to the transfer of heat, reducing the effectiveness of the exchanger and, therefore, the overall efficiency of the process of which the exchanger forms a part. The shortfall in energy recovery has to be made up usually, but not always, from the combustion of fossil fuel, with implications for the environment. Furthermore, the presence of the deposit increases the pressure loss through the exchanger. It also leads to increased maintenance, particularly in respect of cleaning the exchanger when the increasing backpressure can no longer be tolerated. The higher upstream pressure, as a result of the restrictions to flow imposed by the deposit, can also lead to leaking joints in pipe work and greater wear and tear on pumping equipment. In some examples of heat exchanger fouling, the presence of the deposit can lead to problems of corrosion of the heat exchanger surfaces beneath the deposit.

The loss of production during maintenance and reduced throughput because of the reduced capacity of the process plant caused by unwanted deposits can also add substantially to operating costs.

To cope with the presence of the fouling and its effect on the exchanger efficiency, additional heat transfer area is usually incorporated into the design of the exchanger. The additional area may be quite substantial, depending on the anticipated level of fouling. The result is an addition to the capital cost of the process plant.

BASIC MECHANISMS OF DEPOSITION

Three basic steps can be visualized in relation to the accumulation of deposits on heat exchanger surfaces. They are

1. The transport of the foulant material or its precursors from the flowing fluid, across the boundary layers adjacent to the heat exchanger surface.
2. The adhesion of constituents of the deposit on the heat transfer surface.
3. The transport of material that may become detached away from the surface.

The summation of these steps results in the growth of a deposit on the surface. The rate of accumulation of deposit can be simply visualized as the difference between the rate of deposition and the rate of removal. It may be expressed in mathematical terms as:

$$\text{rate of deposit growth} = \phi_D - \phi_R \quad (1)$$

where ϕ_D and ϕ_R are the rates of deposition and removal, respectively.

Curve A in Fig. 1 provides an idealized picture of the growth of foulant on a surface with time. The curve is asymptotic in shape. Three regions can be identified:

1. Adhesion, where the growth rate is relatively small and where there could be a period of initiation before any substantial deposit is present on the surface.
2. A period of relatively rapid growth before the rate of growth begins to slow.
3. A tendency to produce a plateau where the growth is reduced to zero.

In Fig. 1, an indication of two other variations that can occur is also given. The curves show a linear increase (C) and a falling rate (B) of increase in deposit attached to the surface. It is not easy to decide whether these are distinctly different types of curve or simply parts of a different, but still asymptotic curve.

Fig. 2 is what might be regarded as a ''practical'' version of Fig. 1A. It demonstrates that as the deposit grows weaknesses in its structure allow pieces of the deposit to be removed, so that the general shape is retained, but modified by the saw-tooth appearance. The weaknesses in the deposit structure are generally because of some inconsistencies in the depositing material either chemically or physically, or both.

Deposition of Particles

The deposition of particles can occur in heat exchangers both in liquid streams and in processes involving the flow of gases. The origin of the particles is extremely diverse. They may already be in the fluid being processed, unintentionally produced as a result of the process itself, or corrosion products from upstream.

Basic concepts

In general, two processes are responsible for the deposition of particles on surfaces. They are diffusion transport and settling under the influence of gravity. Both these mechanisms are possible causes of particulate fouling of heat exchangers, although particle transport from a moving fluid is by far the most common cause and will form the basis of this discussion; settling usually occurs in stationary or slow-moving fluids.

Particle deposition from a moving fluid involves two aspects. First the individual particles have to be transported to the surface by one or a combination of mechanisms, including Brownian motion, turbulent diffusion, and by virtue of the momentum possessed by the particle, as it is carried in the fluid stream. It will be appreciated that the size of the particle will exert a great influence on the dominant mechanism. Larger particles would be expected to move toward a surface, as a result of the momentum they possess. Finer particles with relatively low momentum can only approach the surface across the boundary layers, by Brownian or eddy diffusion. Having reached the surface to form a part of the foulant layer, the particle has to ''stick'', but it may be removed from the surface by the shear forces produced by the flowing fluid [see Eq. (1)].

In Fig. 3, a particle concentration profile in a turbulent flowing fluid is shown. The concentration is virtually uniform outside the viscous sublayer, i.e., c_b, and the concentration at the surface is c_s. The transport of particles is given by

$$\phi_D = K_t(c_b - c_s) \tag{2}$$

where K_t is the appropriate transport coefficient.

It is possible to consider that the concentration of particles at the surface is zero as the particles at the surface are taken out of the fluid and incorporated into the deposit. It is possible, therefore, to rewrite Eq. (1) as

$$\phi = K_d c_b \tag{3}$$

where K_d is the deposition coefficient and it is only identical with K_t when all the particles that arrive at the surface remain there. When some of the particles that arrive at the surface do not stay, either they

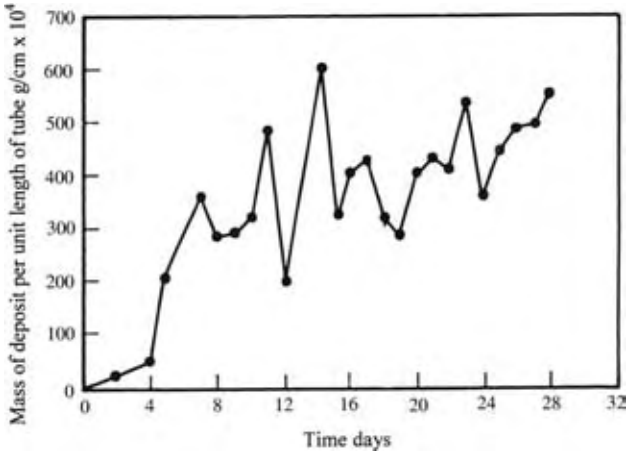

Fig. 2 ''Practical'' deposition curve.

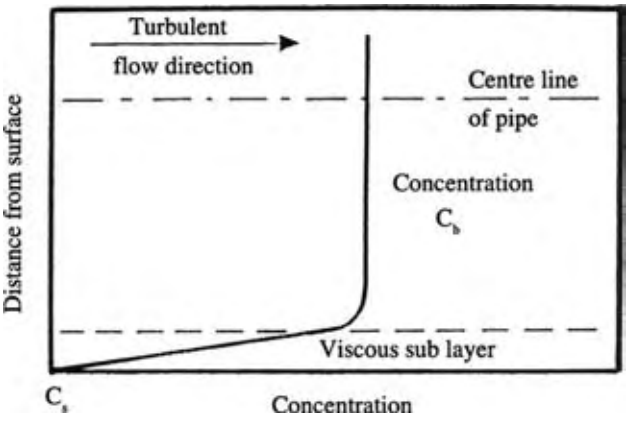

Fig. 3 Particle concentration distribution in a turbulent flowing fluid in a pipe.

rebound back into the fluid or they are swept from the surface by the movement of the fluid, then $K_d < K_t$.

$$K_d = PK_t \quad (4)$$

The surface chemistry of the particles and the surface onto which the particles deposit will also affect the accumulation of the deposit. In addition, the transport properties of the particles will be influenced if agglomeration takes place. Deposition and adhesion are complex phenomena.

In Fig. 4, some data on the deposition of the corrosion product haematite from water flowing through 316 stainless steel tubes at different pH values is provided.[1] Conditions under which these data were obtained include particle size of approximately 0.2 μm, particle concentration of 100 mg/kg, and a Reynolds number of 11,000.

It will be seen that the curves of deposit accumulation with time follow the general pattern of deposition discussed earlier. The effect of water pH is very marked with a maximum deposition occurring at a pH of around 6. The pH controls the magnitude and sign of the charge on the surface to which the particles attach, and the surface of the particles themselves. It might be possible to control particulate deposition by pH adjustment, but the additional problem of corrosion would have to be taken into account.

In combustion systems, it is very likely that the mineral particles going forward with the flue gases will be molten, because of the high temperature in the combustion zone. For this reason, the sticking ability of these particles will be enhanced. It is also possible that the presence of certain combinations of minerals will give a reduced melting point, which will aggravate the fouling problem.

The foregoing discussion applies in general, to isothermal conditions. If particles in suspension are located in a temperature field, there is a tendency for the particles to move down the temperature gradient. The phenomenon is referred to as thermophoresis, but sometimes it is called ''thermal diffusion.'' In heat exchangers, clearly there is a temperature gradient between the hot and the cold fluids, but in many heat exchangers this does not give rise to any significant particle movement, because the temperature difference is relatively small. In addition, the fluid systems are likely to be liquids that exert a resistance, because of their viscosities, on the movement of particles. Thermophoresis effects are more significant in combustion systems, where there is likely to be greater differences between the high temperature flue gases and, say, the surface of heat exchangers in which steam is being generated. In addition, the viscosity of the flue gases is very much lower than that of liquids, so that the viscous drag on the particles is relatively low with the attendant low resistance to particulate transport.

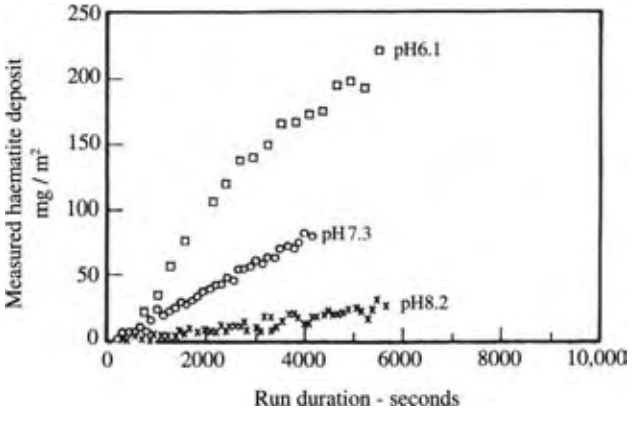

Fig. 4 The effect of pH on hematite deposition inside a tube. (From Ref.[1].)

Scale Formation

The deposition of crystalline salts, which form a scale on heat exchanger surfaces, is a common problem, where naturally occurring waters are used for cooling and in water desalination using evaporators. The deposition of salts from solution in water can take place either on the heat transfer surface itself, or in the bulk water, followed by the migration of the resulting crystals or crystallites to the surface. It will be seen that the distinction between these alternatives is dependent on the temperature distribution in the particular system. Broadly two forms of deposit are possible: a tenacious, ''hard to remove'' accumulation, generally referred to as ''scale,'' and a soft deposit that may be described as ''sludge.''

