Encyclopedia of Chemical Processing

EDITED BY

Sunggyu Lee

Volume 1

Encyclopedia of Chemical Processing

VOLUME I

Encyclopedias from Taylor & Francis Group

Encyclopedia of Biomaterials and Biomedical Engineering (2 Volume Set)
Edited by Gary E. Wnek and Gary Bowlin
ISBN: 0-8247-5562-6

Encyclopedia of Biopharmaceutical Statistics, Second Edition
Edited by Shein-Chung Chow
ISBN: 0-8247-4261-3

Encyclopedia of Chemical Processing (5 Volume Set)
Edited by Sunggyu Lee
ISBN: 0-8247-5563-4

Encyclopedia of Chromatography, Second Edition (2 Volume Set)
Edited by Jack Cazes
ISBN: 0-8247-2785-1

Encyclopedia of Clinical Pharmacy
Edited by Joseph DiPiro
ISBN: 0-8247-0752-4

Encyclopedia of Corrosion Technology, Second Edition
Edited by P.E. Schweitzer
ISBN: 0-8247-4878-6

Encyclopedia of Dietary Supplements
Edited by Paul M. Coates, Marc R. Blackman, Gordon M. Cragg, Mark Levine, Joel Moss, and Jeffrey D. White
ISBN: 0-8247-5504-9

Encyclopedia of Library and Information Science, Second Edition (4 Volume Set)
Edited by Miriam Drake
ISBN: 0-8247-2075-X

Encyclopedia of Medical Genomics and Proteomics (2 Volume Set)
Edited by Jürgen Fuchs and Maurizio Podda
ISBN: 0-8247-5564-2

Dekker Encyclopedia of Nanoscience and Nanotechnology (5 Volume Set)
Edited by James A. Schwarz, Cristian Contescu, and Karol Putyera
ISBN: 0-8247-5055-1

Encyclopedia of Optical Engineering (3 Volume Set)
Edited by Ronald Driggers
ISBN: 0-8247-0940-3

Encyclopedia of Pharmaceutical Technology, Second Edition (3 Volume Set)
Edited by James Swarbrick
ISBN: 0-8247-2825-4

Encyclopedia of Public Administration and Public Policy (2 Volume Set)
Edited by Jack Rabin
ISBN: 0-8247-4748-8

Encyclopedia of Supramolecular Chemistry (2 Volume Set)
Edited by Jerry L. Atwood and Jonathan Steed
ISBN: 0-8247-5056-X

Encyclopedia of Surface and Colloid Science (4 Volume Set)
Edited by Arthur T. Hubbard
ISBN: 0-8247-0633-1

Dekker Agropedia Collection (7 Volume Set)

ISBN: 0-8247-2194-2
(Also available individually)

Encyclopedia of Agricultural, Food, and Biological Engineering
Edited by Dennis R. Heldman
ISBN: 0-8247-0938-1

Encyclopedia of Animal Science
Edited by Wilson G. Pond and Alan Bell
ISBN: 0-8247-5496-4

Encyclopedia of Pest Management
Edited by David Pimentel
ISBN: 0-8247-0632-3

Encyclopedia of Plant and Crop Science
Edited by Robert M. Goodman
ISBN: 0-8247-0944-6

Encyclopedia of Soil Science, Second Edition
Edited by Rattan Lal
ISBN: 0-8493-3830-1

Encyclopedia of Water Science
Edited by B.A. Stewart and Terry Howell
ISBN: 0-8247-0948-9

Coming Soon

Encyclopedia of Biotechnology in Agriculture and Food
Edited by Dennis R. Heldman
ISBN: 0-8493-5027-1

Encyclopedia of Pharmaceutical Technology, Third Edition (6 Volume Set)
Edited by James Swarbrick
ISBN: 0-8493-9399-X

Encyclopedia of Surface and Colloid Science, Second Edition (8 Volume Set)
Edited by Poniss Somasundaran
ISBN: 0-8493-9615-8

Encyclopedia of Energy Engineering (2 Volume Set)
Edited by Barney L. Capehart
ISBN: 0-8493-3653-8

These titles are available both in print and online. To order, visit:

This Encyclopedia is dedicated to
my wife

Kyung Paik Lee

who put up with me,
lovingly supported me,
and helped make this venture
a success

J. R. Burns / *Protensive Ltd., Bioscience Centre, Centre for Life, Newcastle Upon Tyne, U.K.*

Richard V. Calabrese / *Department of Chemical and Biomolecular Engineering, University of Maryland, College Park, Maryland, U.S.A.*

Gregg Caldwell / *3M Company, St. Paul, Minnesota, U.S.A.*

Gerard T. Caneba / *Department of Chemical Engineering, Michigan Technological University, Houghton, Michigan, U.S.A.*

Giovanni Maria Carlomagno / *Department of Energetics, Thermofluidynamics and Environmental Control (DETEC), University of Naples Federico II, Napoli, Italy*

C. Carraro / *University of California–Berkeley, Berkeley, California, U.S.A.*

Eldon D. Case / *Chemical Engineering and Materials Science Department, Michigan State University, East Lansing, Michigan, U.S.A.*

M. R. Cates / *Engineering Science and Technology Division, Oak Ridge National Laboratory (ORNL), Oak Ridge, Tennessee, U.S.A.*

John C. Chadwick / *Dutch Polymer Institute (DPI), Laboratory of Polymer Chemistry, Eindhoven University of Technology, Eindhoven, The Netherlands*

Louay M. Chamra / *Southeast Cooling, Heating and Power Application Center, Department of Mechanical Engineering, Mississippi State University, Mississippi State, Mississippi, U.S.A.*

Jamal Chaouki / *Ecole Polytechnique, Montreal, Quebec, Canada*

Vicki Chen / *UNESCO Centre for Membrane Science and Technology, School of Chemical Engineering, University of New South Wales, Sydney, New South Wales, Australia*

Zhilei Chen / *Center for Biophysics and Computational Biology, University of Illinois, Urbana, Illinois, U.S.A.*

Hyoung J. Choi / *Department of Polymer Science and Engineering, Inha University, Incheon, Korea*

Kyu Yong Choi / *Department of Chemical Engineering, University of Maryland, College Park, Maryland, U.S.A.*

Pyoungho Choi / *Albany Nanotech, The College of Nanoscale Science and Engineering (CNSE), State University of New York, Albany, New York, U.S.A.*

T. C. Chung / *Department of Materials Science and Engineering, The Pennsylvania State University, University Park, Pennsylvania, U.S.A.*

Matthew A. Clarke / *Department of Chemical and Petroleum Engineering, University of Calgary, Calgary, Alberta, Canada*

Gary Combes / *School of Chemical Engineering and Industrial Chemistry, The University of New South Wales, Sydney, New South Wales, Australia*

Richard F. Cope / *Fluid Mechanics and Mixing Group, The Dow Chemical Company, Midland, Michigan, U.S.A.*

Richard Corkish / *ARC Centre of Excellence for Advanced Silicon Photovoltaics and Photonics, University of New South Wales, Sydney, New South Wales, Australia*

R. A. Cottis / *School of Materials, Corrosion and Protection Centre, University of Manchester, Manchester, U.K.*

Sean A. Curran / *Honeywell International Inc., Morristown, New Jersey, U.S.A.*

Wayne R. Curtis / *Department of Chemical Engineering, The Pennsylvania State University, University Park, Pennsylvania, U.S.A.*

Teresa J. Cutright / *Department of Civil Engineering, The University of Akron, Akron, Ohio, U.S.A.*

Qizhou Dai / *Advanced Biomaterials Chemistry, University of British Columbia, Vancouver, British Columbia, Canada*

A. K. Dalai / *Catalysis and Chemical Reactor Engineering Laboratories, Department of Chemical Engineering, University of Saskatchewan, Saskatoon, Canada*

Douglas A. Dale / *Genencor International, Palo Alto, California, U.S.A.*

Rohit P. Datar / *Technical Operations, CPKelco, Okmulgee, Oklahoma, U.S.A.*

Ravindra Datta / *Fuel Cell Center, Worcester Polytechnic Institute, Worcester, Massachusetts, U.S.A.*

Sharad M. Dave / *Bhabha Atomic Research Center, Mumbai, India*

Forrest M. Davidson, III / *The University of Texas, Austin, Texas, U.S.A.*

Frank Davis / *Cranfield University, Silsoe, U.K.*

Mark DeDecker / *Firestone Polymers, Bridgestone/Firestone Research LLC, Akron, Ohio, U.S.A.*

Fariba Dehghani / *School of Chemical Engineering and Industrial Chemistry, The University of New South Wales, Sydney, New South Wales, Australia*

Shuguang Deng / *Chemical Engineering Department, New Mexico State University, Las Cruces, New Mexico, U.S.A.*

Amy S. Determan / *Department of Chemical and Biological Engineering, Iowa State University, Ames, Iowa, U.S.A.*

Glenn B. DeWolf / *URS Corporation, Austin, Texas, U.S.A.*

Partha Dey / *P.A. Consulting, Nashville, Tennessee, U.S.A.*

R. Dhib / *Department of Chemical Engineering, Ryerson University, Toronto, Ontario, Canada*

Huu D. Doan / *Department of Chemical Engineering, Ryerson University, Toronto, Ontario, Canada*

Mildred S. Dresselhaus / *Massachusetts Institute of Technology, Cambridge, Massachusetts, U.S.A.*

Nishith Dwivedi / *Department of Chemical Engineering, Indian Institute of Technology, New Delhi, India*

Vahid Ebadat / *Chilworth Technology, Inc., Princeton, New Jersey, U.S.A.*

Sina Ebnesajjad / *DuPont Fluoroproducts, Chestnut Run Plaza, Wilmington, Delaware, U.S.A.*

Jeremy S. Edwards / *Department of Chemical Engineering, University of Delaware, Newark, Delaware, U.S.A.*

Brian W. Eggiman / *Purdue University, West Lafayette, Indiana, U.S.A.*

J. Richard Elliott, Jr. / *Department of Chemical Engineering, University of Akron, Akron, Ohio, U.S.A.*

Morinobu Endo / *Faculty of Engineering, Shinshu University, Wakasato, Nagano-shi, Japan*

Rolf Erni / *Department of Chemical Engineering and Materials Science, University of California Davis, Lawrence Berkeley National Laboratory, Berkeley, California, U.S.A.*

Arthur W. Etchells / *DuPont Fellow, Philadelphia, Pennsylvania, U.S.A.*

L.-S. Fan / *Department of Chemical and Biomolecular Engineering, The Ohio State University, Columbus, Ohio, U.S.A.*

Rajeev Farwaha / *Celanese Polymers, Bridgewater, New Jersey, U.S.A.*

James J. Feng / *Department of Chemical and Biological Engineering and Department of Mathematics, University of British Columbia, Vancouver, British Columbia, Canada*

D. Ferdous / *Catalysis and Chemical Reactor Engineering Laboratories, Department of Chemical Engineering, University of Saskatchewan, Saskatoon, Canada*

Jim C. Fitch / *Noria Corporation, Tulsa, Oklahoma, U.S.A.*

J. F. Forbes / *Department of Chemical and Materials Engineering, University of Alberta, Edmonton, Alberta, Canada*

Mina Gabriel / *Honeywell International Inc., Morristown, New Jersey, U.S.A.*

Alfred Gaertner / *Genencor International, Palo Alto, California, U.S.A.*

Prabhu Ganesan / *Department of Chemical Engineering, University of South Carolina, Columbia, South Carolina, U.S.A.*

Shubhra Gangopadhyay / *University of Missouri–Columbia, Columbia, Missouri, U.S.A.*

Hugo S. Garcia / *UNIDA, Instituto Tecnologico de Veracruz, Veracruz, Mexico*

Dinesh Gera / *Fluent Incorporated, Morgantown, West Virginia, U.S.A.*

Richard Gilbert / *Department of Wood and Paper Science, North Carolina State University, Raleigh, North Carolina, U.S.A.*

Giuseppe Giorleo / *Department of Materials and Production Engineering (DIMP), University of Naples Federico II, Napoli, Italy*

S. M. Goedeke / *Engineering Science and Technology Division, Oak Ridge National Laboratory (ORNL), Oak Ridge, Tennessee, U.S.A.*

Scott Gold / *Department of Chemical and Biomolecular Engineering, University of Illinois, Urbana, Illinois, U.S.A.*

Vincent G. Gomes / *University of Sydney, Sydney, New South Wales, Australia*

James G. Goodwin, Jr. / *Department of Chemical Engineering, Clemson University, Clemson, South Carolina, U.S.A.*

John R. Grace / *University of British Columbia, Vancouver, British Columbia, Canada*

Brian P. Grady / *School of Chemical, Biological and Materials Engineering, University of Oklahoma, Norman, Oklahoma, U.S.A.*

Dan F. Graves / *Firestone Polymers, Bridgestone/Firestone Research LLC, Akron, Ohio, U.S.A.*

Erich Grotewold / *Department of Plant Cellular and Molecular Biology and Plant Biotechnology Center, The Ohio State University, Columbus, Ohio, U.S.A.*

Rajiv Grover / *Jacobs Engineering Group Inc., Houston, Texas, U.S.A.*

Ronald W. Gumbs / *Gumbs Associates Ltd., East Brunswick, New Jersey, U.S.A.*

L. Jay Guo / *Department of Electrical Engineering and Computer Science, The University of Michigan, Ann Arbor, Michigan, U.S.A.*

Ram B. Gupta / *Department of Chemical Engineering, Auburn University, Auburn, Alabama, U.S.A.*

Byung Gwon Lee / *Environment and Process Technology Division, Korea Institute of Science and Technology, Cheongryang, Seoul, South Korea*

Don C. Haddox / *Waterbury, Vermont, U.S.A.*

Joel M. Haight / *Pennsylvania State University, University Park, Pennsylvania, U.S.A.*

Pradeep Haldar / *Albany Nanotech, The College of Nanoscale Science and Engineering (CNSE), State University of New York, Albany, New York, U.S.A.*

Ian Hamerton / *University of Surrey, Surrey, U.K.*

Youssef K. Hamidi / *School of Aerospace and Mechanical Engineering, University of Oklahoma, Norman, Oklahoma, U.S.A.*

Tobias Hanrath / *The University of Texas, Austin, Texas, U.S.A.*

Douglas P. Harrison / *Gordon A. and Mary Cain Department of Chemical Engineering, Louisiana State University, Baton Rouge, Louisiana, U.S.A.*

Gareth P. Harrison / *Institute for Energy Systems, School of Engineering and Electronics, University of Edinburgh, Edinburgh, U.K.*

Takuya Hayashi / *Faculty of Engineering, Shinshu University, Wakasato, Nagano-shi, Japan*

Douglas G. Hayes / *Department Biosystems Engineering and Environmental Science, University of Tennessee, Knoxville, Tennessee, U.S.A.*