The origin of the water will have a profound influence on its quality in terms of dissolved salts. Much will depend on the chemical composition of the rock, sand, and soil, which the water has encountered after falling as rain or snow, as it flows into a river, lake, or canal. Geothermal water is often used as a source of heat energy in places where it is accessible, and it can give rise to serious fouling problems during utilization. Wherever a saturated solution, whether organic, inorganic, aqueous, or non-aqueous, is passed through a heat exchanger, there could be a risk of deposition occurring.

Basic concepts

A solution of a soluble salt in contact with its solid phase is said to be saturated with respect to that salt at the temperature of the solution. Under certain conditions, however, it is possible to have solutions of a concentration higher than the saturated concentration at the particular temperature; the condition is generally

known as ''supersaturation.'' It is generally accepted that a degree of supersaturation must be present, before scaling can occur on heat transfer surfaces.

Two different solubility/temperature relationships are possible depending on the chemical make up of the salt under consideration. Many salts have greater solubility as the temperature of the solution is raised. Such salts are generally referred to as normal solubility salts, e.g., NaCl and $NaNO_3$. In Fig. 5, it is demonstrated how the initial concentration of the salt at point A is affected as the temperature of the solution is reduced. Eventually, the temperature reaches T_1 on the solubility curve. Further cooling brings the temperature to T_2 at point C and the solution can be regarded as supersaturated and precipitation occurs. Point C is a metastable point. Further cooling brings the solution temperature to T_3 and point D on the saturation curve. The production of crystals in the cooling process could be responsible for fouling in any associated heat exchanger.

In contrast, inverse solubility salts are less soluble as the temperature of the solution is raised. Examples of inverse solubility salts are $CaCO_3$ and $CaSO_4$. It will be readily appreciated that water containing inverse solubility salts used for cooling purposes is likely to cause fouling problems because as heat is abstracted by the water, its temperature will rise, and if it is saturated with inverse solubility salts, precipitation of the salts will occur. In Fig. 6, the sequence of events that occurs when an inverse solubility salt is heated is illustrated. The curve represents the solubility variation with temperature. The solution of the salt at point A is not saturated. As the solution represented by A is heated it will eventually reach the solubility curve at

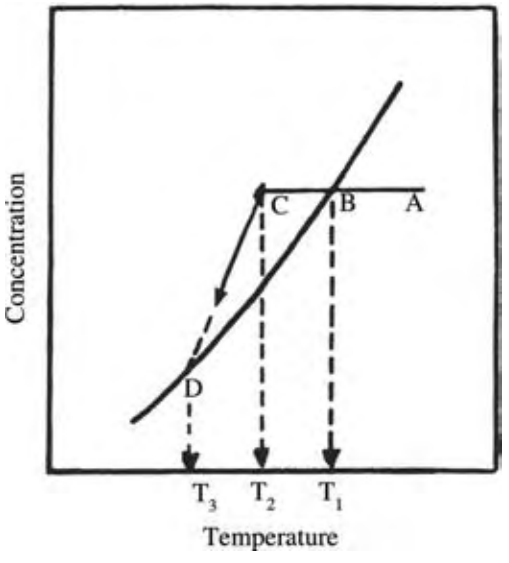

Fig. 5 Cooling a ''normal'' solubility salt solution. (From Ref.[2].)

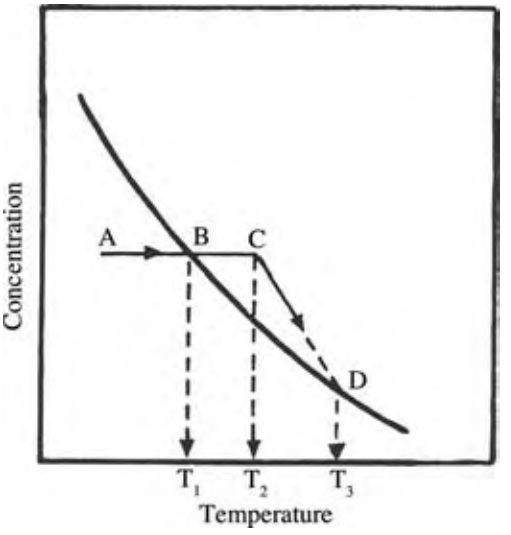

Fig. 6 Cooling an ''inverse'' solubility salt solution. (From Ref.[2].)

B when its temperature is T_1. Further heating brings the solution to C. At this point the solution is supersaturated at a temperature of T_2. It is in a metastable condition and precipitation can be expected. As heating is continued, precipitation reduces the salt concentration till it falls onto the solubility curve at temperature T_3.

The extent of the supersaturation will in general provide the ''driving force'' for the crystallization process. Three steps may be envisaged:

1. Supersaturation is produced.
2. Crystal nuclei and crystallites are formed.
3. Crystal growth is initiated either in the bulk liquid or on the surface.

In general, the initiation of the precipitation process may result from the presence of particulate matter in the bulk water that seeds the crystallization. The process is usually termed ''heterogeneous'' nucleation. It is possible for ''homogeneous'' nucleation to occur when the nucleation is spontaneous. Once nucleation has occurred, crystals can grow, provided that the solution is supersaturated. Suitable nucleation points on the heat transfer surface facilitate deposit formation on the surface. In turbulent flow, it is possible that crystallites that are formed in the bulk fluid may be carried into regions, where they can redissolve.

The deposit resulting from the precipitation from solution would be expected to be crystalline in character, but it is usually accepted that for one reason or another, the structure is not uniform and will contain imperfections. Much will depend on the manner by which the crystals are laid down from the flowing water. If the crystals are formed in situ on the heat

transfer surface, the crystalline structure is likely to be different in detail from crystals formed from crystallites that are produced in the bulk solution and migrate to the surface to be incorporated into the accumulating deposit. A common defect is a missing unit from the crystal lattice leaving a ''hole'' in the structure. The vacant site could be subsequently occupied by an impurity. Furthermore, gaps between crystal units could be filled with ''foreign bodies'', such as solid particles, which are very different from the basic crystal structure. It is also possible to incorporate ions that are different from the ions that form the basic structure of the deposit. All these modifications to the pure crystal habit will introduce imperfections that will affect the robustness of the deposit. In addition, because of the random way in which the structure is formed, there may be ''line imperfections'' where adjacent structures are growing and are unable to blend into a regular crystal structure. As a result, shearing within the deposit is possible under a suitable applied force.

The discussion has concerned the transfer of sensible heat and the associated scale formation. In addition, an important area for processing is when fouling accompanies boiling heat transfer. The problem is encountered in such processing as the crystallization of final products, such as sugar and table salt or in the desalination of seawater by flash evaporation. There is a potential problem of scale formation in boiler plant, but the technology is such that in modern boiler plant, the problem is well controlled by the use of chemical additives.

Circular ''volcano''-shaped deposits can occur as a result of bubble formation in connection with boiling heat transfer and these deposits can act as nucleation points for further evaporation and deposition. As the process of deposition continues, the surface conditions will be modified and the scale may contain fissures, so that steam formation may occur within the deposit. The process is generally referred to as ''wick boiling'' that may influence the mechanism of heat transfer. The process of scale formation under boiling conditions is complex.

The deposition of organic compounds on cooled heat transfer surfaces could be regarded as crystallization, although it might also fall into the category of ''freezing fouling.'' The phenomenon is often associated with the cooling of crude oil or petroleum fractions that contain a mixture of molecules with different molecular weights. The problem is more likely to be a nuisance in the transport of waxy crude oils rather than in heat transfer equipment.

Freezing of a Flowing Liquid

Where a flowing liquid is being cooled, for instance, the production of chilled water, it is possible for solid to be formed on the heat transfer surface, if that surface is below the freezing point of the liquid. The presence of this frozen layer represents a resistance to heat removal from the flowing liquid. The occurrence of liquid solidification as a fouling mechanism is not common, but it can be a problem in certain specific processes. Freezing fouling may occur, for instance, in the condensation of some products, where the surface of the condenser is below the freezing point of the condensate. Clearly this is a complex phenomenon.

Basic concepts

In freezing fouling, the deposit would be expected to be crystalline and this would suggest that it could be regarded as being similar to crystallization. There is a critical difference, however, in that the deposit-forming species is already in contact with the surface, so there is no diffusion required to bring the foulant precursor to the surface prior to deposition. It would be expected that the process of deposit formation would be quite rapid, particularly if there is a relatively low temperature on the other side of the heat transfer surface on which deposition is occurring. The thickness of the deposit will be determined by the limitation imposed by the fact that the outer surface of the deposit will eventually be the freezing point of the flowing liquid. It will be apparent that the lower the temperature of the coolant stream, the thicker will be the accumulation of solidified liquid. The thickness is unlikely to be uniform, however, because the distribution of temperature difference is likely to vary along the length of the heat exchanger. Control of freezing fouling is relatively simple, by adjusting the temperature distribution in the heat exchanger or allowing the temperature to rise on a periodic basis for purposes of ''cleaning.''

Corrosion Fouling

Because of the processing of aggressive fluids or of the conditions under which a heat exchanger is operated, the heat transfer surface may be subject to corrosion, which may be defined as the deterioration and loss of material because of some form of chemical attack. The products of corrosion on the surface offer a resistance to heat transfer. The corrosion is often because of the impurities in the fluid being processed, and it may be accelerated by the presence of other deposits, such as scale or biofilm. It has to be remembered, however, that in many instances a layer of corrosion product, e.g., a thin oxide layer, is necessary to protect the metal from further deterioration. If this protective layer is removed, there could be serious implications for the continued integrity of the equipment involved.

Prevention of corrosion is, of course, possible by the choice of corrosion resistant material, for the construction of the processing equipment, but on the whole, such sophisticated materials are expensive and hence may not be acceptable.

Corrosion is a vast subject in its own right, and it is not possible here to enter into a detailed discussion of corrosion science. It is useful, however, in the consideration of corrosion fouling to provide some basic details that are generally related to iron immersed in water, which provides the background for corrosion fouling.

Basic concepts

Reddish brown rust (ferric hydroxide) is usually evident on the surface of iron or steel subject to the presence of oxygen in the atmosphere and in contact with water. It is produced by the following chemical reaction:

$$4Fe + 3O_2 + H_2O \rightarrow 4Fe(OH)_3$$

The reaction is an electrochemical process, essentially oxidation of iron, which necessitates the removal of electrons from the metal.

$$Fe \rightarrow Fe^{2+} + 2e$$

where e represents an electron,and

$$Fe^{2+} \rightarrow Fe^{3+} + e$$

The removal of metal from the anodic site on the surface of the metal gives rise to metallic ions in solution and an accumulation of excess electrons on the metal surface. The presence of these electrons makes it possible for reactions to occur on an associated cathodic site. A common example is the reduction of dissolved oxygen to hydroxyl ions.

$$O_2 + 2H_2O + 4e \rightarrow 4OH^-$$

The electrochemical corrosion of a metal is illustrated in Fig. 7.

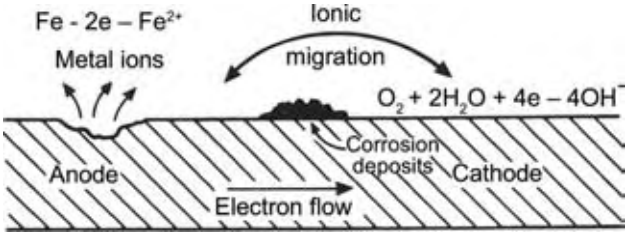

Fig. 7 Electrochemical corrosion of a metal. (From Ref.[2].)

Other reduction reactions are possible for solutions with pH below 7, i.e., under acidic conditions, such as

$$2H^+ + 2e \rightarrow H_2$$

Both anodic and cathodic reactions occur uniformly over the surface in simple examples of corrosion, but the individual sites will depend very much on the surface characteristics such as grain boundaries, crevices and, of course, discontinuities in any protective oxide layer, as the protective film acts as an electrical barrier. The protection realized will depend on the uniformity of the protective layer and the intimacy of its contact with the underlying metal. The potential for corrosion will depend on the pH of the liquid in contact with the metal.

The discussion so far has concentrated on basic corrosion reactions, but enhanced corrosion can occur for a number of reasons.

An expensive special alloy may be employed to eliminate corrosion of the tubes of a shell and tube exchanger from an aggressive liquid flowing through the tubes, but to save capital cost the shell of the exchanger might be fabricated from mild steel. The combination of these metals in the heat exchanger could give rise to corrosion. The less resistant metal of the two is prone to corrode or corrode more rapidly. In Fig. 8, the ionic and electron flow in relation to the two metals in contact in an aqueous environment is shown.[2] Electrons flow across the boundary between metals A and B, while ions are released into solution, and corrosion takes place at C.

Enhanced corrosion can occur for several other reasons:

1. Crevice corrosion is localized attack where there is a crack in the protective oxide layer.
2. Pitting corrosion is localized attack, which could be initiated by occasional fluctuations in

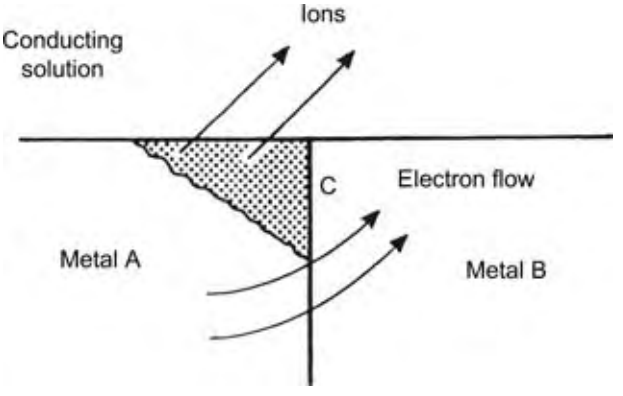

Fig. 8 Electrochemical corrosion with dissimilar metals in contact. (From Ref.[2].)

operating conditions. Oxygen depletion in a pit in the metal will aid the corrosion process.

3. Stress corrosion cracking involves the failure of some alloys in very specific environments under tensile stress conditions present in the heat exchanger.
4. Selective leaching involves the preferential leaching of one of the constituents of an alloy, for instance, the removal of zinc from brass.
5. Corrosion fatigue cracking is the result of a combination of corrosive environment and repeated working, such as the flexing of tubes in a shell and tube heat exchanger.
6. Impingement attack is because of the presence of particulate matter in a fluid passing through a heat exchanger that removes the protective oxide layer.

Corrosion in Gas Streams

The majority of examples of fouling in gas streams generally involve flue gases derived from the combustion of fossil or other fuels. Two different areas, where the problem can arise, are possible based on temperature, but the boundary between the two is not precise.

At relatively low temperatures, the problem of corrosion fouling in heat exchangers is likely to be because of a combination of condensation of water and acidic components from the flue gases, such as SO_2 and SO_3, giving solutions of relatively low pH.

$$SO_2 + H_2O \rightarrow SO_3^{2-} + 2H^+$$

and

$$SO_3 + H_2O \rightarrow SO_4^{2-} + 2H^+$$

The problem will usually occur where the flue gas temperature is reduced to relatively low values in the order of around 120°C, such as in the preheating of the combustion air. To avoid this corrosion problem, it is usual to operate the exchangers involved above the acid dew point temperature, and thus avoiding acid condensation.

Corrosion can occur on the heat transfer surfaces, where heat is being extracted from the combustion gases at high temperatures, e.g., in steam raising plant. In many instances of fossil fuel utilization, it is the impurities in the fuel that give rise to the problem.

In general, high temperature corrosion associated with combustion systems is related to other foulants, such as particulate matter that may be solid or molten. Often corrosion under deposits may be attributed to the presence of alkali sulfates and may cause a severe problem during the combustion of coal. It is possible for sulfates or polysulfates of sodium or potassium to form ionic melts on the heat transfer (or other) surfaces, when the surface temperature is higher than the corresponding melting point.

The molten condition of the deposit can allow electrochemical corrosion cells to be established. Furthermore, the problem may be accompanied by a lowering of the melting point of the deposit because of the presence of fluxing agents. It is at the anodic area that corrosion occurs:

$$Fe \rightarrow Fe^{3+} + 3e$$

At the cathodic site, the electrons are consumed by the reduction:

$$O_2 + 4e \rightarrow 2O^{2-}$$

The molten ash with its ion content provides the pathway that completes the electrical circuit.

As corrosion of metals depends on the presence of aggressive agents in contact with the metal, the availability of these chemical agents is of prime importance. As with other fouling mechanisms, high velocities of the fluid favor diffusion across the boundary layers in contact with the solid surface. The availability of O_2 for the utilization of electrons on cathodic sites will affect the corrosion rate. It could be anticipated that an increased flow rate would raise the rate of corrosion, till it becomes limited by the chemical reaction rate. It is possible also that increased availability of oxygen could improve the quality of the protective oxide layer. The detail of the conditions will determine what occurs at the metal surface. It is probably true to say that each example of corrosion fouling in processing operations is unique.

Chemical Reaction Fouling

Chemical reaction fouling involves the production of insoluble substances in a fluid flowing through a heat exchanger, generally associated with organic substances. It is possible that the metallic surface of a heat exchanger could act as a catalyst to enhance some chemical reactions that lead to surface fouling. The chemical reactions are often complex and may involve autoxidation, polymerization, cracking, and coking reactions. Chemical reaction fouling is to be found principally, although not exclusively, in the mineral oil refining and processing industries, but it may occur in food processing industry also. Because chemical reactions are generally sensitive to temperature, usually temperature is the dominant influence on the extent of any associated chemical reaction fouling in addition to the composition of the material being processed.

The problem of fouling as a result of chemical reaction in petroleum processing can occur in almost all operations, but much will depend on the quality of the feedstock and the intermediates. In petroleum processing, in primary distillation, the crude oil preheaters are very prone to fouling, where the temperature is raised from ambient to around 250°C. Following preheating, the temperature is raised still further in a directly fired pipe still or some similar piece of equipment. Fouling is also prevalent in cracking operations that are used to reduce the molecular weight of the components in the feed stream; the purpose being to provide ''building blocks'' for further processing to meet the market demands.

Chemical reaction fouling can also occur in the pasteurization of milk. Complex chemical deposits appear after a relatively short time so that, apart from overcoming the operational difficulties resulting from the accumulation of deposits, cleaning becomes essential to maintain hygienic conditions in the equipment.

In addition to the organic character of fouling because of the chemical reactions in the petroleum industry, there might be a significant inorganic content including:

1. Corrosion residues from upstream equipment that have been detached and subsequently trapped in the deposits produced by chemical reaction.
2. Organic molecules that contain heteroatoms. Sulfur in some form is contained in most crude oils, incorporated in mercaptans or other organosulfur compounds.
3. Vanadium and nickel are common elements found in certain crude oils existing in combination with complex organic structures.
4. Crude oil may contain an aqueous phase that is likely to contain inorganic salts in solution, despite the inclusion of a ''desalter'' in the process design.

The chemical reactions responsible for the production of deposits that accumulate on heat transfer surfaces may take place on the surface itself. The deposit precursors migrate to the surface from the bulk fluid across the boundary layers by simple diffusion or diffusion brought about by the eddy motion in the fluid stream. An alternative route to the production of deposits from chemical reaction is that the reaction takes place in the bulk and particulate solid products are transported to the surface by mass transfer mechanisms.

As the fouling process is dynamic, the thickness of the deposit will change with time, as indicated in the earlier discussion. As a result, the temperature distribution will change, and if heat passes from the heat transfer surface to the bulk fluid, the surface/deposit interface temperature will rise. The change in temperature may result in a change in the character of the deposit through further chemical reaction, perhaps producing a ''coke like'' dense substrata, whereas the outer layers at the lower temperature remain porous. Over a period of time, the dense portion of the deposit gradually moves outward with a changing influence on the character of the deposit. Released gases from the reactions may produce a porous structure. In general terms, each heat exchanger experiencing chemical reaction fouling will be unique, because of the complexities of the interaction of temperature and process fluid composition. Some observations made as long ago as in 1988 by Crittenden[3] are still relevant:

1. Organic liquids with high molecular weight have a greater tendency to form deposits compared with those with lower molecular weight.
2. Increased deposition rates are apparent for branched chain molecules.
3. Thermally decomposed liquid streams are susceptible to gum formation, but the chemical reactions involved may be modified by the presence of other organic compounds.
4. Dissolved oxygen and its concentration can have a profound effect on chemical reaction fouling rates.
5. Catalytic action by dissolved metallic complexes can enhance the deposition process.
6. Chemicals added to act as corrosion inhibitors might increase the rate of deposit formation.