Donald T. Haynie / *Biomedical Engineering and Physics, Bionanosystems Engineering Laboratory, Center for Applied Physics Studies, Louisiana Tech University, Ruston, Louisiana, U.S.A.*

Roland H. Heck / *Princeton University, Princeton, New Jersey, U.S.A.*

William L. Hergenrother / *Bridgestone Americas Center for Research and Technology, Bridgestone/Firestone Research LLC, Akron, Ohio, U.S.A.*

Andrew M. Herring / *Department of Chemical Engineering, Colorado School of Mines, Golden, Colorado, U.S.A.*

Séamus P. J. Higson / *Cranfield University, Silsoe, U.K.*

Charles G. Hill, Jr. / *Department of Chemical and Biological Engineering, University of Wisconsin–Madison, Madison, Wisconsin, U.S.A.*

John O. Hill / *La Trobe University, Melbourne, Victoria, Australia*

Hugh W. Hillhouse / *Purdue University, West Lafayette, Indiana, U.S.A.*

B. Keith Hodge / *Southeast Cooling, Heating and Power Application Center, Department of Mechanical Engineering, Mississippi State University, Mississippi State, Mississippi, U.S.A.*

J. D. Holladay / *Pacific Northwest National Laboratory, Richland, Washington, U.S.A.*

W. A. Hollerman / *Department of Physics, University of Louisiana at Lafayette, Lafayette, Louisiana, U.S.A.*

W. C. Hsu / *Sino-American Silicon Product Inc., Hsinchu, Taiwan, ROC*

X. D. Hu / *R&D, Süd-Chemie Inc., Louisville, Kentucky, U.S.A.*

Yinlun Huang / *Department of Chemical Engineering and Materials Science, Wayne State University, Detroit, Michigan, U.S.A.*

Anton Huber / *PolySaccharide Initiative, Institut für Chemie, Karl-Franzens, Universität Graz, Graz, Austria*

Kang Moo Huh / *Department of Polymer Science and Engineering, Chungnam National University, Daejeon, South Korea*

Raymond L. Huhnke / *Biosystems and Agricultural Engineering, Oklahoma State Unviersity, Stillwater, Oklahoma, U.S.A.*

Steven C. Hukvari / *Parr Instrument Company, Moline, Illinois, U.S.A.*

Scott M. Husson / *Department of Chemical and Biomolecular Engineering, Clemson University, Clemson, South Carolina, U.S.A.*

Sangchul Hwang / *Department of Civil Engineering and Surveying, University of Puerto Rico, Mayagüez, Puerto Rico*

Oleg Ilinich / *Engelhard Corporation, Iselin, New Jersey, U.S.A.*

R. J. J. Jachuck / *Process Intensification and Clean Technology (PICT) Group, Department of Chemical Engineering, Clarkson University, Potsdam, New York, U.S.A.*

Manish Jain / *3M Company, St. Paul, Minnesota, U.S.A.*

Krishnan Jayaraman / *University of Auckland, Auckland, New Zealand*

Nigil Satish Jeyashekar / *Department of Chemical Engineering, University of Mississippi, University, Mississippi, U.S.A.*

Myung S. Jhon / *Department of Chemical Engineering and Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, Pennsylvania, U.S.A.*

Tyler Johannes / *Department of Chemical and Biomolecular Engineering, University of Illinois, Urbana, Illinois, U.S.A.*

Preface

The *Encyclopedia of Chemical Processing* is an authoritative, dynamic, and most comprehensive multi-volume reference work on the broad subject of chemical processing, which will enable readers to have an enriching experience about general as well as targeted knowledge in this field. The *Encyclopedia* caters to engineers, scientists, researchers, inventors, professors, and students, as well as general readers in academia, industry, research institutions, government, and legal practices. In addition, the *Encyclopedia* has been designed to address the needs of practicing engineers and scientists, businessmen, lawyers, industrial executives, and professionals in the chemical processing and technology arena.

The *Encyclopedia* encompasses the entire realm of chemical processing, offering up-to-date, reliable, and comprehensive coverage of process technologies that have steadily progressed over the years, and at the same time identifying and addressing new breakthroughs and emerging technologies in chemical processing. The *Encyclopedia* contains a large number of entries that are devoted to life science subjects and futuristic materials and technologies, namely, biotechnology, nanomaterials and nanotechnology, and materials and technologies geared for microelectronics. Under the advice of an editorial advisory board comprised of distinguished and renowned scholars from around the world, the *Encyclopedia* will serve as the most respected reference work in the field of chemical processing.

The *Encyclopedia* covers cradle-to-grave information on processing novel materials, emerging process technologies and resultant materials, and manufacturing organic and inorganic chemicals. Specific topics of interest include synthesis reactions, properties and characterization of materials, appropriate choice of catalysts, reactor design, process flowsheets, energy integration practices, pinch design, design of separation equipment and peripherals, environmental aspects of chemical plant operation such as safety and loss prevention, obedience of environmental regulations, waste reduction and management, and much more. The *Encyclopedia* also contains descriptions of different types of reactors and separation systems and their design, unit operations, system integration, process system peripherals such as pumps, valves, and controllers, analytical techniques and equipment, as well as pilot plant design and scale-up criteria.

Fundamental aspects of industrial catalytic processes are detailed including catalyst preparation, characterization, structure-property relationships, deactivation and defouling, and catalyst regeneration methods. Examples of industrial processes that use different types of catalysts for chemical manufacture are also detailed. Identification and utilization of alternative resources for complementing our energy needs are addressed, which include renewable energy resources, oxygenated fuels, biofuels, fuel cells, and batteries.

Polymers are ubiquitous in today's life, and their utilization is limited only by chemists' and chemical engineers' imaginations. The *Encyclopedia* attempts to cover the wide spectrum of polymerization and polymer processing, including metallocene processes, description of structure, properties and end use of different polymers, copolymers, polymer blends and composites, polymer coatings, and rubber compounds. Additional topics of interest that are also covered include but are not limited to polymer characterization, molding technology, and polymer and rubber recycling. Advanced materials being used in myriad applications are also accounted for; examples of these are ceramics, nanomaterials, nanocomposites, carbon nanotubes, hydrophilic polymers, photovoltaic materials, biomaterials, and biomedical materials.

The issues potentially related to global warming cannot be understated in the present world, largely due to the increasing use of fossil fuels by automobiles and industries around the world. The degree to which this environmental issue affects society and the remedial measures needed in order to alleviate these concerns are well-addressed in the *Encyclopedia*, which covers emerging environmental technology, bioremediation, greenhouse gas alleviation, waste minimization, sequestration of carbon dioxide, etc.

Biotechnology is a rapidly growing area of chemical, biological, and life sciences, and as such is also well-covered in the *Encyclopedia*. Enzymes, biomaterials, bioseparation, bioprocessing, bioreactor design, biocatalysis, BioMEMS, protein design, chiral drug separation, and hydrogels are few of the topics of merit that are included.

The *Encyclopedia* also identifies and addresses emerging technologies in great detail including but not limited to nanotechnology, plasma technology, thin film technology, supercritical fluid technology and its applications, as well as microfabrication and micromachining for the microelectronics area.

The authors of this initial printed version of the *Encyclopedia* are recognized experts in their fields, lending credibility and prestige to the *Encyclopedia*. All the authors were invited based on their records of accomplishment in the chosen topical areas. All entries were individually reviewed by peers as well as the Editor. As part of the review and revision processes, every effort was exercised to maintain the consistency, accuracy, readability, and up-to-date nature of the information presented.

The *Encyclopedia* is published in both online and printed formats. The printed version consists of multiple traditional hardbound volumes with articles arranged alphabetically. The online version of the *Encyclopedia* is created by coupling the content of the printed edition with a powerful search engine, user-friendly interface, and customer-focused features. The online database is dynamic and evolving in nature, with additional articles added each quarter.

The Editor feels honored to have been asked to undertake the important and challenging endeavor of developing the *Encyclopedia of Chemical Processing* that will cater to the needs of the rapidly changing world of the 21st century. The Editor is humbled to follow the impeccable work of the previous editor, Professor John J. McKetta, who led the development of the *Encyclopedia of Chemical Processing and Design*, a total of 69 volumes, which has become one of the most authoritative reference sources for scientists, engineers, and practitioners for several decades.

I would like to express my most sincere thanks and appreciation to the authors for their excellent professionalism and dedicated work. Needless to say, an encyclopedia of this nature would never exist if the expert authors had not devoted their valuable time to preparing the authoritative entries on their assigned topics. I wish to thank all my colleagues and friends as well as the editorial board members for all their suggestions, comments, assistance, volunteerism, and patience. In particular, I appreciate the encouragements, guidance, and assistance provided by Mr. Russell Dekker, Dr. Chai-sung Lee, Dr. John C. Angus, Dr. C. C. Liu, Dr. James G. Speight, Dr. Robert Dye, Dr. Sunil Kesavan, Dr. John Zabasajja, Dr. J. Richard Elliott, Jr., Dr. Abhay Sardesai, Dr. Hirotsugu Yasuda, Dr. David G. Retzloff, Dr. Patricia Roberts, Dr. Kelly Clark, Dr. Jeffrey Yen, Dr. Peter Pujado, and Dr. Stephen J. Lombardo. I also would like to thank Mr. Jonathan E. Wenzel, Ms. Leah A. Leavitt, Dr. Teresa J. Cutright, Dr. H. Bryan Lanterman, Dr. Qingsong Yu, and Dr. Patricia A. Darcy for providing various assistance while editing. I am also deeply indebted to the former and current employees of the Publisher for their dedicated work toward successful completion of the project, to name a few, Ms. Alison Cohen, Ms. Oona Schmid, Ms. Marisa Hoheb, Ms. Maria Kelley, Ms. Meaghan Johnson, and Ms. Joanne Jay. The contributions of those mentioned made this *Encyclopedia* possible.

Absorption Equipment

Karl B. Schnelle, Jr.
Chemical Engineering Department, Vanderbilt University, Nashville, Tennessee, U.S.A.

Partha Dey
P. A. Consulting, Nashville, Tennessee, U.S.A.

INTRODUCTION

Absorption is a mass transfer operation in which a soluble gaseous component is removed from a gas stream by dissolving in a liquid. Absorption can be used to recover valuable gaseous components such as hydrocarbons or to remove unwanted gaseous components such as hydrogen sulfide from a stream. A valuable solute can be separated from the absorbing liquid and recovered in a pure, concentrated form by distillation or stripping (desorption). The absorbing liquid is then used in a closed circuit and is continuously regenerated and recycled. Examples of regeneration alternatives to distillation or stripping are removal through precipitation and settling; chemical destruction through neutralization, oxidation, or reduction; hydrolysis; solvent extraction; and liquid adsorption. Absorption is one of the main methods of separation used in the chemical processing industry. Accompanied by chemical reaction between the absorbed component and a reagent in the absorbing fluid, absorption can become a very effective means of separation. Absorption can also be used to remove an air pollutant like an acid gas from stream. Then, the system could be a simple absorption in which the absorbing liquid is used in a single pass and then disposed of while containing the absorbed pollutant.

Operations of Absorption Towers

In the past it was the custom to call absorbers operating as cleanup towers to remove undesirable gaseous effluents by the name of scrubber. At that time most of the effluent gases being removed were acid gases being scrubbed with water. The designation of scrubber to scrub the discharge gas and clean it seemed rather natural. Today the same kind of operation is carried out, but with more stringent regulations imposed by the local air pollution control agency. The name scrubber is now applied to those operations in which particulate matter is removed but the scrubbing operation may also include the simultaneous removal of gaseous pollutants. In this chapter the term absorber will refer to the removal of gaseous contaminants.

General Considerations

Filters, heat exchangers, dryers, bubble cap columns, cyclones, etc., are ordinarily designed and built by process equipment manufacturers. However, units of special design for one-of-a-kind operations such as packed or plate towers are quite often designed and built under the supervision of plant engineers. Thus, there is a large variety of this type of equipment, none of it essentially standard.

TYPES OF ABSORPTION EQUIPMENT

Absorption takes place in either staged or plate towers or continuous or packed contactor. However, in both cases the flow is continuous. In the ideal equilibrium stage model, two phases are contacted, well mixed, come to equilibrium, and then are separated with no carryover. Real processes are evaluated by expressing efficiency as a percentage of the change that would occur in the ideal stages. Any liquid carryover is removed by mechanical means.

In the continuous absorber the two immiscible phases are in continuous and tumultuous contact within a vessel that is usually a tall column. A large surface is made available by packing the column with ceramic or metal materials. The packing provides more surface area and a greater degree of turbulence to promote mass transfer. The penalty for using packing is in the increased pressure loss in moving the fluids through the column, which causes an increased demand for energy. In the usual countercurrent flow column, the lighter phase enters the bottom and passes upward. Transfer of material takes place by molecular and eddy diffusion processes across the interface between the immiscible phases. Contact may be also cocurrent or cross-flow. Columns for the removal of

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007642

air contaminants are usually designed for countercurrent or cross-flow operation.

Absorption can take place in a countercurrent, cocurrent, or cross-flow device. Vertical countercurrent towers are either built with a metal, plastic, or ceramic packing or constructed as plate towers with various types of plates. This chapter will discuss the solvents used to carry out absorption and the various types of absorption equipment.

ABSORPTION SOLVENTS

Absorption systems can be divided into those that use water as the primary absorbing liquid and those that use a low-volatility organic liquid. The gas solubility should be high in the absorbing solvent. The gas leaving an absorber is usually saturated with the solvent; therefore, the solvent should have a low vapor pressure. A lower viscosity solvent is advantageous to promote more rapid absorption rates and improve flooding characteristics. The solvent should not be corrosive to the materials of construction of the absorber. It should be nontoxic and nonflammable. Depending on the region where the absorber is to be constructed, the solvent should have a low freezing point.

Nonaqueous Systems

At first glance, an organic liquid appears to be the preferred solvent for absorbing hydrocarbon and organic vapors from a gas stream because of improved solubility and miscibility. The lower heat of vaporization of organic liquids results in energy conservation when solvent regeneration must occur by stripping. Many heavy oils such as No. 2 fuel oil or heavier and other solvents with low vapor pressure can do extremely well in reducing organic vapor concentrations to low levels. Care must be exercised in picking a solvent that will have sufficiently low vapor pressure so that the solvent itself will not become a source of volatile organic pollution. Obviously, the treated gas will be saturated with the absorbing solvent. An absorber–stripper system for recovery of benzene vapors has been described by Crocker.[1] Other aspects of organic solvent absorption requiring consideration are stability of the solvent in the gas solvent system, for example, its resistance to oxidation, and its possible fire and explosion hazard.

Although water is the most common liquid used for absorbing acidic gases, amines (monoethanol-, diethanol-, and triethanolamine; methyldiethanolamine; and dimethylaniline) have been used for absorbing SO_2 and H_2S from hydrocarbon gas streams. Such absorbents are generally limited to solid particulate free systems because solids can produce difficult to handle sludge as well as use up valuable organic absorbents. Furthermore, because of absorbent cost, absorbent regeneration must be practiced in almost all cases.