The effects of operating variables

In common with all fouling mechanisms, two process variables can have a profound influence on the extent and the rate of the fouling process: temperature and fluid velocity across the heat transfer surface.

It is well known that an increase in temperature usually favors chemical reactions, with an exponential increase in the rate constant (r_c). The Arrhenius equation states:

$$r_c \propto \exp(-E/RT)$$

where E is the activation energy, R the universal gas constant, and T the absolute temperature.

A wide range of activation energies has been reported varying between 15 and 120 kJ/mol.[4]

Crittenden[3] observes that there are generally a minimum temperature below which fouling will not be observed and a critical upper temperature above which the deposition rate falls away because of the changes in the underlying reaction. Two aspects of fluid velocity have to be appreciated in connection with the effects of velocity on chemical reaction fouling: heat and mass transfer, both of which are dependent

on the level of turbulence, which is itself dependent on the fluid velocity. Increased turbulence (as a result of increased velocity) will assist not only the rate of arrival of reactants (or intermediates and precursors), but also the removal of products of the reactions from the vicinity of the heat transfer surface. If the production of a foulant on the heat transfer surface is controlled by reaction rate, then an increase in mass transfer, brought about by increased turbulence, will not affect the rate of accumulation of deposit. The effect of the level of turbulence on the viscous sublayer will also affect the temperature of the heat transfer surface with the attendant effect on the rate of reaction and hence the rate of deposition.

It is not possible to provide ''rule of thumb'' indications of the expected effect of changes in the variables such as velocity, temperature, or impurity and its concentration, as the interaction between them can be seen to be quite complex. It is probably for this reason that there are apparent contradictions in the literature, regarding the effects of velocity on deposit accumulation resulting from chemical reactions.

Biofouling

The accumulation of living matter on heat transfer surfaces may be divided into two groups depending on the size of the organisms involved: microorganisms such as bacteria, algae, and fungi and macro-organisms that include mussels, barnacles, hydroids, and serpulid worms, and vegetation such as seaweed. This discussion will focus on macro-organisms on surfaces, as the accumulation of micro-organisms on surfaces was discussed in the entry dealing with biofilms.

In general, the problems associated with macro-organisms relate to water systems, almost exclusively to cooling operations using seawater, in particular to the operation of power plants. The employment of sea or brackish water for cooling operations is usually based on the ''once through'' concept, i.e., the water is abstracted, put through the coolers, and returned to its source. Fouling often occurs in intakes and open culverts, and elaborate screening and filtering techniques are employed to reduce the incidence, or eliminate altogether, the build up of deposits on surfaces.

Restrictions because of filtering and the accumulation of waterborne material (living and dead) may cause restrictions in water flow that might impair the operation of the whole system, including heat exchangers.

In general, conditions favor the development of macrofouling communities, with a continuous flow of aerated seawater that brings food with it to sustain the colonies of living matter. In addition, there is a lack of competition from algae in culverts owing to restricted light conditions and a reduced presence of predators. The waste products from this marine life, together with the decomposition products of dead materials, are potential nutrients for micro-organisms. In the fouling process, it is generally accepted that, initially, the surfaces are colonized by bacteria, forming slime layers that condition the surface to facilitate the attachment of macro-organisms.

As far as the heat exchanger fouling is concerned, problems can occur as a result of the small larvae of mussels and barnacles being carried forward with the water and settling in the parts of heat exchangers where the velocities are low. Partially blocked water tubes of shell and tube heat exchangers may encourage settlement in those tubes. In turn, this can lead to pitting corrosion where growth occurs and also for problems of erosion-corrosion. Accumulation of living material in the header boxes of shell and tube heat exchangers may cause water distribution problems in the heat exchanger.

Mixed Fouling

The discussion has of necessity centered on recognized mechanisms for specific examples of fouling in heat exchangers. It will be appreciated that in most systems, individual mechanisms are not responsible for fouling problems. Combinations of fouling mechanisms are present in most industrial processing operations. The combinations encountered will be very dependent on the operating conditions and the origin and quality of the fluids passing through the heat exchanger. A complex situation exists where it is possible that the different sources and mechanisms of fouling interact. It is impossible to provide specific information on the likely interaction; each example of mixed fouling is likely to produce different effects. The approach would have to be empirical—based on the individual examples.

All kinds of interactions and combinations are possible. In cooling water, for instance, the deposits are likely to include micro-organisms, particles, scale, and corrosion products. In flue gas systems, the fouling may be because of particle deposition, chemical reaction, and corrosion. In crude oil processing, the deposits may be products of reaction, combined with particle deposition and corrosion.

CONCLUSIONS

Where heat is being transferred across a surface, the accumulation of unwanted deposits is possible. The existence of such a deposit impairs the heat transfer and leads to inefficient operation. Furthermore, because of the restrictions to flow imposed by the

deposit, the energy required for pumping for a given flow rate is increased. Combating the problem of fouling on-line may be a necessity to maintain plant operation and, in addition, there is often a need to clean heat exchangers periodically to restore efficient operation. All these detrimental effects increase operating costs.

Six mechanisms have been identified as being responsible for heat exchanger fouling, but it is seldom that one mechanism is responsible for a particular fouling problem; a combination of mechanisms is much more likely, although one mechanism may be dominant. The variables that have the greatest influence on these mechanisms, apart from the nature of the fluids being processed, are temperature and flow rate.

Fractal Geometry: Applications

Douglas K. Ludlow
Chemical and Biological Engineering, University of Missouri–Rolla, Rolla, Missouri, U.S.A.

INTRODUCTION

The concept of the non-Euclidian geometry, known as fractal geometry was introduced in the late 1970s. During the 1980s and 1990s there was an explosion of scientific and engineering research and journal publications involving fractals as the concept of nature inspired geometry was tried in numerous applications. The beauty of the underlying mathematics and the ability to describe complex spatial and temporal structures utilizing the concepts of fractal geometry inspired a generation of researchers seeking applications and uses of fractal geometry. Originally, it was thought to be able to fill the need and provide the ability to model complex systems and morphologies and was nearly considered a panacea. Time and maturity of the topic has tempered some of the initial exuberance; however, numerous applications have been found in areas of science, engineering, economics, etc. Because many of the systems important to chemical processing occur at the molecular scale where morphologies are fractal over the length scale range of interest, there have been several important applications of fractal geometry in chemical systems.

FRACTAL GEOMETRY

Benoit Mandelbrot's *The Fractal Geometry of Nature* made the world aware of the underlying universal order that can be found in many spatial and temporal phenomena.[1] Prior to that, such phenomena at best could be referred to as ''complex'' and described in terms such as ''rough,'' ''ramified,'' or ''fragmented.'' The presence of scaling laws had been recognized for a number of individual objects and systems, but the significance of the concepts of fractal geometry was to unify these and to recognize the importance of the underlying symmetry. Many objects and phenomena scale with noninteger exponents. The concept of fractal geometry implies the invariance of details when magnified. This symmetry is essential in understanding the object or phenomena, and helps to describe, characterize, and to measure. Many objects in nature exhibit self-similar features and are of fractal shape. A mathematical fractal object has details at all scales, whatever the magnification, and is invariant under its generating transformation. These objects show both self-similarity and self-affinity. The mathematics of fractal geometry is yet to be fully developed. Until now the use of fractals in applied sciences and engineering has been mostly limited to phenomenological descriptions related to the empirical discovery of power laws. Nearly a decade after Mandelbrot's seminal work, scientists began reporting applications for these concepts. *The Fractal Approach to Heterogeneous Chemistry* described the application of several fractal concepts to chemistry.[2] A few years later, *Fractals in Chemistry, Geochemistry and Biophysics* made further inroads in the application of fractal geometry concepts to chemistry and chemical processes.[3] Half a decade later *Fractals in Chemistry* followed and had the advantage in that the field had matured somewhat, so that critical reviews and opinions could be expressed concerning at least some of the aspects of the use of fractals in chemistry in the chemical processing industry.[4]

During the later part of the 1980s, as Mandelbrot's concepts reached a wider audience, sessions in the American Physical Society, the American Chemical Society, and the American Institute of Chemical Engineers gave many optimistic hopes for the application of the relationship:

$$Property \propto Scale^{\beta}$$

to numerous different phenomena. It almost appeared that many thought the formalism of fractals and the exponential scale β (slope of power–law relationship) was a panacea to reduce many complex situations to one simple explanation, a fractal dimension. However, deeper thought and time have shown that in many cases the exponential scaling factor β is not truly a fractal dimension, and that fractals do not answer well all of the questions initially thought to be accessible through their formalism. *Nature Inspired Chemical Engineering* by Coppens points out not only some of the limitations but also many of the exciting vistas that can occur through the application of the concepts of fractal geometry to applied physical science and engineering.[5] Indeed, fractals are everywhere, but not everything is fractal: A noninteger exponent is not necessarily a fractal dimension. The distinction is not critical if the noninteger scaling exponent is to be

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120025846

used only for phenomenological descriptions, but is crucial in more advanced, deductive modeling and in building new applications.

The key to applying fractal geometry to any field, including chemical engineering, is to understand the underlying assumptions. Some property X vs. some scale δ, may be plotted as $\log(X)$ vs. $\log(\delta)$ and can be fitted to a straight line, so that $X \sim \delta^{\beta}$. Typically, this scaling relationship is only determined over a fairly narrow range of scales, because is it difficult to get experimental data over a wide range of scales. No object or phenomenon in nature is scaling over an infinite range of scales as is the case in a mathematical fractal object. The limit of $\delta \rightarrow 0$, necessary in mathematical theorems involving fractal measures, is impossible to take in practice. In the nonmathematical world, scaling can only be measured within a finite range, and if the range of the measurements is wide enough, the curve of $\log(X)$ vs. $\log(\delta)$ will deviate from a straight line outside of the interval of $[\delta_{\min}, \delta_{\max}]$, the fractal scaling range. When this concept is ignored in applications of fractal geometry the results are misunderstood and even misused. If the experimentally available interval is too narrow, say less than a factor of 10, then there may be a noninteger exponent that might be wrongly considered a fractal dimension when, owing to the limited experimental range, it is unclear whether there is an underlying self-similarity or self-affinity to the phenomena.

Fractal Surfaces[6]

One place where the concepts of fractal geometry have found use is in the quantitative description of surfaces and surface ruggedness. In nature, most surfaces are not smooth except over some limited ranges. In the classical, ''what is the length of the coastline of England?'' problem, it is evident, that the total length of the coastline determined will be dependent on the length of the ruler that you use to measure it. With the ruggedness of the actual coastline, if your ruler length is 10 km, many features that are smaller will be disregarded. If a smaller ruler is used, more of the detail will be followed. It is found that the length of the coastline measured scales to the length of the ruler in a way that can be related to a fractal dimension. This same concept can be applied to surfaces. If a rugged surface area is to be determined by measuring the number of equal sized particles that just cover it (monolayer coverage), then the surface area determined will depend on the size of the particles used as the yardstick. Thus, the fractal dimension of a surface can be estimated by determination of the number of objects (molecules) of a given size that would completely cover the surface for a series of different sized objects. This concept has been used in several different techniques to determine the fractal dimension of a surface, such as gas adsorption using a homologous series of adsorbates, liquid adsorption of a series of different sized polymers or latex beads, etc.

The surface property of a solid is characterized by the nature of the surface boundary. The surface boundary is expected to be related to the underlying geometric nature of the surface, hence its fractal dimension. Many properties of the solid depend on the scaling behavior of the entire solid and of the pore space. The distribution of mass in the porous solid and the distribution of pore space may also reflect the fractal nature of the surface. If the mass and the surface scale are alike, that is, have the same power–law relationship between the radius of a particle and its mass, then the system is referred to as a mass fractal. In a similar manner if the pore volume of porous material has the same power–law relationship between the pore volume and radius as that of the surface, then it is described as a pore fractal.

Powdered and porous materials can also be characterized from additional techniques that do not depend on probing the surface with a molecule. Image analysis techniques (but still using the concept of varying the length of the ruler) have been developed. Techniques have also been developed to determine a surface fractal dimension from scattering experiments using neutrons, visible light, and x-rays. Although no solid surface is fractal over all scales in a mathematical sense, many surfaces in the range where molecules interact (single-surface molecules up through macropore networks in the particles) can be described and characterized with a fractal dimension. This has been one of the useful applications of fractal theory, being able to quantitatively describe surface/interface ruggedness by the fractal dimension. Prior to fractal analysis, surfaces could be described as being more rugged, or more ramified, or more pitted than other surfaces. Using fractal analysis, the fractal dimension of the surface can be measured and quantified.

Aggregates

Another area where the application of fractal geometry concepts has provided insight into physical phenomena is in the characterization and understanding of aggregation and growth. Aggregates are formed from smaller, nearly identical particles. Because mechanisms for formation contain random elements, we can expect three main structural phenomena arising in aggregated objects. First, mass fractality, because the process of formation often leads to more or less diaphanous aggregates. Second, fractal pore domains consisting of interstitial void elements of a wider range of linear

size. Third, surface fractality from the interfaces between pore and mass regions.

Fractal geometry has been found to be very useful in describing aggregates.[2–4,7] For several decades it has been known that diffusion and randomness play an important part of aggregate growth. In the simplest form diffusion-limited aggregation (DLA), a randomly drifting/diffusing particle is in a system with a preexisting nucleus/aggregate. When the diffusing particle hits the nucleus/aggregate, then there is an instantaneous and irreversible attachment. As more and more particles stick to the growing nucleus a branching, tree-like structure is formed. For a mass–distance scaling relationship, the number of particles, N, within a given radius, R, scales by:

$$N \sim R^D$$

Image analysis of two-dimensional representations of aggregates, such as planar projections can be used to determine a fractal dimension using the technique above. Numerous computational and theoretical studies of DLA clusters generated on computers have found that in DLA structures in which there is a high sticking probability, the fractal dimension, D, of a DLA cluster formed in a two-dimensional lattice is close to 1.7 and for a three-dimensional lattice, it is close to 2.5. As the sticking probability is decreased and as relaxation of the structures is allowed, the numerical models indicate for the two-dimensional lattice systems that the scaling relationship will approach 2.

Many experimental aggregate structures show this branch-like nature. Besides being formed in cases of diffusion limited growth, there will also be varying kinetics of aggregation, which can be classified into two kinds, slow and fast aggregation, each with a different rate-limiting physics. Systems that demonstrate either diffusion limited and/or reaction limited aggregation form fractal particles. Aggregation of solid particles or monomers in the liquid or in the gas phase far from saturation forms mass fractals. Of course if there is some form of relaxation or equilibrium of the structures formed the fractal nature of the particles will change. Aggregation conditions closer to saturation lead to denser structures, with a smooth or fractally rough surface. In the latter case these are surface fractals. It has been demonstrated that when the planar projections of numerous different aggregate particles are analyzed using the scaling relationship, the dimension determined is in the range of $D \sim 1.77$. If the same types of particles are formed under conditions where the kinetics of aggregation are slow, then more compact particles are formed and the planar projections give a scaling close to 2. Hence, the mass scaling relationship with the size of aggregates gives one indication of the kinetics of formation. There are several books dedicated to the study and aspects of fractal growth of aggregates and this has been one area where the concepts of fractal geometry have found many applications.

Techniques have been developed to determine the fractal dimension of experimental aggregate particles in solution using small-angle scattering techniques, from x-ray, light, or even neutron sources. In these techniques the scattering intensity, $I(q)$, is proportional to the scattering vector, q, raised to the mass fractal dimension by:

$$I(q) \sim q^{-D_m}$$

This technique has been successfully applied in numerous studies to determine the fractal dimension of aggregate particles.

Closely related to the aggregates formed in colloidal aggregation in gels and sols is the deposition of aggregate particles during electrodeposition. The complex structures formed from electrodeposition have been analyzed using fractal methods. There have been several studies in which dentritic structures are formed that are statistically simple and self-similar, i.e., fractal in nature. These are typically formed under conditions of diffusion-limited growth. The growth of deposits on the cathodes of batteries is often the main factor limiting the lifetime of the batteries and other electronic parts. There have been studies that show that the fractal nature of the electrodes and/or deposits on the electrodes affects the efficiency of the battery.

Dissolutions and Etchings

The chemical reaction between a solid and a reactive fluid is of interest in many areas of chemical engineering.[8] The kinetics of the phenomenon is dependent on two factors, namely, the diffusion rate of the reactants toward the solid/fluid interface and the heterogenous reaction rate at the interface. Reactions can also take place within particles, which have accessible porosity. The behavior will depend on the relative importance of the reaction outside and inside the particle. Fractal analysis has been applied to several cases of dissolution and etching in such natural occurring caves, petroleum reservoirs, corrosion, and fractures. In these cases fractal theory has found usefulness for quantifying the shape (line or surface) with only a few parameters: the fractal dimension and the cutoffs. There have been some attempts to use a fractal dimension for reactivity as a global parameter. Finally, fractal concepts have been used to aid in the interpretation of experimental results, if patterns quantitatively similar to DLA are obtained.

Diffusion and Reactions

One area that has seen much interest by chemists and chemical engineers is the study of diffusion and reaction on fractals. Many of the heterogenous reaction systems contain structures that have a fractal-like nature. Several numerical studies of diffusion and transport on fractals have been completed with the aim of being able to describe the effect of fractal structure on flow and diffusion of species. Utilizing concepts of fractal lattices as models for more realistic porous media, several numerical studies have been carried out to characterize the flow and diffusion through porous media. Numerical studies of the diffusion and reaction of reactant systems occurring in a fractal space vs. a traditional Euclidean space has led to predictions of anomalous diffusion and reaction kinetics. The application of fractal concepts has been useful in modeling permeation and percolation through porous structures.

Nature Inspired Chemical Engineering

One of the positive by-products of the application of fractal theory to various different physical phenomena has been the realization that many structures found in nature demonstrate a fractal nature over a limited range and more importantly that these self-similar and self-affine structures have a natural optimization. For instance a tree has to control the essential processes at the scale of the elementary microunits such as the cells in the leaves and this is realized in the specific structure of the veins within the leaves. Yet, the tree can only function well if the nutrients can access the leaves easily, thus there is a different fractal structure of the trunk and branches. We find similar behavior in lungs and kidneys. Through the fractal structure of the tree branches, there is a fast and uniform transport to the microunits or cells, covering a high surface area or volume, from one or a few points (the stem). These hierarchical structures are found throughout nature because they lead to easy transport of molecules and energy and also give mechanical strength and flexibility while making efficient use of available materials. Researchers have successfully applied such concepts to the design of fluid injectors for fluidized bed with the injector having a fractal shape. It was found that the fractal, nature inspired, injectors gave more uniform fluid flow in the solids with greater mixing and contact.

CONCLUSIONS

In the mid-1980s, there was an explosion of research seeking applications for fractal theory to various aspects of physical phenomenon in physics, chemistry, and engineering. The sessions at the professional conference that dealt with fractals would leave one almost breathless with the vast variety of topics and experimental results that were being analyzed in terms of fractal concepts. It seemed that everywhere we looked we found fractals and that many phenomena were scaled by a power–law relationship. It has been said that indeed, exuberance sort of ran away from sober reflection, and that perhaps the scaling exponent was taken too frequently for a fractal dimension without deeper investigation.[4] Perhaps, the concept of fractals was just filling the human need to be able to explain complex and seemingly intractable systems in a simple manner. Time has found that fractals are neither simple nor have they answered all of the questions initially thought to be accessible through their formalism. Nevertheless, a fractal approach to the modeling of many phenomena has been successful and helpful in our understanding of these phenomena. At the same time, and despite many theoretical highlights, real technological applications of fractals are still strikingly scarce for such a fundamental, universal concept. Many natural objects and phenomena, such as trees and turbulence, are scaling within a finite scaling range. Fractals become useful when recognizing this finite range, and measuring the scaling range by correctly interpreting the measurement results, remembering that too narrow of a range may lead to a bias on the value of the dimension determined. Fractal geometry, like Euclidean geometry, is useful within the range it applies to. Many important physical, chemical, biological, geological, economical, and other phenomena occur exactly within the range where the underlying structure is geometrically scaling and hereby fractal.

INTRODUCTION

Free-radical polymerization is an important industrial process to manufacture synthetic high polymers. It is a chain polymerization process utilizing free-radical reactions for chain growth. This process utilizes monomers with carbon–carbon double bonds that are susceptible to free-radical attack and cleavage. The attack of a free radical leads to the cleavage of a double bond with the monomer unit being attached to the previous radical at one of the cleavage sites and the radical being stabilized at the other cleavage site.