Aqueous Systems

Absorption is one of the most frequently used methods for removal of water-soluble gases. Acidic gases such as HCl, HF, and SiF_4 can be absorbed in water efficiently and readily, especially if the last contact is made with water that has been made alkaline. Less soluble acidic gases such as SO_2, Cl_2, and H_2S can be absorbed more readily in a dilute caustic solution. The scrubbing liquid may be made alkaline with dissolved soda ash or sodium bicarbonate, or with sodium hydroxide, usually with no higher a concentration in the scrubbing liquid than 5–10%. Lime is a cheaper and more plentiful alkali, but its use directly in the absorber may lead to plugging or coating problems if the calcium salts produced have only limited solubility. A technique often used is the two-step flue gas desulfurization process, where the absorbing solution containing NaOH is used inside the absorption tower, and then the tower effluent is treated with lime externally, precipitating the absorbed component as a slightly soluble calcium salt. The precipitate may be removed by thickening and the regenerated sodium alkali solution is recycled to the absorber. Scrubbing with an ammonium salt solution can also be employed. In such cases, the gas is often first contacted with the more alkaline solution and then with the neutral or slightly acid contact to prevent stripping losses of NH_3 to the atmosphere.

When flue gases containing CO_2 are being scrubbed with an alkaline solution to remove other acidic components, the caustic consumption can be inordinately high if CO_2 is absorbed. However, if the pH of the scrubbing liquid entering the absorber is kept below 9.0, the amount of CO_2 absorbed can be kept low. Conversely, alkaline gases, such as NH_3, can be removed from the main gas stream with acidic water solutions such as dilute H_2SO_4, H_3PO_4, or HNO_3. Single-pass scrubbing solutions so used can often be disposed of as fertilizer ingredients. Alternatives are to remove the absorbed component by concentration and crystallization. The absorbing gas must have adequate solubility in the scrubbing liquid at the resulting temperature of the gas–liquid system.

For pollutant gases with limited water solubility, such as SO_2 or benzene vapors, the large quantities of water that would be required are generally impractical on a single-pass basis, but may be used in unusual circumstances. An early example from the United Kingdom is the removal of SO_2 from flue gas at the Battersea and Bankside electric power stations, which is described by Rees.[2] Here, the normally alkaline

water from the Thames tidal estuary is used in a large quantity on a one-pass basis.

PACKED TOWERS

There are two major types of packing, random dumped pieces and structured modular forms. The structured packing is usually crimped or corrugated sheets. The packing provides a large interfacial area for mass transfer and should have a low-pressure drop. However, it must permit passage of large volumes of fluid without flooding. The pressure drop should be the result of skin friction and not form drag. Thus, flow should be through the packing and not around the packing. The packing should have enough mechanical strength to carry the load and allow easy handling and installation. It should be able to resist thermal shock and possible extreme temperature changes, and it must be chemically resistant to the fluids being processed.

Random or Dumped Packing

Random packings are dumped into the tower during construction and are allowed to fall at random. The tower might be filled with water, first to allow a gentler settling and to prevent breakage, especially with ceramic-type packing. Random dumped tower packing comes in many different shapes. Two of the most popular are rings and saddles. Sizes range from 0.25 in. to 3.5 in., with 1 in. being a very common size. The choice of a packing is mostly dependent on the service in which the tower will be engaged. Packings are made of ceramic, metal, or plastic, depending on the service. Ceramic materials will withstand corrosion and are therefore used where the solutions resulting are aqueous and corrosive. Metals are used where noncorrosive organic liquids are present. Plastic packing may be used in the case of corrosive aqueous solutions and for organic liquids that are not solvents for the plastic of which the packing is made. Metal packing is more expensive, but provides lower pressure drop and higher efficiency. When using plastic materials, care must be taken that the temperature is not too high and that oxidizing agents are not present. Ring-type packings are commonly made of metal or plastic, except for Raschig rings, which are generally ceramic. Ring-type packings lend themselves to distillation because of their good turndown properties and availability in metals of all types that can be press formed. Usually, ring-type packings are used in handling organic solutions when there are no corrosive problems. However, rings do not promote redistribution of liquids, and Raschig rings may even cause maldistribution. Saddles are commonly made from ceramic or plastic and give good corrosion resistance. Saddles are best for redistribution of liquid and, thus, serve as a good packing for absorption towers.

Structured Packing

Early on after the production of random packings had been used extensively, stacked beds of the conventional random packings such as larger-sized Raschig rings were used as ordered packings. Owing to the high cost of installation of this type of packing, it was largely discontinued. At that time multiple layers of corrugated metal lath formed into a honeycomb structure came into use. Later on, a woven wire mesh arranged in rows of vertically corrugated elements came into use. Subsequently, other wire-mesh structures have gained favor. Then, a sheet metal structured packing was developed to reduce the expense of the wire-mesh type. The use of this structured type of packing not only promotes mass transfer owing to increased surface area, but also has less pressure drop in many different services.

Tower Considerations

Materials of construction

Random packing can be made from ceramic materials, plastic, or metal. Most structured packing and plates in staged towers are made from metal although there are simple woven types of plastic materials that can be considered as structured packing. The tower packing, plates, and tower materials must be compatible with the fluids flowing through the towers. Of particular significance would be acid gases that may have a deleterious effect on metal tower internal parts and organic solvents that may have a serious effect on plastic materials. It is also necessary to consider the case where there may be a high heat of absorption emitted. The internal tower may have to be cooled to withstand the temperature that results from the heat of absorption.

Flow arrangements

In diffusional operations such as absorption where mass is to be transferred from one phase to another, it is necessary to bring the two phases into contact to permit the change toward equilibrium to take place. The transfer may take place with both streams flowing in the same direction, in which case the operation is called concurrent or cocurrent flow. When the two streams flow in the opposite direction, the operation is termed countercurrent flow, an operation carried out with the gas entering at the bottom and flowing

upward and the liquid entering at the top and flowing down. This process is illustrated in Fig. 1. A combined operation in which the contaminated gas is first cleaned in a countercurrent operation, as shown in Fig. 2, and then the gas is further treated to remove more of the contaminant as shown in the cocurrent operation that follows.

Countercurrent operation is the most widely used absorption equipment arrangement. As the gas flow increases at constant liquid flow, liquid holdup must increase. The maximum gas flow is limited by the pressure drop and the liquid holdup that will build up to flooding. Contact time is controlled by the bed depth and the gas velocity. In countercurrent flow mass transfer driving force is maximum at the gas entrance and liquid exit. Cocurrent operation can be carried out at high gas velocities because there is no flooding limit. In fact, liquid holdup decreases as velocity increases. However, the mass transfer driving force is smaller than in countercurrent operation.

Some processes for both absorption and the removal of particulates employ a cross-flow spray chamber operation. Here, the water is sprayed down on a bed of packing material. The carrier gas containing pollutant gas or the particulate flows horizontally through the packing, with the spray and packing causing the absorbed gas or particles to be forced down to the bottom of the spray chamber where they can be removed. Fig. 3 illustrates a cross-flow absorber. The design of cross-flow absorption equipment is more difficult than vertical towers because the area for mass transfer is different for the gas and liquid phases.

Continuous and steady-state operation is usually most economical. However, when smaller quantities of material are processed, it is often more advantageous to charge the entire batch at once. In fact, in many cases this is the only way the process can be done. This is called batch operation and is a transient operation from start-up to shut-down. A batch operation presents a more difficult design problem.

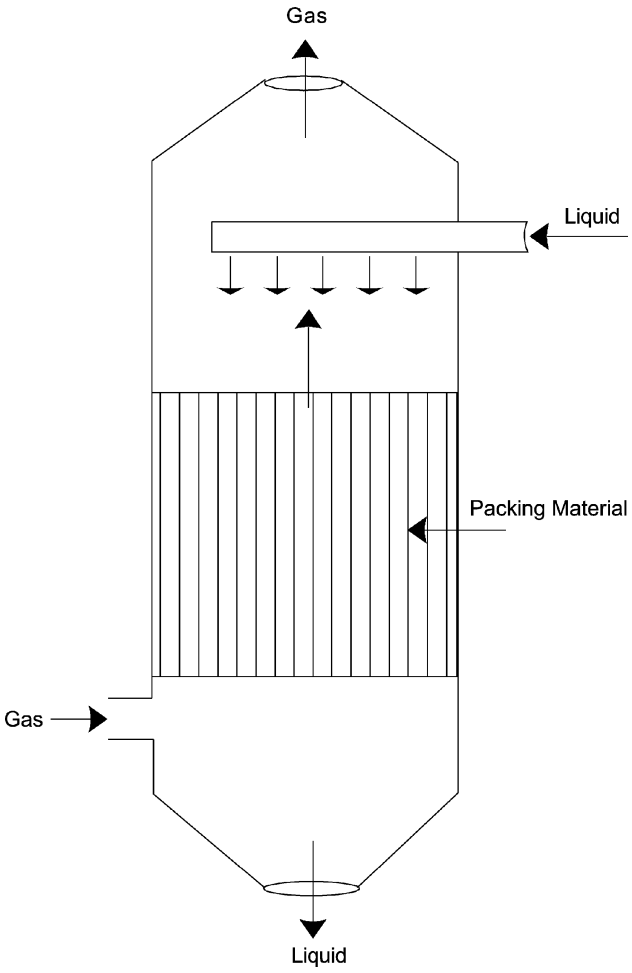

Fig. 1 Countercurrent flow packed tower.

Packed tower internals

In addition to the packing, absorption towers must include internal parts to make a successful piece of operating equipment. Fig. 4 illustrates the placement of the tower internals. These internals begin with a packing support plate at the bottom of the tower. The packing support plate must physically support the weight of the packing. It must incorporate a high percentage of free area to permit relatively unrestricted flow of downcoming liquid. A flat plate has the disadvantage in that both liquids and gases must pass countercurrently through the same holes. Therefore, a substantial hydrostatic head may develop. Furthermore, the bottom layer of packing partially blocks many of the openings reducing the free space. Both of these conditions lower tower capacity. A gas injection plate provides separate passage for gas and liquid and prevents buildup of hydrostatic head.

Liquid distributors are used at all locations where an external liquid stream is introduced. Absorbers and strippers generally require only one distributor, while continuous distillation towers require at least two, at the feed and reflux inlets. The distributors should be 6–12 in. above packing to allow for gas disengagement from the bed. The distributor should provide uniform liquid distribution and a large free area for gas flow.

Liquid redistributors collect downcoming liquid and distribute it uniformly to the bed below. Initially, after entering the tower the liquid tends to flow out to the wall, the redistributor makes that portion of the liquid more available again to the gas flow. It also breaks up the coalescence of the downcoming liquid, and it will eliminate factors that cause a loss of efficiency in the tower and reestablish a uniform pattern of liquid

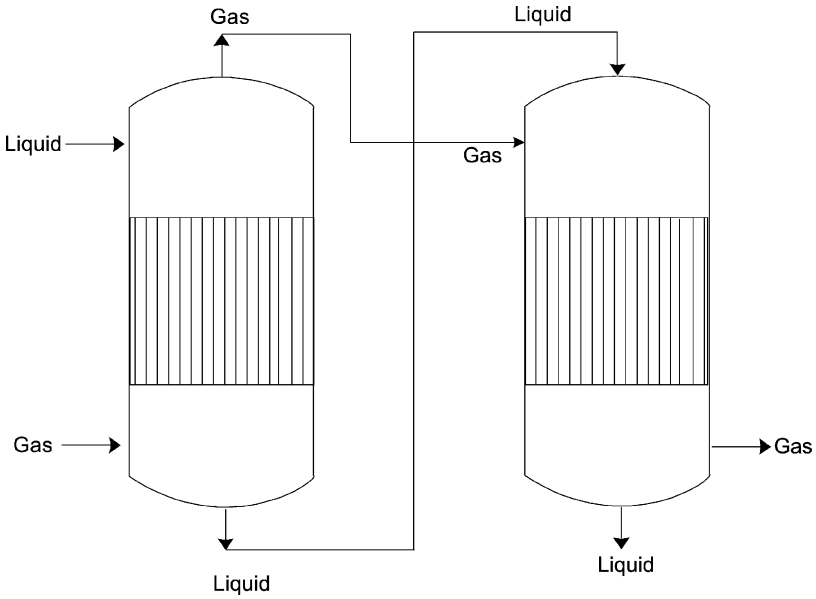

Fig. 2 Combined countercurrent and cocurrent operation.

irrigation. A bed depth of up to 6 m (20 ft) should be alright before redistribution is needed.

Retaining and hold-down plates are used only with ceramic or carbon tower packing. They prevent the upper portion of the packed bed from becoming fluidized and from breaking up during surges in pressure or at high-pressure drop. The plates rest directly on packing and restrict movement by virtue of the weight of the plate. Retainers or bed limiters prevent bed expansion or fluidization. When operating at high-pressure drops, retainers are fastened to the wall. They are designed to prevent individual packing pieces from passing through the plate openings.

PLATE TOWERS

Plate or tray towers are vertical cylinders in which the gas and liquid are contacted on horizontal plates in a stepwise fashion. By the nature of the operation plate towers are countercurrent flow devices. Fig. 5 shows a typical arrangement. In plate columns the gas is introduced at the bottom. Contact between gas and liquid is obtained by forcing the gas to pass upward through small orifices, bubbling through a liquid layer flowing across a plate. The liquid is introduced at the top and passes downward by gravity over the plate and through a downcomer onto the next plate. The

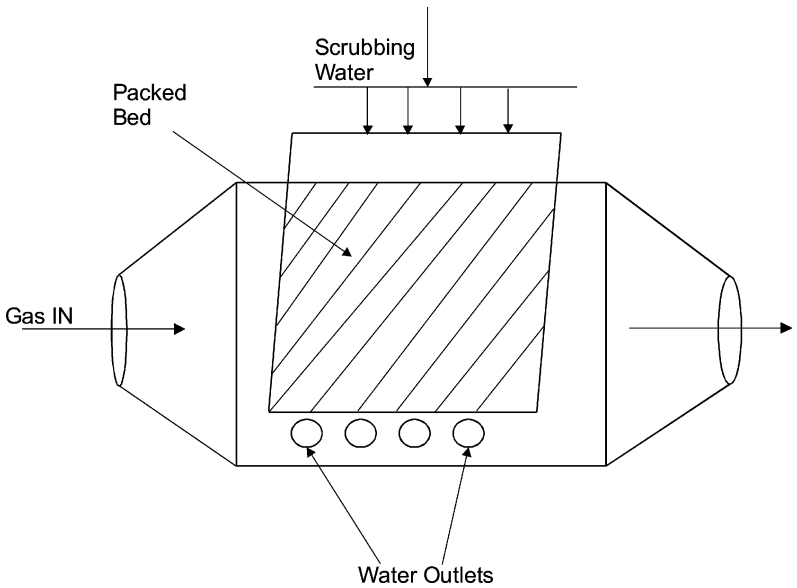

Fig. 3 Cross-flow absorber operation.