Many industrial free-radical polymerization processes have been developed and commercialized for a variety of monomer and polymer types. A variety of monomers and polymerization processes have been commercially exploited. Further, there have been significant developments in synthesizing polymers with controlled architectures using free-radical polymerization during the last two decades. Materials synthesized include block copolymers, graft copolymers, and radial polymers. These materials find use in many common industrial and household applications such as adhesives, paints and coatings, textiles, nonwoven fabrics, personal care products, wallpaper, construction materials, specialty additives, and many other areas.

This entry on free-radical polymerization discusses relevant aspects from a chemical processing perspective. It briefly discusses the chemistry and mechanism, the types of reactors and processes typically used in the industry, and other relevant reaction engineering and processing aspects. This should provide an introduction to the process with more detailed information included in the references herein.

MECHANISM FOR FREE-RADICAL POLYMERIZATION

The mechanism of free-radical polymerization has been studied extensively.[1,2] Most monomers that have a double bond can undergo free-radical polymerization (with certain notable exceptions including vinyl ethers). The double bond is attacked by a free radical, either on the end of a polymer chain or newly formed by an initiating species. Four main types of reactions occur in this system: chain initiation, propagation, termination, and transfer reactions. Each of these steps has reaction rate constants (K_{reaction}) that follow the Arrhenius relationship as shown in Eq. (1):

$$K_{\text{reaction}} = A\text{e}^{-(E_a/RT)} \tag{1}$$

where E_a is the activation energy for each reaction considered. The subscript ''a'' and the subscript for K_{reaction} may be replaced by ''d'', ''p'', ''t'', or ''tr'' representing decomposition (for initiator), propagation, termination, or transfer, respectively. T is the absolute temperature, R is the universal gas constant, and A is a constant.

Initiation

Free-radical polymerization is typically initiated by a compound, called an initiator or catalyst, that undergoes chemical change to yield free radicals. Many types of initiators have been used depending on the polymerization process. Initiation mechanisms include free-radical forming agents activated by temperature, ultraviolet radiation, gamma radiation, redox reactions, ultrasonic energy, or other high-energy producing techniques.

A thermal initiator is typically either an azo compound or a peroxide based initiator, e.g., 2,2′-azobis-isobutyronitrile. Each initiator molecule can decompose to give one or two primary radicals ($R^{\bullet}$) and possibly inert by-products. Initiation rate constants for several common thermal initiators are listed in Table 1. Each primary radical can attack a monomer molecule (M) to initiate a polymer chain ($P_1^{\bullet}$). The recombination

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007776

Table 1 Rate constants for common thermal initiators in various solvents

of initiator molecules and the resulting inefficiency are the result of the so-called cage effect. An initiation efficiency, f, is used to account for this loss of free radicals.

$$I \rightarrow R^{\bullet}$$

$$R^{\bullet} + M \rightarrow P_1^{\bullet}$$

$$2R^{\bullet} \rightarrow I' \quad \text{(recombined inactive initiator molecule)}$$

Redox reactions can be used to initiate free radicals as well. Typical examples include persulfate/bisulfite systems. Redox initiation can be used at lower temperatures than thermal initiation reactions. This is useful for polymerization systems that are unstable or show undesirable side reactions at higher temperatures.

Propagation

Each primary polymer radical ($P_1^{\bullet}$) can add a monomer molecule to produce a dimer ($P_2^{\bullet}$) and then a trimer ($P_3^{\bullet}$), and so on. This series of successive additions of monomer molecules to a polymer chain is called chain propagation. The propagation reaction step is very fast and almost as soon as a radical is initiated it can lead to the formation of very high molecular weight polymer.

$$P_n^{\bullet} + M \rightarrow P_{n+1}^{\bullet}$$

Termination

The loss of the propagating free radical at the end of a polymer chain ends chain growth. This is called chain termination. Polymer chains can mutually end their propagation in two ways. Termination by combination occurs when two polymer radicals react with each other to produce one polymer chain. Termination by disproportionation is the result of the abstraction of an atom, typically hydrogen, from one chain by the other. This results in one chain with a double bond at the end and another with a saturated carbon atom.

$$P_n^{\bullet} + P_m^{\bullet} \rightarrow D_n + D_m \quad \text{(Disproportionation)}$$

$$P_n^{\bullet} + P_m^{\bullet} \rightarrow D_{n+m} \quad \text{(Combination)}$$

Termination can also occur by the reaction of polymer free radicals with primary initiator radicals (called primary termination) or free-radical scavenging species, especially oxygen. Activation energies for propagation and termination for some typical monomers are listed in Table 2.

Chain Transfer

A polymer radical can take part in a chain transfer reaction, which results in a terminated polymer chain and a radical derived from the molecule that accepted the transfer. Chain transfer can take place to monomer, solvent, or other polymer molecules. It could also take place to impurities in the system. The general transfer reaction can be represented as

$$P_n^{\bullet} + CT \rightarrow D_n + CT^{\bullet}$$

Table 2 Energies of activation for propagation (E_p) and termination (E_t) in free-radical polymerization

Monomer	E_p (kcal/mol)	E_t (kcal/mol)

where CT is the chain transfer agent, which could be either of the agents mentioned above. The rate of chain transfer is determined by the chain transfer constant C_{tr}, which is defined as the ratio of the rate of chain transfer to the rate of propagation for two different molecules (Table 3).

Inhibition

Some chemicals retard or suppress free-radical polymerization by reacting with primary radicals or macroradicals to yield radicals that are very stable to further reaction or yield nonradical products. These materials could be retarders or inhibitors. Retarders slow down the formation of polymer but inhibitors completely eliminate it. Oxygen is one of the most commonly known inhibitors for vinyl polymerization and good practice requires the removal of air from the reactor vessels before the reaction is started. It combines with active radicals to form unreactive peroxy radicals.

Commercial monomers are sold with added inhibitor to prevent their premature polymerization during storage and transportation. These inhibitors are either removed or extra initiator is added to reactor vessels to reactively consume the inhibitors. Retarders and inhibitors differ only in the frequency with which propagating radicals react with them rather than monomer and also in the ability of these resulting macroradicals to reinitiate. Fig. 1 schematically illustrates the difference in polymerization kinetics in the presence of retarders and inhibitors.

Copolymerization

Copolymerization of two or more monomers during free-radical polymerization is an effective way of altering the properties of polymers. The discussion here is based on the copolymerization of two monomers, but it is possible to extend it to multiple monomers as well. If the reactive species are M_1 and M_2, the composition of the resulting polymer is not a mixture or blend of homopolymers of M_1 and M_2, but a statistical copolymer of both the monomers. Commercial polymer products can be copolymers of several monomers that provide a unique property or functionality to the product. The reactivity of monomers varies with the type and concentration of other species in the reaction mixture feed.

Theoretical studies of the polymerization of two or more monomers have been conducted on various reaction systems since Dostal first proposed the concept of the terminal model in 1936.[5] In the terminal model, it is assumed that the reactivity of the growing polymer chain is determined merely by the last added monomer unit (i.e., terminal unit), independently of the chain length and composition. For a two-component (M_1 and M_2) copolymerization, the terminal model leads to the following four propagation reaction equations:

$$\sim\sim\sim M_1^{\bullet} + M_1 \xrightarrow{k_{11}} \sim\sim\sim M_1^{\bullet}$$

$$\sim\sim\sim M_1^{\bullet} + M_2 \xrightarrow{k_{12}} \sim\sim\sim M_2^{\bullet}$$

$$\sim\sim\sim M_2^{\bullet} + M_1 \xrightarrow{k_{21}} \sim\sim\sim M_1^{\bullet}$$

$$\sim\sim\sim M_2^{\bullet} + M_2 \xrightarrow{k_{22}} \sim\sim\sim M_2^{\bullet}$$

in which $\sim\sim\sim M_1^{\bullet}$ and $\sim\sim\sim M_2^{\bullet}$ are the growing chains with M_1 and M_2 as the terminal units, respectively, and k_{11}, k_{12}, k_{21}, k_{22} are the reaction constants. Based on the propagation equations, the consumption

Table 3 Chain transfer constants (C_{tr}) of solvents to styrene in free-radical chain polymerization at 60°C

Transfer agent	$C_{tr} \times 10^4$	Transfer agent	$C_{tr} \times 10^4$

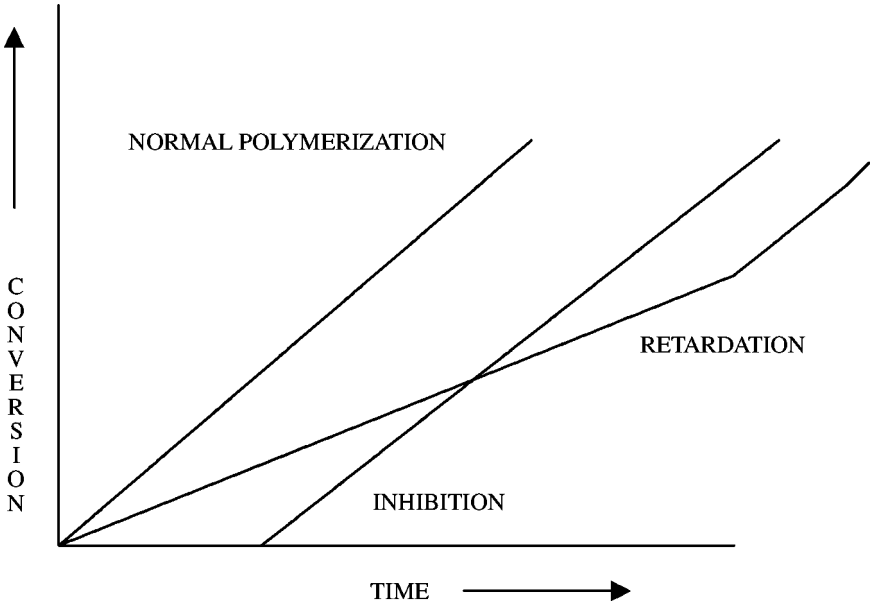

Fig. 1 Conversion vs. time for normal polymerization as well as inhibited and retarded free-radical polymerizations. (From Ref.[3].)

rates of M_1 and M_2 can be given by

$$-\frac{d[M_1]}{dt} = k_{11}[\sim\sim\sim M_1^*][M_1] + k_{21}[\sim\sim\sim M_2^*][M_1] \quad (2)$$

$$-\frac{d[M_2]}{dt} = k_{12}[\sim\sim\sim M_1^*][M_2] + k_{22}[\sim\sim\sim M_2^*][M_2] \quad (3)$$

It should be noted that the monomer consumption in the initiation step is neglected in the above equations owing to the small amount of initiator used in most systems. Furthermore, Mayo and Walling suggested that radical concentrations (i.e., $\sim\sim\sim M_1^*$ and $\sim\sim\sim M_2^*$) should remain constant at steady state because of the relatively short lifetime of the radicals.[6] This means that the rates of the conversion between $\sim\sim\sim M_1^*$ and $\sim\sim\sim M_2^*$ should be equal, which is given by the following equation:

$$k_{21}[\sim\sim\sim M_2^*][M_1] = k_{12}[\sim\sim\sim M_1^*][M_2] \quad (4)$$

Rearrangement of Eqs. (2)–(4) to eliminate the terms of radical concentrations yields[7]

$$\frac{d[M_1]}{d[M_2]} = \frac{[M_1](r_1[M_1] + [M_2])}{[M_2]([M_1] + r_2[M_2])} \quad (5)$$

where

$$r_1 = \frac{k_{11}}{k_{12}}, \quad r_2 = \frac{k_{22}}{k_{21}}$$

r_1 and r_2 are known as monomer reactivity ratios, which are the ratios of the reaction rates of homo-polymerization to cross-polymerization for individual radicals.

If we let

$$f_1 = 1 - f_2 = \frac{[M_1]}{[M_1] + [M_2]}$$

$$F_1 = 1 - F_2 = \frac{d[M_1]}{d[M_1] + d[M_2]}$$

in which f_i is the molar fraction of M_i in the reaction medium, and F_i is the corresponding molar fraction of M_i unit in the instantaneously formed copolymer, where i = 1 or 2. Substitution of f_1 and F_1 in Eq. (5) gives the copolymer composition equation

$$F_1 = \frac{r_1 f_1^2 + f_1 f_2}{r_1 f_1^2 + 2 f_1 f_2 + r_2 f_2^2} \quad (6)$$

This is the fundamental equation, upon which various methods were suggested to determine the monomer reactivity ratios of M_1 and M_2. These methods will be discussed in a later section.

Various methods have been used to determine monomer reactivity ratios for various copolymerization systems. According to Eq. (6), a series of monomer molar fractions (f_1) and their corresponding instantaneous copolymer compositions (F_1) are required to obtain monomer reactivity ratios. The most common experimental procedure is to carry out a set of copolymerizations with the feed ratios of M_1 to M_2 ranging from 0.1 to 0.9, and the conversions are kept below 5%. It is noted that owing to the relatively low conversion, the instantaneous copolymer composition can be approximated by the composition of the final copolymer

measured by IR, UV, or NMR. Even though this treatment is defective, errors in calculated reactivity ratios are tolerable enough for such a simple method.

In 1944, Mayo and Lewis proposed a method called ''intersection method,'' based on a rearrangement of Eq. (5):[7]

$$r_2 = \frac{F^2}{f} r_1 + F\left(\frac{1}{f} - 1\right) \tag{7}$$

where

$$F = \frac{d[M_1]}{d[M_2]}, \quad f = \frac{M_1}{M_2}$$

For each pair values of F and f, plotting r_2 against r_1 should generate a straight line. In an ideal case, all the lines should intersect at one specific point, which represents the monomer reactivity ratios. However, the inevitable experimental errors could lead to an intersection area instead of a point. Consequently, which point in the area should be chosen would be a problem.

A useful method for calculating reactivity ratio values for free-radical polymerizations called the Q–e scheme was proposed by Alfery and Price in 1947. For a system of two monomers with reactivity ratios r_1 and r_2 as exhibited in Table 4, Q_1 and Q_2 are related to reactivity and e_1 and e_2 are related to the polarity of monomers M_1 and M_2, respectively. Styrene with Q and e values of 1 and -0.8 is used as a comparative standard. Higher Q values indicate greater resonance stability, and higher e values (less negative) indicate greater electron withdrawing power of the alpha substituent on the vinyl monomer.

$$k_{11} = P_1 Q_1 e^{-e_1^2} \tag{8}$$

$$k_{12} = P_1 Q_2 e^{-e_1 e_2} \tag{9}$$

$$r_1 = \frac{k_{11}}{k_{12}} = \frac{Q_1}{Q_2} e^{-e_1(e_1 - e_2)} \tag{10}$$

$$k_{22} = P_2 Q_2 e^{-e_2^2} \tag{11}$$

$$k_{21} = P_2 Q_1 e^{-e_1 e_2} \tag{12}$$

$$r_2 = \frac{k_{22}}{k_{21}} = \frac{Q_2}{Q_1} e^{-e_2(e_2 - e_1)} \tag{13}$$

$$r_1 r_2 = e^{-(e_1 - e_2)^2} \tag{14}$$

In 1950, Fineman and Ross suggested another method called ''FR method'' or ''linear least square method,'' which is based on Eq. (7).[8] For a set of values of F and f from experiments, a plot of $(1 - f)/F$ vs. f/F^2 should be a straight line with the slope r_2 and the intercept $-r_1$. Similarly, owing to experimental errors, all points may not sit on one line but be scattered instead. To obtain the optimal values for r_2 and r_1, the linear least square method should be used.

It is noted that for both methods, the instantaneous copolymer composition, F, is approximated by the composition of the final copolymer, and the actual drift in the monomer feed ratio, f, is neglected because of the low conversions for the experiments. Therefore, the reactivity ratios obtained from both methods might be inaccurate for high conversion.

To minimize the effect of the drift in the monomer feed ratio, Kelen and Tüdõs proposed a new method.[9] In their work, the following equation was introduced, based on Eq. (5):

$$\frac{G}{\alpha + H} = \left(r_1 + \frac{r_2}{\alpha}\right)\frac{H}{\alpha + H} - \frac{r_2}{\alpha} \tag{15}$$

where

$$x = \left(\frac{[M_1]_f}{[M_2]_f} + \frac{[M_1]_0}{[M_2]_0}\right)\Big/2, \quad y = \frac{dM_1}{dM_2},$$

$$G = \frac{x(y - 1)}{y}, \quad H = \frac{x^2}{y}$$

$[M_1]_f$ and $[M_1]_0$ are the final and initial molar concentrations of M_1, respectively. If we let

$$\eta = \frac{G}{\alpha + H} \quad \text{and} \quad \xi = \frac{H}{\alpha + H}$$

Eq. (15) can be written as

$$\eta = \left(r_1 + \frac{r_2}{\alpha}\right)\xi - \frac{r_2}{\alpha} \tag{16}$$

where α is an arbitrary constant to make the variables η and ξ lie in the interval (0, 1). Kelen and Tüdõs suggested the following optimal value for α:

$$\alpha = \sqrt{H_m H_M} \tag{17}$$

where H_m and H_M are the smallest and biggest values of H, respectively. Plotting η vs. ξ should give a straight line, from which r_1 and r_2 can be obtained. Additionally, the following equations are given for r_1 and r_2, using the least squares method:

$$r_1 = \frac{\sum \eta\xi(n - \sum \xi) - \sum \eta\left(\sum \xi - \sum \xi^2\right)}{n\sum \xi^2 - \left(\sum \xi\right)^2}$$

$$r_2 = \frac{\sum \eta\xi \sum \xi - \sum \eta \sum \xi^2}{n\sum \xi^2 - \left(\sum \xi\right)^2} \tag{18}$$

where n is the number of a set of experimental data.

Table 4 Typical free-radical chain-copolymerization reactivity ratios

M_1	M_2	r_1	r_2	r_1r_2
Vinyl acetate	Vinyl chloride	0.23	1.68	0.39
	Vinyl laurate	1.4	0.7	0.98
Styrene	Vinyl acetate	55	0.01	0.55
	Vinyl chloride	17	0.02	0.34
Methyl acrylate	Styrene	0.18	0.75	0.14
	Vinyl acetate	9	0.1	0.90
Butadiene	Styrene	1.39	0.78	1.08

(From Ref.[5].)

To overcome the errors brought in by the approximation for instantaneous copolymer composition and the drift in monomer feed ratio, the integration equation for Eq. (5) was used to determine the monomer reactivity ratios, which was given as[10]

$$\ln x_2 = r_2 \ln x_1 + \frac{1 - r_1 r_2}{1 - r_1} \times \ln\left[\frac{(1 - r_2)x_2 - (1 - r_1)x_2 x}{(1 - r_2)x_2 - (1 - r_1)x_1 x}\right] \qquad (19)$$

in which

$$x_i = \frac{[M_i]}{[M_i]_0}, \quad x = \frac{[M_1]_0}{[M_2]_0}$$

where $[M_1]_0$ is the initial molar concentration of M_1.

Besides the above methods, Tosi suggested a new method called ''method of grouping,'' which was claimed to have minimal computation difficulty, but only provides approximate values.[11] Tidwell and Mortimer proposed a nonlinear least square method by minimizing the difference between the observed and calculated copolymer compositions.[12] This method was claimed to circumvent the subjective judging of experimental data and lead to better results compared to other methods, although its computation process is quite complicated.

The methods described here as well as other methods proposed can typically be divided into two groups: one is based on the differential composition equation [Eq. (5)], while the other employs the integration composition equation [Eq. (19)]. The latter is preferred because it is free of the limitation on conversion and can produce more accurate values. However, the former methods based on the differential composition equation were widely used because of their simplicity and tolerable errors.

The values of the calculated monomer reactivity ratios can be affected by various factors, such as the estimation method employed, the accuracy of the experimental data, and even the reaction medium (solvent).[13] Reactivity ratios for some common monomers are listed in Table 4.

Controlled Free-Radical Polymerization

Free-radical polymerization is an inherently statistical process with the probability of the reactions being discussed in the earlier sections being dictated by their rate coefficients. However, during the last 10 yr, a lot of effort has been directed toward controlling the statistical nature of this process.[14]

A number of approaches have been proposed that reduce the probability of termination by adding reversible termination agents, highly efficient chain transfer agents, or by reducing the diffusional mobility of polymers in poor solvents. The processes developed in recent years can be used to control polymer microstructure and composition with high yield, efficiency, and specificity. The ability to do this has led to a variety of novel materials, properties, and applications.