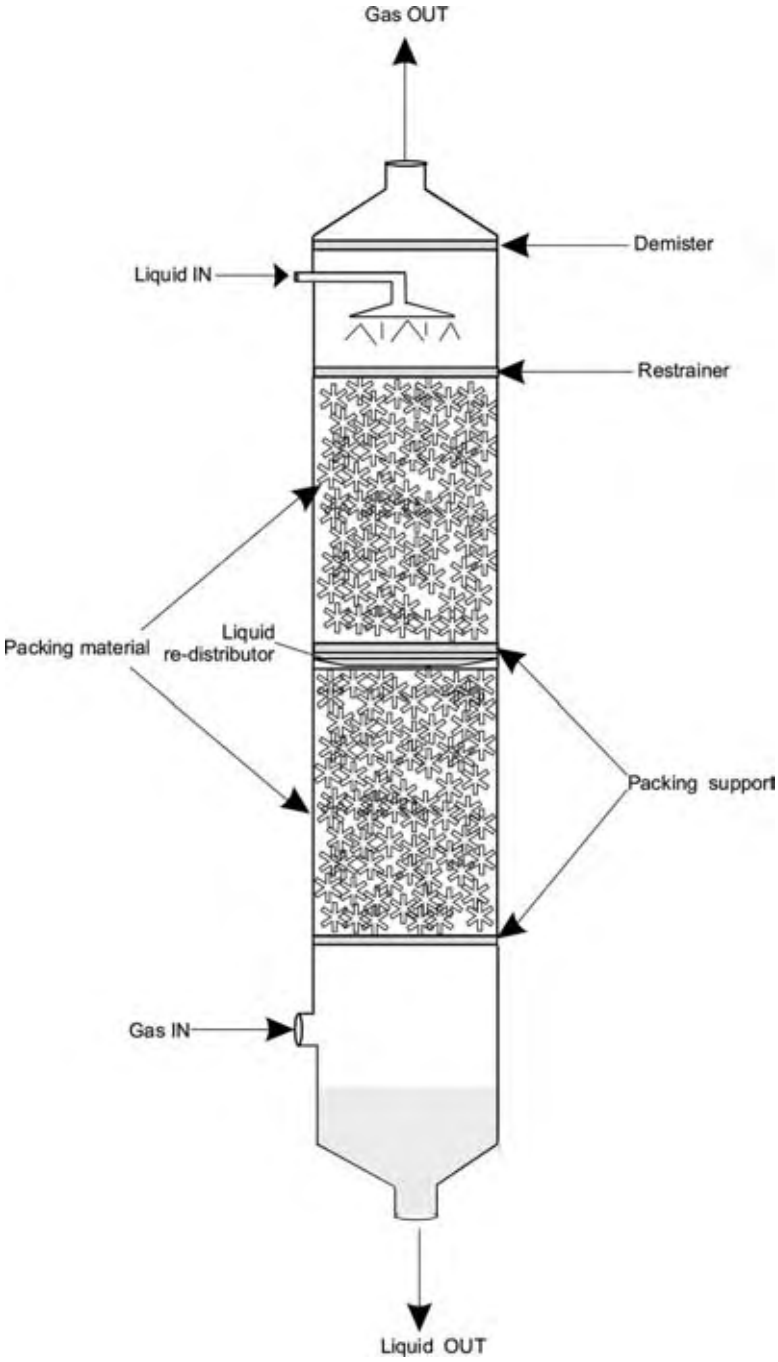

Fig. 4 Packed column with internal hardware indicated. *(View this art in color at www.dekker.com.)*

bubble cap tower is the classical contacting device. Each plate of the tower is a stage in which interphase diffusion occurs and the fluids are separated. Ideally, the vapor and liquid would reach equilibrium at each stage. The number of these ideal stages that are required is determined by the difficulty of separation. The number is calculated from the mass and energy balances around the plate and the tower. The stage or tray efficiency is determined by the mechanical design. Higher contact times result in higher efficiencies. Deeper pools of liquid on the plates promote higher contact times, and higher gas velocities promote better efficiency as well. Unfortunately, these conditions can lead to flooding of the plates and a severe drop in efficiency or foaming of the liquid on the plates. Thus, an inoperative situation might result. Turndown ratio is defined as the ratio of design rate to minimum rate. In many instances of tower design and operation, the performance when operating below the design rate becomes important. Furthermore, plate towers experience the same materials limitations as discussed earlier for packed towers. When selecting

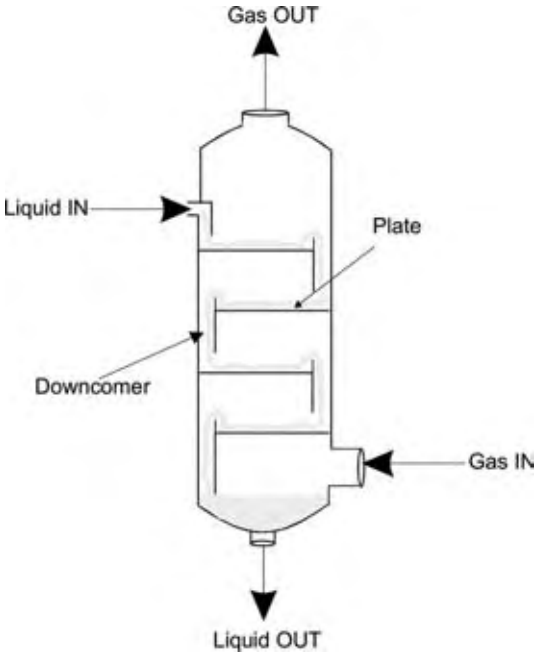

Fig. 5 Plate column. *(View this art in color at www.dekker.com.)*

plate types in addition to materials of construction, turndown ratio, pressure drop, capacity, and efficiency must be considered.

Plate Types

A plate type column may be operated in either a cross-flow or a counterflow method. Cross-flow plates are the most common types. Perry and Green and Wankat discuss the advantages of both type plates.[3,4] Cross-flow plates use a downcomer to transport the liquid from the upper plate to the lower plate. They offer greater mass transfer efficiency and operating range. The downcomer may be located to control the liquid flow pattern. Newer designs of cross-flow plates employ perforations, which may be simple round orifices or may contain movable valve-like vents that act like variable orifices. These type plates will be discussed in the following section.

In counterflow plates there are no downcomers and the liquid and gas use the same openings for flow. The openings are usually round perforations or long slots. The plates may be corrugated to segregate the liquid and gas flow.

Bubble Caps

Bubble cap trays, a cross-flow type of plate, were originally the most common type of tray. On these trays risers lead the gas up through the tray and underneath a cap that is mounted on top of the riser. A series of slots are cut into the cap through which the gas passes into the liquid that is flowing across the plate. They have the advantage of being able to handle wide ranges of liquid and gas flows. However, the new types of trays are much less expensive; therefore, bubble caps are being phased out of use in new tower designs.

Sieve Trays

Sieve plates are simple flat plates perforated with small holes. The advantages are low cost and high plate efficiency but they have narrow gas flow operating ranges. These trays may be subject to flooding because of liquid backing up in the downspouts or excessive entrainment. Fig. 6 is a schematic illustrating bubble cap and sieve trays. Efficiency remains good at design conditions. However, turndown is relatively poor, and therefore, the trays are not flexible in operating conditions. Sieve trays are relatively resistant to clogging and they can have large holes that make them easier to clean. Entrainment is much less than that experienced in bubble cap trays; therefore, plate spacing can be smaller than in bubble cap trays.

Valve Trays

A variation of the bubble cap tray is the valve tray, which permits greater variations in gas flow without dumping the liquid through the gas passages. Valve trays are also cross-flow type and can be described as sieve trays with large variable openings. The openings are covered with movable caps that rise and fall as the gas rate increases and decreases. This keeps the gas velocity through the slots essentially constant. Valve

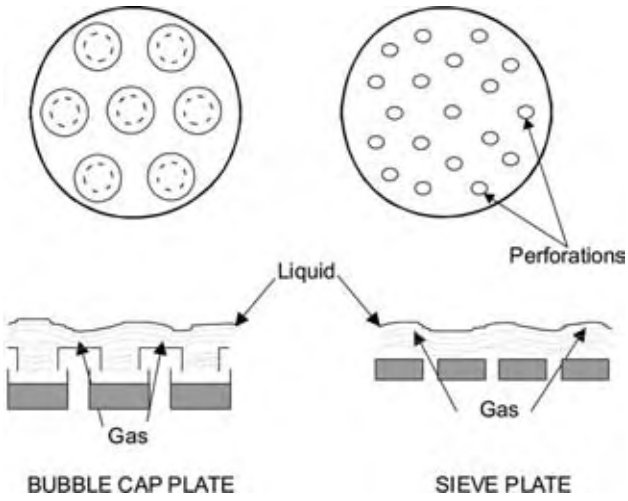

Fig. 6 Bubble cap and sieve tray. *(View this art in color at www.dekker.com.)*

trays are designed to have better turndown ratios than sieve trays and their efficiency remains high as the gas rate drops. Valve trays are more likely to plug if solids are present and are more costly than sieve trays.

Baffle Tower

A counterflow plate-contacting device for absorption is the baffle tower, which has been employed occasionally when plugging and scaling problems are expected to be severe. Fig. 7 illustrates a baffle tower. Gases passing up the tower must pass through sheets of downwardly cascading liquid, providing some degree of contact and liquid atomization. Baffle tower design may use alternating segmental or disk and doughnut plates. Here, the gas alternately flows upward through central orifices and annuli traversing through liquid curtains with each change in direction. Mass transfer is generally poor, and information on design parameters is hard to find.

Spray Chambers

A liquid may be introduced into a tower as fine drops through a nozzle. This device is known as a spray chamber. The flow could be cocurrent or countercurrent. A countercurrent spray chamber is shown in Fig. 8. These towers are considerably more resistant to plugging when solid particulates are present in the inlet gas. However, difficulties with plugging in spray towers and erosion can be troublesome when the spray liquid is recycled. Particle settling followed by fine strainers or even coarse filters is beneficial to eliminate

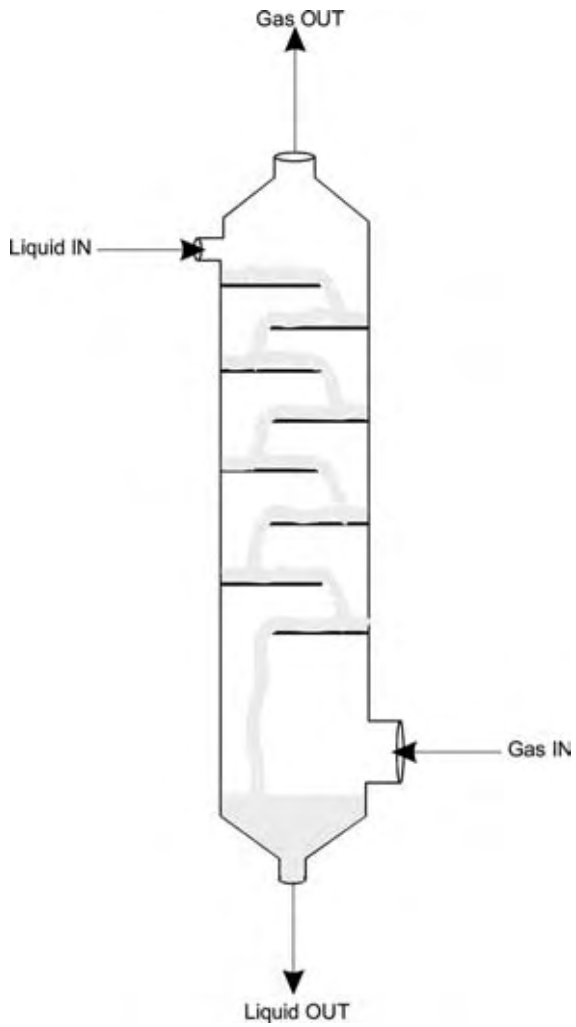

Fig. 7 Baffle tray tower. *(View this art in color at www.dekker.com.)*

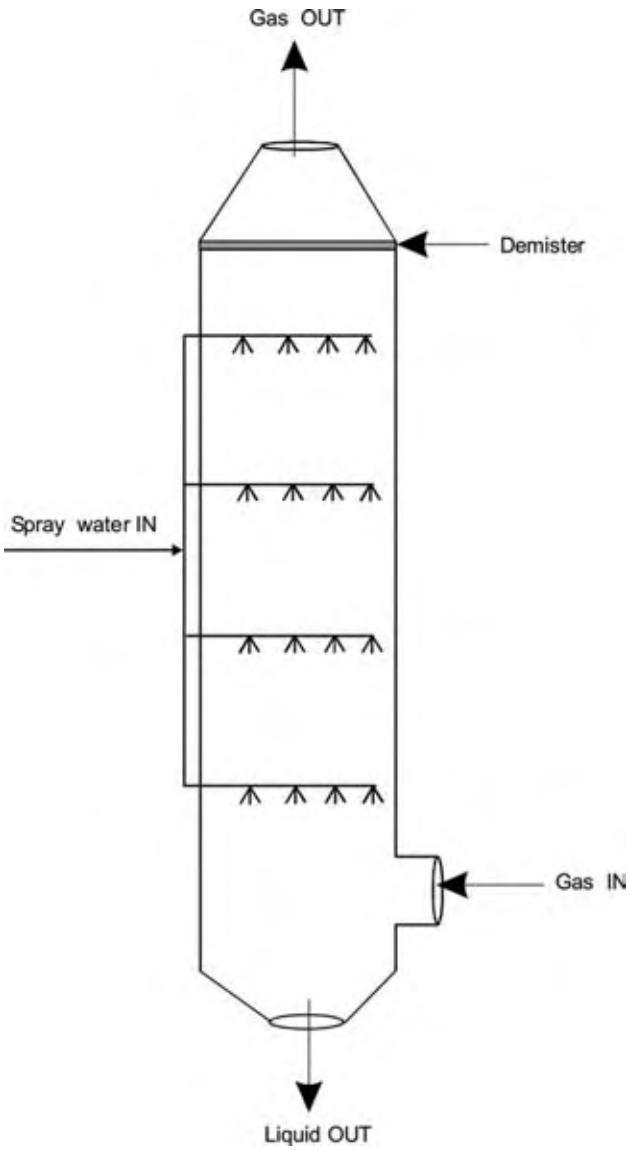

Fig. 8 Spray chamber. *(View this art in color at www.dekker.com.)*

this problem. These devices have the advantage of low-pressure drop but there is a tendency for the liquid to be entrained in the gas leaving the tower. Mist eliminators can help reduce this problem. An additional disadvantage is the cost of pumping the liquid to force it through the nozzles. The efficiency of spray chambers can be improved by introducing the feed into the tower in a cyclonic manner.