Controlled free-radical polymerization (CFRP) has been used successfully to produce block, graft, and other controlled architecture copolymers within the last decade for a variety of free radically polymerizable monomers. The main techniques include reversible addition fragmentation and transfer (RAFT) polymerization, stable free-radical polymerization (SFRP) mediated by nitroxide/alkoxyamine based radicals, atom transfer radical polymerization (ATRP), diphenyl ethylene (DPE) mediated polymerization, and novel precipitation/emulsion polymerization based methods like free-radical retrograde precipitation polymerization (FRRPP).[15]

Nitroxide mediated SFRP, DPE mediated polymerization, ATRP, RAFT polymerization, etc. achieve polymerization control through the use of kinetic mediators or transfer agents, which protect a propagating free radical from undesirable transfer and termination reactions. The emulsion block copolymer method is unique in that it does not require the use of any chemical mediators to achieve this control. Polymerization control is achieved by physically trapping radicals by

precipitation. This minimizes the reaction of the radicals with each other by severely restricting their mobility in the reaction medium.

The ability of these methods in delivering block copolymer structures has been well demonstrated. The ATRP, RAFT, and SFRP methods could all be used to make diblock and triblock copolymers, as well as radial polymers using multiarm initiators. Because these methods are based on free-radical polymerization, they give access to a wider variety of monomer systems than are currently available through non-free-radical polymerization based techniques. They can also lead to controlled polymerization under more industrially practicable conditions as compared to ionic polymerization.

Each of these techniques has unique capabilities and drawbacks that make it extremely useful for certain types of monomers, but not that effective for others. Table 5 shows a summary of the available technology options.

COMMON TYPES OF POLYMERIZATION PROCESSES[16,17]

Radical polymerization can be carried out under homogenous as well as heterogenous conditions. This difference is classified based on whether the initial mixture and/or final product are homogenous or heterogenous. Some homogenous mixtures become heterogenous as polymerization proceeds as a result of insolubility of the resulting polymer in the reaction media. There are many other specialized processes that are used to synthesize materials via free-radical polymerization. These include interfacial polymerization, gas phase reactions (''popcorn polymerization''), as well as the use of specialized media like supercritical fluids.[18] Current research efforts include the study of such processes to understand and control them. Table 6 summarizes and compares some common processes.

Table 5 Summary of CFRP

Name	Technology
ATRP	Transition metal mediators
RAFT	Thioesters, thiophosphates, xanthates, and other chain transfer agent mediators
SFRP	Nitroxides/alkoxyamines, functional nitroxides, imidazoline, piperizinones, morpholones, and related mediators
DPE	Diphenyl ethylene mediator
FRRPP	Physical immobilization of free radicals to reinitiate polymerization
Others	Telomerization, macromers by chain transfer, bimetallic chain transfer, electron donors, alkyl iodide mediators

Bulk Polymerization

Many polymers of industrial importance are made by bulk polymerization. This is the simplest of all polymerization processes based on the ingredients used. Typical ingredients are just monomer and initiator. The polymer formed leads to great changes in viscosity and volume in the reaction vessel. For this reason, most bulk polymerizations are either not carried out to complete conversion or are conducted in specialized equipment like polymer extruders.

Solution Polymerization

Solution polymerization of vinyl monomers is carried out in large agitated reactors in organic solvents. Both propagation and termination rates are impacted by the nature of organic solvent used. The rate of initiator decomposition is independent of the solvent used. The auto acceleration impact (Trommsdorff effect) is less pronounced in solution polymerization than in bulk or suspension polymerization because of dilution and lower viscosity of the continuous phase. To prevent a runaway reaction, the reactants are added gradually to the reactor. The polymer molecular weight is controlled through the proper choice of chain transfer agent, and by initiator concentration and amount. The other contributors are solvent type, monomer type, and reaction temperature.

A typical recipe is shown in Table 7. The solution polymerization is carried out at 140°C by adding the monomer and initiator mixture uniformly for over 4 hr. After the addition of initiator, the reaction is continued over 2 hr.

Emulsion Polymerization

Emulsion polymerization is a heterogenous reaction process in which unsaturated monomers are dispersed in continuous phase with the aid of emulsifiers and polymerized by free-radical initiators. The resulting product is a dispersion of polymer particles, typically smaller than 1 μm in size, in water and is referred to as polymer latex.

The emulsion polymerization process has various advantages as compared to bulk or solution polymerization as the reaction proceeds at low viscosity. The low viscosity during the process allows adequate removal of heat of polymerization and the production of higher solid latexes in combination with high monomer conversion and short cycle time. This process is

Table 6 Comparison of different types of free-radical polymerization processes

Type	Advantages	Disadvantages
Bulk (batch)	Simpler equipment No diluent impurities	May require solution and subsequent precipitation for purification and/or fabrication May require reduction to usable particle size Broad molecular weight distribution Inefficient heat and mass transport at higher conversion
Bulk (continuous)	Easier to control heat and mass transport Narrower molecular weight distribution	Reactant recycling May require solution and subsequent precipitation for purification and/or fabrication May require reduction to usable particle size Complex equipment
Solution	Easier to control heat and mass transport Wide range of accessible molecular weights Easier to transport reagents and products	Needs agitation Solvent removal and recycling Chain transfer to solvent may lead to undesirable effects Inefficient heat and mass transport at high conversions and/or concentrations
Emulsion	Easy heat control, easy agitation, latex may be directly usable, high polymerization rates, molecular weight control, usable small particle size,usable in producing tacky soft solid products, access to higher molecular weight ranges	Polymer may require additional cleanup and purification Difficult to eliminate entrenched coagulants, emulsifiers, surfactants, etc. Often requires rapid agitation at different stages
Precipitation/ dispersion	Molecular weight and molecular weight distribution control via environment, ease of isolation	May require solution and subsequent precipitation for purification and/or fabrication Precipitation may limit molecular weight
Suspension	Easy agitation, higher-purity product when compared to emulsion	Sensitive to agitation Particle size difficult to control Difficult to eliminate residual reagents

(From Ref.[2].)

applied on an industrial scale to produce a variety of products such as paints, paper coatings, adhesives, carpet and textile coating binders, wall paper ground coat, nonwoven binders, glass fiber sizing, personal care, pressure sensitive adhesives, etc.

Classical emulsion polymerization is divided into three kinetic stages. At the start of the process, the unsaturated monomers are dispersed into small droplets, stabilized with surfactants. Additional surfactant aggregates into micelles. These micelles are very small ($\sim$10 nm) relative to monomer droplets ($\sim$1–10 μm). During stage 1 the initial formation of polymer particles takes place by initiation within micelles. In stage 2 the polymerization precedes with a constant supply of new unsaturated monomer, which results in the growth of polymer particles. At the end of stage 2 the monomer supply ceases and subsequently the rate of polymerization decreases gradually to yield latex particles.

A recipe to synthesize a vinyl acrylic latex for paint formulation is shown in Table 8.

Table 7 Typical recipe for methyl methacrylate solution polymerization

Ingredient	Function	Parts (by weight)
Xylene	Solvent	28
Ethoxyethanol	Solvent	14
Methyl methacrylate	Monomer	60
t-Butyl perbenzoate	Initiator	1.1

Table 8 Typical emulsion polymerization recipe

Components	Parts (by weight)	Function
Vinyl acetate	80	Monomer
Butyl acrylate	20	Monomer
Water	180	Continuous phase
Surfactant	2–4	Stabilizer
Sodium bicarbonate	0.05	pH adjuster
Sodium persulfate	0.1	Initiator
Ascorbic acid	0.01	Reductant

(From Ref.[19].)

Water is used as a dispersing medium and a heat sink for the heat of polymerization. Surfactant is an essential part of the emulsion polymerization process. It provides the large surface area needed for the process and stabilizes the final product. The initiator used is typically water soluble and initiation usually takes place within the aqueous phase.

Emulsion polymerization typically refers to the polymerization of a nonaqueous material in water. The polymerization of a water-soluble material in a nonaqueous continuum has been called inverse emulsion polymerization. The inverse emulsion polymerization technique is used to synthesize a wide range of polymers for a variety of applications such as wall paper adhesive, waste water flocculant, additives for oil recovery fluids, and retention aids. The emulsion polymerization technique involves water-soluble polymer, usually in aqueous solution, emulsified in continuous oil phase using water in oil emulsifier. The inverse emulsion is polymerized using an oil- or water-soluble initiator. The product is a colloidal dispersion of submicroscopic particles with particle size ranging from 0.05 to 0.3 μm. The typical water-soluble monomers used are sodium *p*-vinyl benzene sulfonate, sodium vinyl sulfonate, 2-sulfo ethyl acrylate, acrylic acid, and acrylamide. The preferred emulsifiers are Sorbitan monostearate and the oil phase is xylene. The proposed kinetics involve initiation in polymer swollen micelles, which results in the production of high molecular weight colloidal dispersion of water-swollen polymer particles in oil.

Another type of emulsion-like process is called miniemulsion polymerization. Miniemulsions are stable oil in water emulsions with average droplet diameter of 80–400 nm, prepared using a mixture of an anionic emulsifier and a cosurfactant such as a long-chain fatty alcohol or *n*-alkane. The polymer latexes are prepared by initiation of polymerization in the miniemulsion droplets.

Microemulsion polymerization is a term used to describe thermodynamically stable surfactant-rich microemulsions and polymerization therein.

Precipitation/Dispersion Polymerization

Dispersion polymerization is a technique that permits the preparation of polymer particles typically in the range of 1–15 μm in a rapid process with high conversion. In a dispersion polymerization process, the continuous phase is chosen to be a solvent for monomer to be polymerized, a nonsolvent for the resultant polymer. A steric stabilizer is used to produce a colloidally stabilized dispersion. In the absence of stabilizer, the polymerization produces macroscopic particles of polymer of an uncontrolled size, and is called precipitation polymerization.

The minimum requirements for a dispersion polymerization are monomer, solvent/nonsolvent, initiator, and steric stabilizer. The monomer must be soluble in the reaction mixture and its polymer, insoluble. The monomers used in systems of commercial interest are methyl methacrylate, vinyl chloride, vinylidene chloride, vinyl esters, hydroxyl alkyl acrylates. A typical recipe for dispersion polymerization is shown in Table 9.

Uses for dispersion polymers include surface coatings for metal coatings, particularly for the automotive industry, food can coating, chromatographic medium, electrophotographic toners, and pressure sensitive adhesives.

Suspension Polymerization