ABSORPTION FOR AIR POLLUTION CONTROL

Absorption plays a major role today in air pollution control. In the first part of this chapter it was noted that absorption was referred to as scrubbing especially when associated with cleaning up a stream containing an acid gas before it was emitted to the atmosphere. Today in air pollution control technology the term scrubber continues to be used with reference to cleanup of pollutant gases but usually when the equipment used also removes particulate matter. The combined action of removal of particulates and gases takes place in venturi scrubbers, spray towers, plate towers, and other types of devices. Absorption of sulfur oxides and nitrogen oxides are the most common devices where the combined action of particulate removal and absorption of gases takes place. It must be noted, however, that if an absorption process is going to be used to remove sulfur oxides it should not precede an electrostatic precipitator. Removal of the sulfur molecules before the precipitator will change the electrical properties of the gas and may result in loss of the ability to remove the particulate matter in the precipitator.

There continue to be many absorbers for the removal of water-soluble gases. Acid gases and some volatile organic compounds can be absorbed readily in water by the types of equipment previously discussed. These processes are essentially absorption with chemical reaction. For a discussion of absorption in air pollution control and a description of several absorption systems for sulfur dioxide and nitrogen oxide removal, see Schnelle and Brown.[5] A more detailed discussion of many more processes for flue gas desulfurization employing absorption is given by Lunt and Cunic.[6]

The United Kingdom has a long history of flu gas desulfurization. The world's first such system was installed in a power plant at Battersea, England, in 1936.[7] At Bankside a 228 MW boiler was the first installed. It was fitted with a once-through scrubber system using water from the condensers, which was dosed with alkali. A further unit was commissioned in 1949. Both units continued to operate until the early 1970s. At Fulham power station, a 120 MW boiler system was operated with recycled lime dosed scrubbing liquor from 1936 to 1940.

It should also be noted that absorption has been used to remove contaminants from natural gas streams during processing. In the early 1930s di-ethanolamine was used as an absorbent for both hydrogen sulfide and carbon dioxide.[8] This process became known as the ''Gerbitol Process.'' Other alkanolamines such as mono-ethanolamine and di-isopropanolamine have also found wide application.

Plate Towers

Originally, bubble cap plates had been used for absorption of pollutant gases such as sulfur dioxide. However, the solids in the slurries used as absorbents can more readily plug bubble caps. Typical absorbents used in current processes include, for example, conventional lime slurry; lime-limestone slurries; mixed sodium sulfite/lime slurries; and magnesium sulfite/bisulfite mixed with lime slurries. Conventional lime slurry towers may consist of a multilevel spray tower combined with a venturi scrubber. Venturi scrubbers will be discussed briefly below. Mixed sodium sulfite/lime slurries may be contacted in a plate tower. Sieve plates might be used with larger than normal holes to help prevent plugging due to the solids in the slurries.

Venturi Scrubbers

Venturi scrubbers are designed on the basis of the venturi flow-metering device. The flow channel is narrowed down so that the velocity will greatly increase at the throat. Then, as in the flow-metering device the flow channel widens out. For ease of fabrication venturi scrubbers are designed with a rectangular cross section. The absorption fluid is injected into the Venturi at the throat where the velocity is the greatest. For particulate removal plain water could be used. As in the plate columns discussed above, for the simultaneous removal of particulate matter and sulfur dioxide, soda ash or caustic soda slurries could be used for absorption of the gas. Venturis are frequently used in conjunction with plate towers. They also serve as stand-alone removal devices in some cases.

CONCLUSIONS—A COMPARISON OF PACKED COLUMNS AND PLATE COLUMNS

Absorption is a mass transfer operation that is commonly used to recover valuable gaseous components or to remove undesirable components of a gas stream. It is one of the main methods of separation in the chemical process industries. Absorption can take place in packed towers or in plate towers. Perry and Green (9) compare the advantages of packed and plate towers.[3]

Table 1 Economic factors in packed tower design operating and capital cost factors

Operating costs	Capital costs
Pumping power for gas and liquid	Tower and shell, packing or plates
Labor and maintenance	Packing support
Steam and cooling water	Gas and liquid distributor
Loss of unabsorbed material	Pumps, blowers, and compressors
Disposal of absorbed material	Piping and ducts
Solvent makeup	Heat exchangers
Solvent purification	Solvent recovery system

When column diameters are less than 0.6 m (2.0 ft) packed towers can be considerably cheaper. However, if alloy metals are necessary, plate towers may result in less cost. Using ceramic or other similar resistant materials for packing and materials of construction, packed towers can serve to handle corrosive materials and acids. Because the gas flow in packed towers may offer less degree of agitation, packed tower operation may be better for liquids that tend to foam. When liquids are thermally sensitive, packed columns may offer less holdup and thus prevent changes taking place in the liquids due to thermal reaction.

When solids are contained in liquids or when solids have the chance of condensing out of the gas steam, plate columns offer the advantage of being able to be designed to be more readily cleaned. Plate columns can more readily absorb thermal expansion, which might result in breakage of packing as it is inserted into the column or during the operation. Cooling coils can be more readily installed in plate towers than in packed towers. Flooding may occur with high liquid rates in packed columns, whereas a plate tower may be designed to handle the higher liquid rate. Low liquid flow rates may result in poor wetting of packing, thereby resulting in poor mass transfer. Thus, a plate tower may more readily handle lower liquid flow rates.

Economic Factors Affecting Packed Tower Construction

When a tower is designed for treating a given quantity of gas per hour, the height of the tower, especially in packed towers, is determined from mass transfer considerations. The diameter or cross-sectional area is determined by fluid dynamics from the gas velocity in the empty tower cross section in packed towers and by the velocity through the bubble caps or other openings in plate towers. The smaller the diameter of the tower, the higher the gas velocity that will help the gas to overcome the tower pressure drop. This could result in a lower cost of pushing the gas through the tower. The chief economic factors to be considered in tower design are listed in Table 1.

Activated Sludge Process

Shankha K. Banerji
Department of Civil and Environmental Engineering, University of Missouri–Columbia, Columbia, Missouri, U.S.A.

INTRODUCTION

Wastewater treatment occurs in a treatment plant in several stages depending on the degree of treatment desired. In the first stage, the preliminary treatment processes prepare the influent wastewater for treatment in subsequent processes. Bar screens, grit chamber, and flow equalization tank are some of the processes included in the preliminary treatment. There is no significant removal of biodegradable organic matter expressed in terms of 5-day biochemical oxygen demand (BOD) or suspended solids by these processes. The next stage is the primary treatment process where settleable (and floatable) solids present in the wastewater are removed by gravity sedimentation. In some rare instances, the flotation process can be used instead of gravity sedimentation for the removal of settleable solids. The primary treatment process can remove up to 40% of the incoming BOD and 50–70% of the suspended solids.[1] The subsequent stage is the secondary treatment process, which is needed to remove the remaining soluble and colloidal organic matter from the wastewater that was not removed during the primary treatment processes. The secondary processes invariably use aerobic biological treatment processes to remove the soluble and colloidal organic matter from the wastewater. The biological treatment process converts the soluble and colloidal organic matter into settleable solids and micro-organisms (sludge), which are removed in the secondary settling tank leaving a clearer supernatant effluent for discharge. Thus, the settling tank following the aeration tank is an integral part of the process. In this entry, the secondary tank details are not included. These processes in combination with the primary process can remove 90+% BOD (carbonaceous BOD) and suspended solids. Thus, the secondary wastewater treatment processes can meet the current US Environmental Protection Agency mandated effluent requirements of 30 mg/L of BOD and 30 mg/L of suspended solids for municipal wastewater treatment.[1]

There are two types of secondary aerobic biological treatment processes: suspended growth processes and attached growth processes. In the suspended growth process, the micro-organisms responsible for the biochemical conversion of organic matter are kept in suspension by aeration or agitation in a tank where the wastewater is introduced. The micro-organisms assimilate the organic compounds for synthesis of new cells (biomass) and for respiration, which provides the energy for the synthesis and other cellular processes. Activated sludge process and its modifications are suspended growth processes. In the attached growth process, the micro-organisms are present in an attached form (biofilm) on a medium, either stone, treated wood, or synthetic plastic materials. The wastewater comes in contact with these attached micro-organisms, and the same biochemical processes as in the suspended growth process take place, namely, cell synthesis and respiration. Trickling filters and rotating biological contactors are the two most common attached growth secondary biological treatment processes used.[1]

In this article, activated sludge process and some of its modifications are discussed at some length. Only the details of carbonaceous BOD removal from wastewater are included.

CONVENTIONAL PROCESS

The conventional activated sludge process consists of an aeration tank followed by a settling tank, as shown in Fig. 1. The wastewater from the primary settling tank enters the aeration tank and mixes with the micro-organisms or biomass present. A portion of the settled sludge (biomass) in the secondary settling tank is recycled back to the head of the aeration tank. This recycled sludge is referred to as return activated sludge (RAS). The term sludge in the secondary settling tank refers to solids that have settled in the tank bottom because of gravity forces. The recycling of the sludge maintains a desired amount of biomass concentration in the aeration tank. The solids responsible for the bio-oxidation of organic matter consist of micro-organisms (biomass), biodegradable and nonbiodegradable organic matter, and some inert solids in the aeration tank known as mixed liquor suspended solids (MLSS). The mixture of wastewater and these solids is called mixed liquor. The organic components of the MLSS are known as mixed liquor volatile suspended

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007653

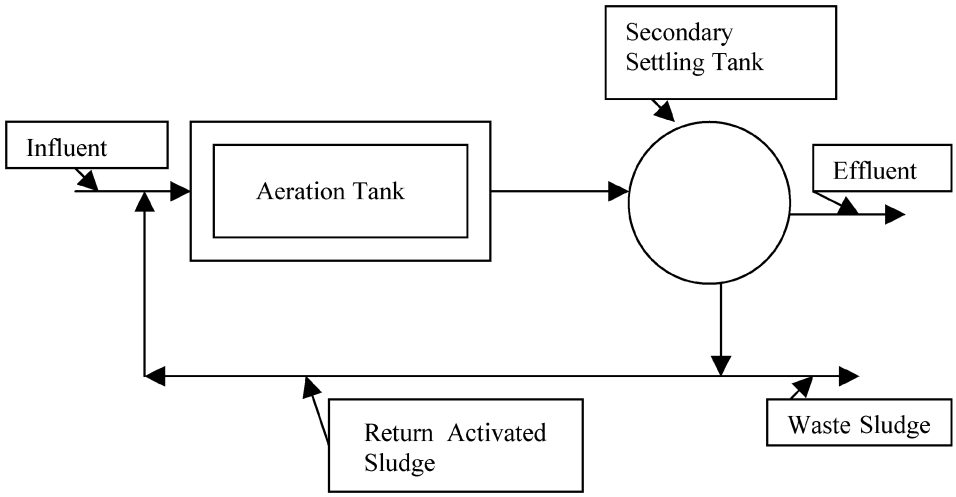

Fig. 1 Conventional activated sludge process.

solids (MLVSS). Mixed liquor volatile suspended solids are often considered to represent the active biomass in the system. The remaining settled sludge from the secondary settling tank is withdrawn as waste activated sludge (WAS) for further processing before disposal.

The biological oxidation process taking place in the aeration tank can be described by the following equation:

$$\text{Organic matter} + \text{N} + \text{P} + \text{O}_2 + \text{micro-organisms} = \text{CO}_2 + \text{H}_2\text{O} + \text{new micro-organisms}$$

In the above equation, N and P are the nitrogen and phosphorus compounds (sometimes called nutrients) that are needed for micro-organism metabolism and growth. In most instances, they are already in excess amounts in domestic wastewater, but for special cases they have to be supplied if not present in adequate quantities. The nutrient requirements in an aerobic biological treatment process are based on the BOD load imposed on the system. For every 100 kg of BOD introduced to the system, 5 kg of N and 1 kg of P should be available.[2] The oxygen needed has to be in a dissolved state to be available to the cells. The organic matter must be a biodegradable type that can be utilized by the micro-organisms present. The transport of the organic molecules inside the cells occurs through a microbial cell membrane having a pore size of the order of 5 Å, which means only small molecules that are soluble can be assimilated by the cell. Larger molecules are broken down to smaller sizes outside the cell through exogenous enzymes secreted by the microbes. The pH of the process should be within the range 6.5–8.5. Under some conditions, the ammonia present in the wastewater can be oxidized by the nitrifying bacteria to nitrite and nitrate molecules. This is known as nitrification process. If necessary, nitrification can be achieved in the process by appropriate sludge recycling and the organic loading rate of the process. The nitrification process is not discussed in this entry, but more information can be obtained in Ref.[1].

The activated sludge process was developed in England by Ardern and Lockett in 1914 based on experiments conducted at the Lawrence Experiment Station in Lawrence, MA, in the early 1900s.[2] Presently, it is one of the most common secondary treatment processes used throughout the world. The conventional process has been modified to improve its performance. These modifications are described later.

MICROBIOLOGY OF THE PROCESS

The micro-organisms present in the aeration tank of the activated sludge process are quite varied and depend on the type of wastewater being introduced and the environment of the aeration tank (e.g., temperature, pH, etc.). The predominant micro-organisms constantly change depending on the environmental conditions. The micro-organisms range from very small virus particles to much larger multicellular worms. But the predominant species are heterotrophic bacteria, with lesser amounts of autotrophic bacteria. Taxonomically, bacteria are prokaryotic protista, having mostly single-cell structure. The heterotrophic bacteria use organic compounds as their source of energy and cell carbon (electron donor), while autotrophic micro-organisms oxidize inorganic compounds for generating energy (electron donor) and use inorganic carbon (bicarbonates or CO_2) as a source of cell carbon. One of the prominent autotrophic bacteria present is the nitrifying bacteria, which transforms ammonia to nitrite and finally to nitrate.[1]

Usually, there are large numbers of bacterial species present, making the system a mixed culture. Because the wastewater contains many different types of organic compounds, the presence of these different micro-organisms with varied metabolic capabilities enhances the possibility of degradation of these compounds. Most of the bacteria present in the activated sludge process are aerobic, meaning that they use oxygen as the ultimate electron acceptor, which produces energy for their growth and other uses. There are some facultative anaerobic bacteria present as well, which can survive in the presence or absence of oxygen. In the absence of oxygen, they can use organic compounds as the ultimate electron acceptor to form reduced organic compounds.

Besides bacteria, other micro-organisms present are protozoa, fungi, and rotifers. Protozoa are eukaryotic protists. Most of the protozoa are unicellular organisms. Wastewater contains many different species of protozoa—flagellates, ciliates, amoebas, and rotifers. These organisms are predators for the bacteria and may help in flocculation and clarification in the secondary settling tank. Fungi are common in the activated sludge process operating at lower pH values. They include organisms such as yeasts and molds. They are basically saprophytic organisms feeding on organic matter. Their numbers are smaller than other species in activated sludge. In addition to these organisms, activated sludge may also contain nematodes (roundworms) and other worms. They play no part in the wastewater treatment process.

The activated sludge occurs in the aeration tank in the form of flocs. These flocs are made up of micro-organisms, inorganic and organic colloidal, and particulate matter. They are bound together in an organic matrix. Their size may vary from 50 to 1000 μm.[3] The shape depends on the materials encased, the organisms present, and the mechanical forces applied inside the tank. The floc containing mixed liquor leaves the aeration tank and normally settles out in a compact form in the secondary settling tank within 2–4 hr. Sometimes the settling of the sludge in the secondary settling tank is disrupted. The sludge is said to be a ''bulking sludge.'' One of the proposed theories on bulking suggests that the preponderance of filamentous bacteria can cause poor settling sludge. It has been suggested that in a good settling sludge floc, the floc forming bacteria and filamentous bacteria are present in balanced numbers to give a compact sludge mass. In the floc, the filamentous bacteria form a backbone that provides its structure and strength, while the floc forming bacteria grow around the filamentous types. The gelatinous matrices of the floc forming bacteria, sometimes known as *Zoogloea* bacteria, entrap other micro-organisms, colloidal and particulate matter to give the floc its shape. The preponderance of filamentous bacteria over floc forming bacteria could cause an unbalanced situation and hence poor settling of the resulting floc. The filamentous bacteria found in activated sludge are *Thiotrix* spp., *Nocardia* spp., *Sphaerotilus natans*, *Beggiatoa*.[4]

KINETICS AND DESIGN EQUATIONS FOR CONVENTIONAL PROCESSES

The design of conventional biological wastewater treatment processes depends on the reaction rates of the metabolism of organic matter by the micro-organisms present. They use a part of the substrate (organic matter) for cell growth and the balance to produce energy to satisfy the cell needs. The reactor (tank) hydraulics is also an important factor in the design of the process. There are two idealized flow patterns that are considered in a suspended growth reactor—completely mixed and plug-flow conditions. In the completely mixed reactor, the influent flow is instantaneously mixed with the reactor content such that the concentration of the organic matter in terms of (BOD or COD) is the same throughout the reactor and in the effluent. In the plug-flow reactor, there is no such mixing in the longitudinal direction, but right angles to the flow there is complete mixing in the reactor section. Thus, there is a substrate concentration gradient longitudinally along the reactor as the wastewater organic matter is metabolized by the micro-organisms. From reactor engineering, it can be shown that for the same influent substrate concentration, reaction rate, and set removal efficiency, plug-flow reactor will have a lower volume than a completely mixed reactor. Thus, for most municipal wastewater treatment applications, where the wastewater does not contain toxic ingredients, plug-flow reactors have been most commonly used.

However, there are instances where a completely mixed reactor may be advantageous. In situations where periodically hazardous or toxic wastes are present in the influent wastewater, the entry of such a waste to the reactor causes an immediate reduction of concentration of the toxic component because of dilution with the entire tank content. This may reduce the adverse impact of the toxic component to the micro-organisms present with no significant impact on their waste treatment ability. If such a waste were introduced to a plug-flow reactor, it would cause an immediate toxic effect on the micro-organisms at the head end of the plant causing progressive process failure. In addition, the oxygen uptake rates throughout the completely mixed reactor are the same, which makes the design of the aeration process simpler. In a plug-flow reactor, the oxygen uptake rate is higher at the head end and decreases as the wastewater proceeds

down the reactor length. This may cause an unbalanced oxygenation system in the tank, especially if the aeration devices are equally spaced throughout the tank length. Higher influent substrate concentration at the head end of the plug-flow reactor also favors the floc forming bacteria over the filamentous type in the reactor, which helps in the settling of these micro-organisms later in the settling tank.[4]

Completely Mixed Reactor with Recycle

Using a mass balance on biomass X and substrate S around the reactor in Fig. 2 under steady state conditions ($dX/dt = 0$ and $dS/dt = 0$), one can arrive at the following equation:

$$\mu = \frac{(Q - Q_w)X_e + Q_w X_r}{VX} \quad (1)$$

where

μ is the specific growth rate of cell mass (time^{-1}) $= \frac{dX/dt}{X}$;

V is the aeration tank (reactor) volume (m^3);

Q is the wastewater influent flow rate (m^3/day);

Q_w is the sludge waste rate from the settling tank bottom (m^3/day);

X is the biomass concentration in the aeration tank (g VSS/m^3);

X_e is the concentration of biomass in the effluent (g VSS/m^3); and

X_r is the concentration of biomass in the return sludge (g VSS/m^3).

It should be noted that substrate S is expressed as BOD or soluble COD (sCOD). The sCOD is obtained by using a wastewater sample that has been filtered through a 0.45 μm membrane filter.

The inverse of the term on the left-hand side of Eq. (1) is known as solid retention time (SRT) or sludge age, θ_c:

$$\theta_c = \frac{VX}{(Q - Q_w)X_e + Q_w X_r} \quad (2)$$

The specific growth rate constant μ is affected by the substrate concentration S. The relationship between S and μ is given by the following equation named after Monod:[1]

$$\mu = \frac{\mu_m S}{K_s + S} \quad (3)$$

where

μ_m is the maximum specific growth rate coefficient (time^{-1});

S is the substrate concentration (BOD or sCOD) in the reactor (g/m^3);

and

K_s is the half-velocity constant (g/m^3).

K_s represents the substrate concentration at half the maximum specific substrate utilization rate, μ_m. K_s is a measure of the affinity of the micro-organism to the substrate. The lower the K_s value, the greater is the affinity of the organism to the substrate. When two organisms are competing for the same substrate in a limiting substrate condition, the organism with lower K_s value will have more success in growing. It should be recognized that with a mixed culture containing mixed substrate as in typical wastewater, the Monod

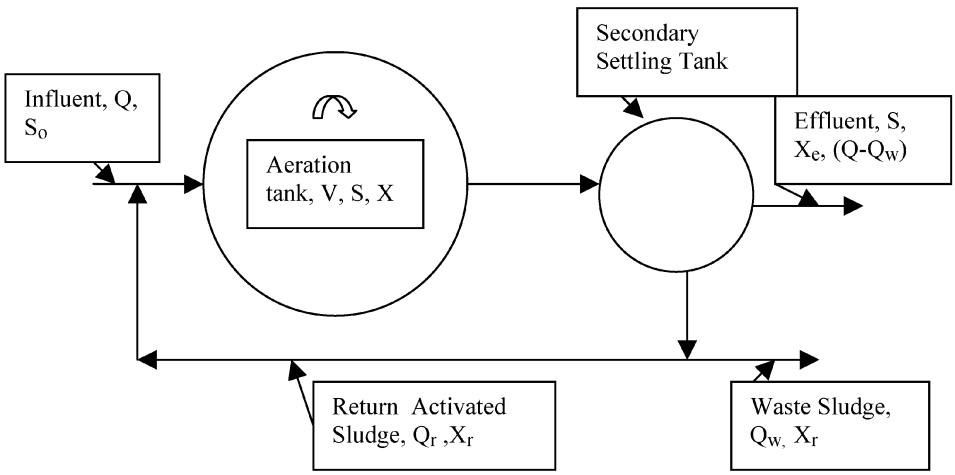

Fig. 2 Completely mixed activated sludge process schematic diagram. (*Note*: The aeration tank is a completely mixed reactor.)

equation described here gives only an approximation of the process kinetics.

Another term used is the food to micro-organism ratio (F/M), which is given by the equation:

$$\frac{F}{M} = \frac{QS_o}{VX} \tag{4}$$

where

F/M is the food to micro-organism (biomass) ratio (g BOD/g MLVSS day); and

S_o is the influent BOD or biodegradable sCOD (g/m^3).

F/M ratio is related to the term U, the specific substrate utilization rate as follows:

$$U = \frac{(F/M)E}{100} \tag{5}$$

E is the % BOD or sCOD removal efficiency in the process

$$E = \left(\frac{S_o - S}{S_o}\right)100 \tag{6}$$

By substituting the expressions for F/M and E, Eq. (5) can be rearranged as:

$$U = \frac{(S_o - S)Q}{VX} \tag{7}$$

U is also given by the equation:

$$U = \left(\frac{dS}{dt}\right)\Big/X = \frac{kS}{K_s + S} \tag{8}$$

because

$$\frac{dS}{dt} = \frac{kSX}{K_s + S}$$

where k is the maximum substrate utilization rate (g substrate (BOD)/g biomass day).

The amount of cell synthesis or growth can be related to the substrate removed by the micro-organisms. Cell yield Y is given by (g biomass produced/g substrate utilized).

$$Y = \frac{dX/dt}{dS/dt} = \frac{\mu_m}{k} \tag{9}$$

where Y is the yield coefficient (g VSS/g BOD or sCOD).

The observed yield coefficient, especially at low growth rates, is less than that given by Eq. (9). This is because of the need for maintenance energy by the cells for nongrowth needs. Eq. (10) provides an expression for observed yield coefficient, Y_{obs}:

$$Y_{obs} = \frac{Y}{1 + k_d\theta_c} \tag{10}$$

where

k_d is the endogenous respiration coefficient (g VSS/g VSS day); and

θ_c is the solid retention time, or sludge age ($time^{-1}$).

The reactor biomass (MLVSS) X is given by the following equation:

$$X = \frac{\theta_c Y(S_o - S)Q}{V(1 + k_d\theta_c)} = \frac{\theta_c Y(S_o - S)}{t(1 + k_d\theta_c)} \tag{11}$$

where $V/Q = t$ is the hydraulic retention time (hr).

The relationship between θ_c and U is shown in Eq. (12):

$$\frac{1}{\theta_c} = YU - k_d \tag{12}$$

If the process θ_c has been selected, then U will have a fixed value as Y and k_d are constants.

Substituting U from Eq. (8) we get:

$$\frac{1}{\theta_c} = \frac{YkS}{K_s + S} - k_d \tag{13}$$

The reactor substrate concentration (also the effluent substrate concentration) S is given by the equation:

$$S = \frac{K_s(1 + k_d\theta_c)}{\theta_c(Yk - k_d) - 1} \tag{14}$$

The production of excess biomass or waste activated sludge per day can be calculated from the following equation:

$$P_x = Q\left[\frac{Y(S_o - S)}{1 + k_d\theta_c} + X_{inv} + X_{ivn}\right] \tag{15}$$

This is the amount of excess sludge that is formed by the conversion of soluble and colloidal organic matter to settleable sludge (biomass) in the aeration tank. This sludge has to be properly treated and disposed of. Typical sludge treatment may consist of thickening,

stabilization (anaerobic digestion), followed by land application.[1]

In Eq. (15) the last two terms, X_{inv} and X_{ivn}, are the nonvolatile (inorganic) suspended solids and influent volatile nonbiodegradable solids, respectively, entering the secondary process. These solids pass through the process unchanged.

The amount of RAS from the secondary settling tank can be obtained from the following equation:

$$\frac{1}{\theta_c} = \frac{Q}{V}\left(1 + R - R\frac{X_r}{X}\right) \tag{16}$$

where

R = sludge recycle ratio = Q_r/Q;

Q_r is the rate of settled sludge recycle (m^3/day);

X_r is the concentration of settled sludge in secondary settling tank (g/m^3) = concentration of recycled sludge (g/m^3).

The poor settling of the sludge in the secondary settling tank causes X_r to be lower, which requires a higher sludge recycle ratio to maintain the same mixed liquor concentration in the aeration tank.

The oxygen required for the biooxidation of organic matter can be estimated from Eq. (17):

$$R_o = Q(S_o - S) - 1.42P_x \tag{17}$$

where R_o is the mass of oxygen required for oxidation of organic matter per day (kg/day).

The factor 1.42 represents the oxygen equivalent of cell mass produced. For only BOD removal, the oxygen requirements can vary from 0.8 to 1.3 kg O_2/kg BOD removed for most conventional activated sludge processes.

Process stability depends on the process solid retention time (θ_c). For a particular influent wastewater quality, reactor configuration, and a given microorganism community in the reactor, Y, K_s, k_d, and k are relatively constant. For a selected process U value, the θ_c becomes fixed. If the operating θ_c is below a specific value, the process becomes unstable and biomass washout may occur. This minimum θ_c value (θ_{c_m}) can be determined from Eq. (13) by putting $S = S_o$, the influent substrate concentration indicating no wastewater treatment:

$$\frac{1}{\theta_{c_m}} = \frac{YkS_o}{K_s + S_o} - k_d \tag{18}$$

In most situations, K_s is much smaller than S_o and can be ignored. Hence, Eq. (18) becomes:

$$\frac{1}{\theta_{c_m}} \approx Yk - k_d = \mu_m - k_d \tag{19}$$

Activated sludge treatment processes should not be designed with θ_c less than θ_{c_m}.

The details about the derivation of the equations in the preceding section can be found in several studies, notably Metcalf & Eddy.[1]

Plug-Flow Reactor with Recycle: The flow schematic of a plug-flow reactor is shown in Fig. 3. The modeling of a plug-flow reactor is mathematically more challenging than the completely mixed activated sludge process. By assuming biomass change to be negligible compared to the total amount present (i.e., MLVSS in the tank is constant), the integration of the substrate mass balance equation yields:[5]

$$(S_i - S) + K_s \ln\left(\frac{S_i}{S}\right) = \frac{\mu_m X_{av} V}{Y(1 + R)} \tag{20}$$

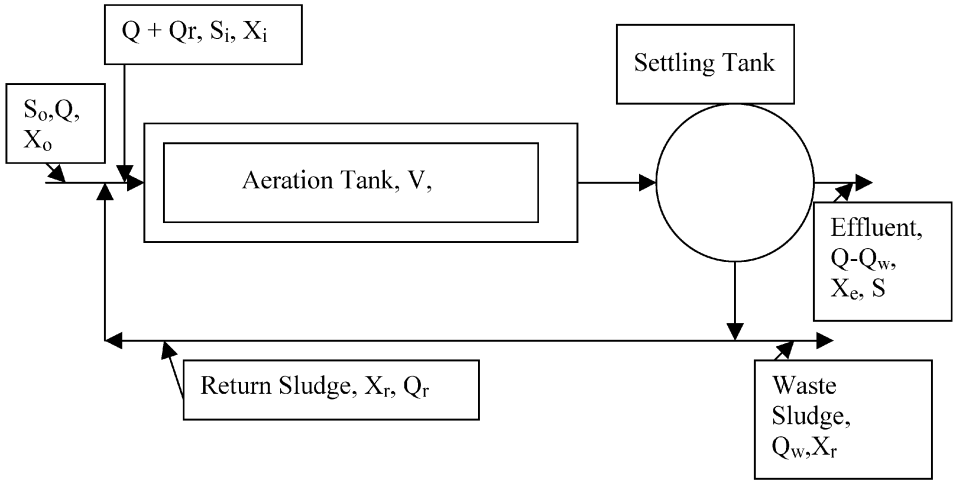

Fig. 3 Plug-flow activated sludge process schematic. (*Note*: The aeration tank is a plug-flow reactor with an average biomass concentration of X_{av} and effluent substrate concentration of S.)

where S_i is the concentration of substrate in the aeration tank after mixing with the recycle sludge flow,

$$S_i = \frac{S_o + RS}{1 + R} \tag{21}$$

where

X_{av} is the average biomass concentration in the tank (g/m^3); and

S is the concentration of substrate in the effluent from the aeration tank (g/m^3).

The small change in biomass is given by:

$$X - X_i = Y(S_i - S) - \frac{k_d X_{av} V}{Q(1 + R)} \tag{22}$$

where X_i is the concentration of biomass in the aeration tank after mixing with the recycle sludge flow,

$$X_i = \frac{X_o + RX_r}{1 + R} \tag{23}$$

where X_o is the concentration of biomass in the influent flow (g MLVSS/m^3) = usually 0. Eq. (23) becomes:

$$X_i = \frac{RX_r}{1 + R} \tag{24}$$

θ_c can be approximated by the following equation:

$$\frac{1}{\theta_c} = \frac{Yk(S_o - S)}{(S_o - S) + (1 + R)K_s \ln(S_i/S)} - k_d \tag{25}$$

In actual practice, a truly plug-flow or completely mixed-flow regime in a reactor is not attained because of longitudinal dispersion and nonideal mixing conditions. The equations reported here approximate the actual conditions in the field.

AERATION AND MIXING REQUIREMENTS

The aeration is a necessary part of the activated sludge treatment process as it supplies the dissolved oxygen (DO) needed for the biooxidation of the organic matter. If a liquid is unsaturated with respect to DO concentration, the natural diffusion process would transport enough oxygen from the air to bring the liquid to saturation value. This transport is based on Fick's law of diffusion.

The oxygen transfer to the liquid phase is best described by the two-film theory. According to this theory, oxygen mass to the liquid is transported through air and water films at the interface because of the concentration gradients. For gases with low solubility such as oxygen, the diffusion through the liquid film is the rate limiting step.[5]

Fig. 4 shows the oxygen concentration gradients at the water interface during mass transport operation. The mass transport process can be expressed by Fick's equation:

$$\frac{dM}{dt} = -D_l A \frac{dC}{dy_f} \tag{26}$$

where

M is the mass of oxygen transported (g);

D_l is the diffusion coefficient for oxygen in water (m^2/time);

C is the dissolved oxygen concentration (g/m^3);

A is the cross-sectional area through which O_2 transport occurs (m^2);

and

y_f is the liquid film thickness (m).

As the liquid film thickness is quite small, the differential quantity dC/dy_f can be replaced by linear approximation of the concentration gradient as:

$$\frac{dC}{dy_f} \approx \frac{C_s - C}{y_f} \tag{27}$$

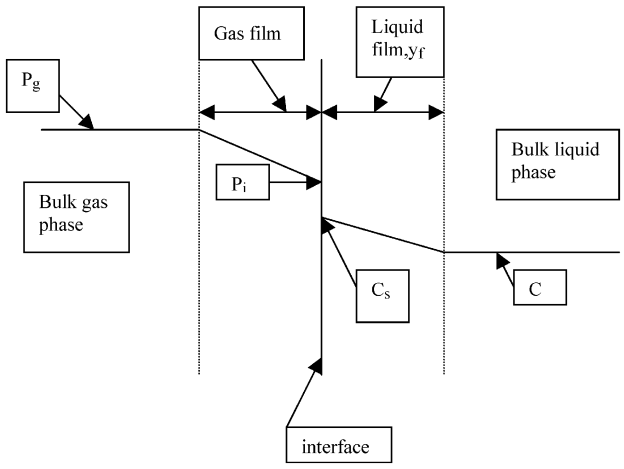

Fig. 4 Two-film oxygen mass transfer theory at liquid interface. (*Note*: P_g = partial pressure of oxygen in bulk gas phase; P_i = partial pressure of oxygen at the interface; C_s = saturation concentration of dissolved oxygen at the interface; C = dissolved oxygen concentration in bulk liquid.)

where

C_s is the saturation dissolved oxygen concentration at the interface layer (g/m^3); and

C is the dissolved oxygen concentration in the bulk liquid (g/m^3).

Dividing both sides of the Eq. (26) by V, the volume of the liquid in the container, and substituting the dC/dy_f from Eq. (27), we get:

$$\frac{dM}{V\,dt} = \frac{dC}{dt} = -D_l A \frac{C_s - C}{V y_f} \tag{28}$$

As y_f cannot be measured easily, it is combined with D_l to form another constant:

$$K_1 = \frac{D_l}{y_f}\ (\text{m/time})$$

Eq. (28) becomes:

$$\frac{dC}{dt} = -K_1 \frac{A}{V}(C_s - C) \tag{29}$$

The area of the bubbles through which the oxygen mass transfer takes place is quite difficult to measure. Hence, the parameters A/V are combined and represented by a, the specific surface area. Eq. (28) is simplified as:

$$\frac{dC}{dt} = K_l a(C_s - C) \tag{30}$$

where $K_l a$ is the overall mass transfer coefficient (time^{-1}).

Under turbulent conditions in the bulk liquid, Eq. (30) can be integrated with boundary conditions: at time $= t_0$, $C = C_o$; at time $= t$, $C = C$:

$$K_1 a = \frac{\ln[(C_s - C_o)/(C_s - C)]}{t - t_0} \tag{31}$$

The coefficient $K_l a$ is a good measure of the efficiency of an aerator. It depends on many factors, such as temperature, wastewater composition, tank geometry, and turbulence.

Measurement of $K_l a$ of aeration devices in clean water can be determined by standard procedures developed by the American Society of Civil Engineers.[6] In the standard procedure, the clean water (usually tap water) in a tank is deoxygenated by adding a reducing agent, sodium sulfite, and a catalyst, cobalt chloride. Thereafter, aeration is resumed with DO being measured periodically at several points in the tank to measure the rate of aeration. The $K_l a$ can be determined from the slope of a plot of $\ln(C_s - C)$ vs. time. The value of C_s, the DO saturation, for the temperature and dissolved solid concentrations of the test water can be obtained from several studies including Ref.[1]. For extrapolation of the clean water $K_l a$ to field conditions with wastewater, some corrections must be applied. Wastewater constituents (especially surface active agents) can reduce the field $K_l a$ value. A factor α can be used to make a correction to the measured clean water $K_l a$:

$$\alpha = \frac{K_1 a_{\text{wastewater}}}{K_1 a_{\text{cleanwater}}} \tag{32}$$

Another factor β corrects for the difference in DO saturation value of clean water and wastewater:

$$\beta = \frac{C_{s_{\text{wastewater}}}}{C_{s_{\text{cleanwater}}}} \tag{33}$$

Eq. (34) shows a temperature correction factor for $K_l a$

$$K_l a_{T^0} = K_l a_{20^0} \theta^{(T-20)} \tag{34}$$

where

θ is the temperature correction factor for reaeration, with a usual value of 1.024.

$K_l a_{T^\circ}$ is the overall mass transfer coefficient at T°C (time^{-1}); and

$K_l a_{20^\circ}$ is the overall mass transfer coefficient at 20°C (time^{-1}).

The standard oxygen transfer rate (SOTR) in clean water can be calculated by knowing the average $K_l a$ in the tank at 20°C and at zero DO concentrations:

$$\text{SOTR} = V(K_1 a_{\text{av}} C_{\text{sav}})(\text{kg } O_2/\text{hr}) \tag{35}$$

where

V is the volume of the aeration tank;

$K_l a_{\text{av}}$ is the average $K_l a$ value in the tank (time^{-1}); and

C_{sav} is the average DO saturation value in the tank (g/m^3);

The field oxygen transfer rate (OTR) in wastewater can be estimated from the SOTR by applying the

appropriate correction factors:

$$\mathrm{OTR} = \alpha\left(\frac{\beta C_s - C}{C_{s,20}}\right)1.024^{(T-20)}\mathrm{SOTR} \quad (36)$$

where

C_s is the DO saturation in clean water in the aeration tank at the prevailing pressure and temperature (g/m^3);

C is the operating DO concentration (g/m^3);

$C_{s,20}$ is the DO saturation in clean water at 20°C (g/m^3).

Details about different types of aeration system for the activated sludge process can be found in Metcalf and Eddy.[1]

Mixing of the mixed liquor is also accomplished by the aeration system. The mixed liquor solids must be kept in suspension for proper operation of the process. The mixing requirement depends on types of aeration equipment, depth, and width of the tank. Typically, a mixed liquor velocity of 0.15 m/sec in the aeration tank provides adequate mixing. For mechanical aerators, power input of 16–30 W/m^3 is often specified for mixing of biomass in the tank.[2]

DESIGN PARAMETERS

The design of an activated sludge system requires the determination of the following items: aeration tank volume V, oxygen requirement, daily sludge wasting rate, and sludge recycle rate R.

The selection of the process θ_c value usually depends on past experience rather than kinetic considerations, because use of kinetic equations gives a much smaller θ_c value.[2] The θ_c is selected to provide mixed liquor that settles well in the settling tank. For a conventional activated sludge process, it varies from 5 to 15 days[7] (see Table 1). Once θ_c has been selected, the tank volume can be calculated from Eq. (11) for a completely mixed reactor or from Eq. (21) for a plug-flow reactor. The constants Y, k_d, k, and K_s must be estimated for calculating the volume V, and X must also be selected. Typically, X in the aeration tank varies from 1500 to 3000 mg MLVSS/L. The selection of the MLVSS in the aeration tank depends on the influent BOD load and desired U or θ_c values. The oxygen requirement for carbonaceous BOD removal can be estimated from Eq. (17). The aeration equipment can be selected to supply the needed oxygen based on the manufacturer's information. The sludge mass wasted per day can be calculated from Eq. (15). The volume of the wasted sludge will depend on the settled sludge concentration and specific gravity of the settled solids. The sludge recycle rate R depends on the settled sludge concentration as shown in Eq. (16). If the settled sludge concentration is low, more sludge has to be recycled, making R greater.

Conventional activated sludge process loading rate in terms of F/M ratio (mass loading; g BOD/g MLVSS day) varies from 0.2 to 0.6. In some instances, the loading rate is based on the tank volume. The volumetric loading rate in terms of BOD applied per unit tank volume varies from 0.3 to 0.6 kg BOD/m^3 day.[7] The hydraulic residence time (V/Q) varies from 4 to 8 hr.

PROCESS MODIFICATIONS

Over the years, the conventional activated sludge process has been modified to improve or to suit a specific operational condition. Some of the more common modifications are extended aeration process, contact

Table 1 Design and operating parameters for activated sludge process and its modifications

	Hydraulic retention time, t (hr)	F/M (kg BOD/kg VSS day)	Solid retention time, θ_c (day)	Volumetric loading rate (kg BOD/m^3 day)	MLSS (mg/L)
Conventional plug-flow	4–8	0.2–0.4	5–15	0.3–0.6	1500–3000
Extended aeration	18–36	0.05–0.15	20–30	0.1–0.4	1500–5000

[a]In contact tank.
[b]In stabilization tank.
(From Ref.[7].)

stabilization process, step aeration, tapered aeration, high rate, and pure oxygen process.

Extended Aeration Process: This process is very much like the conventional process but the loading rates are much lower. The sludge age is high and the hydraulic residence time is higher than the conventional process. These conditions result in a better effluent quality, with some nitrification of the wastewater. In addition, the process is quite stable under varying loading rates, producing good settling sludge. The design parameters for this process are given in Table 1. The high hydraulic residence time increases the capital and operating cost for the process. A modified configuration of this process is known as oxidation ditch, where the mixed liquor is moved around a racetrack style reactor. The movement of the wastewater and aeration along the ditch is facilitated by a brush type or vertical rotor aerator, which ensures a fluid velocity of about 0.3 m/sec so that the mixed liquor solids are not settled out in the channels.

Contact Stabilization Process: In this modification of the conventional process, the waste is contacted in the aeration tank with the return sludge (which has been previously aerated) for a relatively short time, about 30–60 min. The mixed liquor is then separated in a settling tank, with the settled sludge being aerated in a separate tank for 3–6 hr before it is returned to the aeration tank (see Fig. 5). The short contact time allows the colloidal and particulate waste constituents to adsorb onto the micro-organism flocs. The stabilization of the adsorbed organic matter occurs when the sludge is reaerated. By following this scheme, the overall tank volume requirement reduces by about 50%.[5] The process is only successful where a large fraction of the influent BOD is in colloidal or particulate form, but for normal domestic wastewater it does not provide equivalent secondary treatment effluent quality.

Step Aeration: In this process, the influent feed is introduced into the plug-flow reactor at two or more points, which distributes the organic load along the length of the tank (Fig. 6). Thus, the oxygen uptake rate along the tank length becomes more uniform rather than high at the start and low at the end as in the conventional system. This gives a better performance during most operating conditions. All other design parameters are the same as in the conventional system as seen in Table 1.

Tapered Aeration: This process corrects the problem of unbalanced aeration supply in a plug-flow conventional activated sludge system by providing more diffusers at the head end, which decrease progressively along the length of the tank as the BOD concentration decreases. The loading rates are the same as in a conventional system (Table 1). This arrangement reduces blower capacity and operating costs, and provides a greater degree of operational flexibility.[8] Fig. 7 shows a schematic of the process.

High Rate: This process is characterized by a shorter hydraulic retention time of the mixed liquor in the aeration tank and a higher loading rate than the conventional process. Consequently, the effluent leaving the process is not as high a quality as in the conventional process, i.e., it has a higher BOD and suspended solids. It often precedes a second-stage nitrification process.

Pure Oxygen Process: This process uses compressed pure oxygen instead of air, resulting in increased DO in the mixed liquor. Advantages include reduced power for oxygen diffusion, faster rate of organic matter stabilization, better settling sludge, and the ability to treat higher BOD wastewater. The process uses covered, completely mixed tanks in three or four stages with oxygen gas and wastewater entering at the head end. Each stage is mixed with a surface aerator. The exiting offgas contains only about 10% oxygen as the rest is used up in the biochemical reactions inside the reactors. In recent practice, the MLSS concentrations in the tanks vary from 1000 to

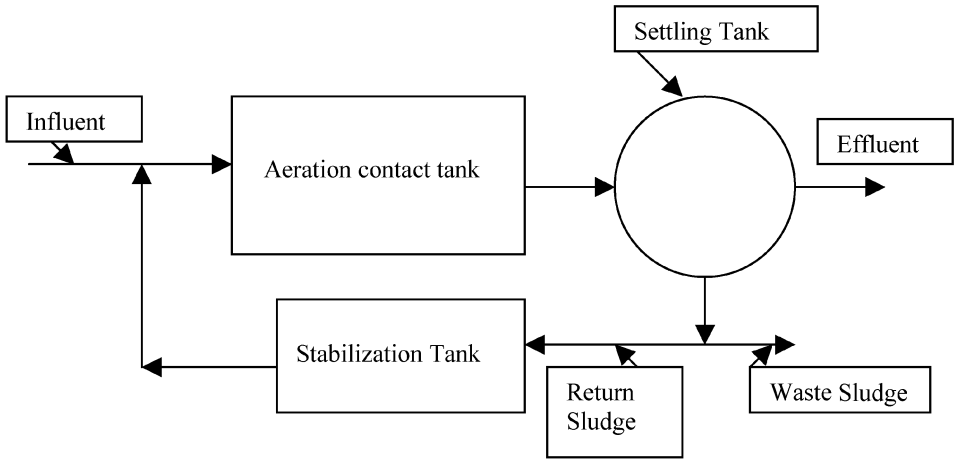

Fig. 5 Contact stabilization process.

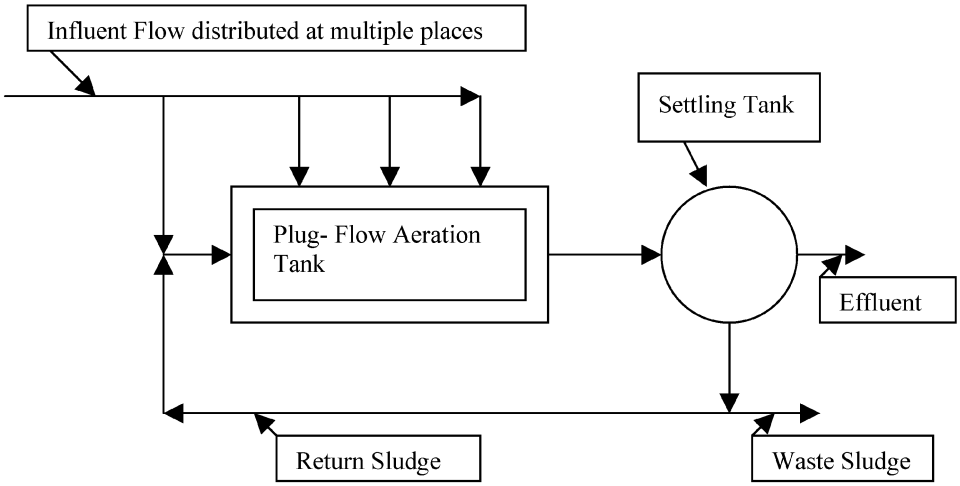

Fig. 6 Step aeration process.

3000 mg/L with DO levels typically in the range of 4–10 mg/L.[9] The hydraulic retention in the aeration tank is usually 1–3 hr. The loading rate for this process is higher than the conventional process, which requires less aeration tank volume than the conventional process for comparable wastewater quality. The oxygen needed for the process has to be produced in situ, which increases the construction cost for the process. The common methods for producing oxygen gas are cryogenic process, pressure swing adsorption, and vacuum swing adsorption. Details of these processes can be found in Ref.[9]. There have been debates whether these processes have significant advantages over the conventional process. The consensus is that the advantages, if any, are marginal at best.[5] Nitrification of the wastewater may occur as a result of higher DO levels. The process does create foaming because of Nocardia accumulation in the aeration tank. It can also depress the pH of the mixed liquor as the CO_2 formed is not stripped by nitrogen gas as with the air diffusion system. The construction materials for the tank and accessories have to be selected properly as the atmosphere inside is more corrosive.[2]

OPERATIONAL PROBLEMS

The activated sludge plant often has operational problems, which could be attributable to unusual characteristics of the influent wastewater or could be because of improper design and operation. These problems can be characterized by two factors: low soluble BOD removal and poor settling of solids in the secondary settling tank.

The low BOD removal could be caused by many reasons such as higher influent organic loading, influx of toxic or inhibitory chemicals, change of pH in the aeration tank beyond the acceptable range 6.5–8.5, insufficient aeration, and insufficient biomass in the aeration tank.

An increased F/M ratio beyond the process design value caused by higher influent BOD concentration

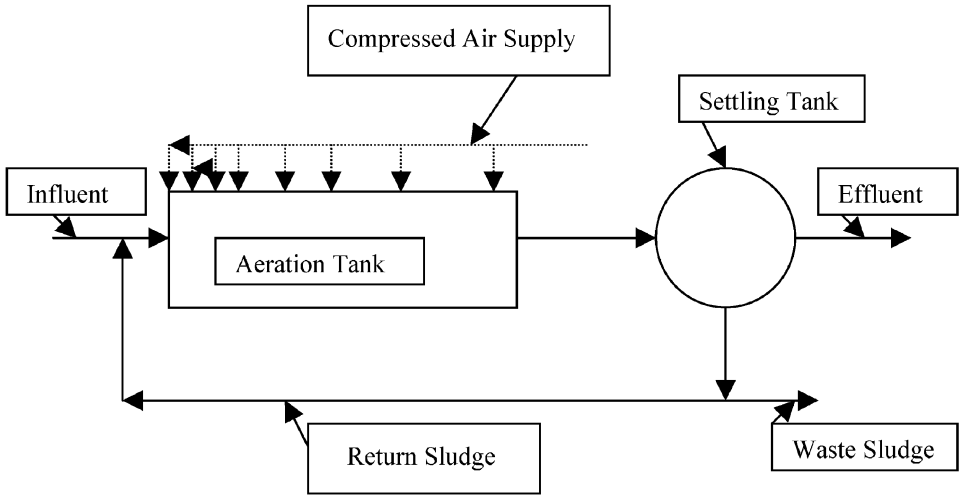

Fig. 7 Tapered aeration process.

could eventually cause low BOD removal. Increased sludge recycle rate will increase process micro-organism concentration and balance the F/M ratio, which will correct the poor performance results. Variable and shock influent organic loading rates could also cause poor BOD removals. An equalizing tank at the head end could minimize the effects of shock or variable BOD influent conditions. Equalizing tank equalizes the diurnal flow variations by providing storage for the excess flow during peak flow hours and a constant withdrawal throughout the day.

Toxic and inhibitory chemicals come as a result of a spill or temporary problems at chemical or other industrial plants discharging effluents into the sewer system. Sewer use ordinance prohibits the discharge of these materials; but in case of accidents these chemicals can inhibit the activities of the micro-organisms in the process. If detected early the wastewater containing the toxic wastes can be diverted to a holding tank, if available, and the unaffected micro-organisms can be nurtured under proper environment till nontoxic wastewater flow is resumed. In some cases where most of the micro-organisms have been destroyed, later external seed sludge may need to be imported to make the process restart. Accidental discharge of acidic or basic wastes from industries may change the wastewater pH beyond the acceptable range of 6.5–8.5. Prolonged operation of the process at these pH values may affect the performance of the plant. Neutralizing chemical may be needed to correct the pH to a safer range.

In a conventional activated sludge plug-flow plant with diffused aeration, the inlet end has a higher oxygen uptake rate than at the end. In cases where the influent BOD load exceeds the oxygen supply, oxygen deficiency may occur and the effluent performance could suffer. The effluent could be high in suspended solids as well as BOD. This type of condition can be remedied by changing the aeration system to the tapered aeration process mentioned earlier or changing the feed introduction by following the step aeration process. In addition, if the air blower capacity is limited, it can be replaced by a larger unit.

Insufficient biomass in the aeration tank could occur if the return sludge pumps do not have enough capacity to supply the increased sludge flow needed at higher influent BOD loading conditions. It could also occur if the settled sludge has a low concentration because of poor settling properties of the sludge, which would require a much higher sludge return flow rate. Addition of larger sludge return pump could help this situation to some extent but may not be able to cope with poor settling sludge conditions.

The problem of poorly settling sludge in the secondary settling tank could be caused by two separate conditions. The first, known as ''bulking sludge,'' is the most common problem of the activated sludge plants. The sludge does not settle well in the tank, giving a low solids concentration to the settled sludge. This requires a much larger amount of the settled sludge recycle rate to maintain a set MLSS level in the aeration tank. In some extreme cases where the sludge is too bulky, no amount of sludge recycling can maintain the process performance. The escape of unsettled sludge through the settling tank weirs can cause higher than the required BOD and suspended solids concentrations. Common factors that cause bulking are nutrient (N and P) deficiency, addition of septage to the influent, insufficient aeration capacity, low pH conditions, and influx of toxic wastes. The nutrient deficiencies of the influent wastewater can be fixed by adding appropriate amounts of nitrogen and phosphorus compounds. A preaeration system included for the septage before it enters the aeration tank could reduce its adverse impacts. Adding additional aeration capacity or modifying the aeration system to tapered aeration could reduce the problems of bulking sludge caused by insufficient aeration capacity. Low pH could occur from the entry of some industrial acidic wastes with the influent wastewater. This can cause the growth of fungi, which are filamentous, and bulking. Proper pH control can overcome this problem. Inadvertent influx of toxic wastes to the plant could also cause a change in the biota of the process and eventually cause bulking. The control of entry of such wastes can correct this problem. In some situations where the bulking is caused by the growth of filamentous organisms, the addition of an oxidizing agent such as chlorine or hydrogen peroxide can selectively reduce their numbers and solve the problem. Chlorine doses from 0.1 to 2.5 g Cl_2/kg of returned sludge dry mass have been successful in controlling sludge bulking.[8]

The other sludge settling problem is called ''rising sludge.'' In this case, settled sludge flocs tend to float up to the top giving it the name. This occurs in situations where the wastewater is nitrified to a great extent with nitrate-N present in the liquid phase. The environment at the bottom of the settling tank is suitable for denitrification of the nitrate molecules, i.e., anoxic conditions with organic carbon available from sludge deposits. Under these conditions, nitrogen gas bubbles are formed from nitrate molecules that attach onto the sludge flocs to float them to the top. By reducing the length of time the settled sludge stays at the settling tank bottom and by increasing the sludge recycle rate to the aeration tank, denitrification can be reduced in the settling tank.[8] In addition, if nitrification is not needed, increased organic loading rate to the aeration tank can reduce nitrification and remove the rising sludge problem.

CONCLUSIONS

Activated sludge process is one of the most common secondary treatment processes available for treating wastewater. It depends on the microbial metabolism of soluble and colloidal organic matter in the presence of dissolved oxygen and nutrients. The resulting biomass from the process is subsequently settled in a settling tank and a portion of the settled biomass (sludge) is recycled back to the aeration tank. Excess biomass from the process is further treated before disposal. The process in combination with the primary treatment can remove up to 90+% of the incoming carbonaceous BOD and suspended solids. Under some conditions, it can also convert influent ammonia to nitrate, i.e., nitrification. The reactors used for the aeration process could be plug-flow or completely mixed type. In most cases, plug-flow configuration is used. The design of the reactor depends on the biokinetic parameters of the mixed micro-organisms developed in the aeration tank for the type of wastewater entering the system. The design of the system requires the determination of the following items: aeration tank volume, oxygen requirement, daily sludge wasting, and recycling rates.

Many modifications for the conventional process have been proposed for improving the system or for treating a specific type of wastewater. These modified processes are extended aeration, contact stabilization, step aeration, tapered aeration, high rate, and pure oxygen process.

Operational problems to activated sludge process can cause low soluble BOD removal and poor settling of the sludge in the secondary settling tank. The reasons for these problems could be because of unusual characteristics of the influent wastewater, or improper design and operation.

Adsorption

Shivaji Sircar
Chemical Engineering Department, Lehigh University, Bethlehem, Pennsylvania, U.S.A.

INTRODUCTION

The separation and purification of fluid mixtures (gas or liquid) by adsorption is a major unit operation in the chemical, petrochemical, environmental, pharmaceutical, and electronic gas industries. A list of the key commercial applications of this technology is given in Table 1.[1] The phenomenal growth in the development of this technology is demonstrated by Fig. 1, which shows a year-by-year tally of U.S. patents issued between 1980 and 2000 on five different topics of adsorption.[1] The total number of patents is overwhelming.

ADSORPTION AS A SEPARATION PROCESS

Adsorption is a surface phenomenon. When a multicomponent fluid mixture is contacted with a solid adsorbent, certain components of the mixture (adsorbates) are preferentially concentrated (selectively adsorbed) near the solid surface creating an adsorbed phase. This is because of the differences in the fluid–solid molecular forces of attraction between the components of the mixture. The difference in the compositions of the adsorbed and the bulk fluid phases forms the basis of separation by adsorption. It is a thermodynamically spontaneous process, which is exothermic in nature. The reverse process by which the adsorbed molecules are removed from the solid surface to the bulk fluid phase is called desorption. Energy must be supplied to carry out the endothermic desorption process. Both adsorption and desorption form two vital and integral steps of a practical adsorptive separation process where the adsorbent is repeatedly used. This concept of regenerative use of the adsorbent is key to the commercial and economic viability of this technology.

Three generic adsorptive process schemes have been commercialized to serve most of the applications shown in Table 1. They include 1) temperature swing adsorption (TSA); 2) pressure swing adsorption (PSA); and 3) concentration swing adsorption (CSA).[2–9] The fluid mixture (feed) to be separated is passed over a regenerated adsorbent (contained in an adsorber vessel) to produce a stream enriched in the less strongly adsorbed components of the mixture, followed by desorption of the adsorbed components, which produces a stream enriched in the more strongly adsorbed components of the mixture. The TSA processes are generally designed for removal of trace impurities from a mixture (gas or liquid), where the desorption is effected by heating the adsorbent. The PSA processes are designed for separation of the components of a bulk gas mixture or for removal of dilute impurities from a gas stream, where the desorption is effected by lowering the gas phase partial pressure of the adsorbed components within the adsorber. The CSA processes are designed for separation of bulk liquid mixtures, where the desorption is effected by flowing a less selectively adsorbed liquid (eluent or desorbent) over the adsorbent. Numerous variations of these processes have been developed to achieve different separation goals by using 1) different modes and conditions of operation of the adsorption and the desorption steps in conjunction with a multitude of other complementary steps (designed to improve separation efficiency and product quality); 2) different types of adsorbents; 3) different process hardware designs; 4) different process control logic, etc.

Several families of micro- and mesoporous adsorbents offering a spectrum of adsorption characteristics are also available for these separations. Consequently, the technology has been a very versatile and flexible separation tool, which provides many different paths for a given separation need. This availability of multiple design choices is the driving force for innovations.[10] Commercial success, however, calls for a good marriage between the optimum adsorbent and an efficient process scheme. Several emerging concepts in this field can potentially expand its scope and scale of application. These include 1) rapid PSA processes; 2) novel adsorber configurations; 3) use of reversible chemisorbents; 4) adsorbent membranes; 5) simultaneous sorption and reaction, etc.[10]

The design and optimization of adsorptive processes typically require simultaneous numerical solutions of coupled partial differential equations describing the mass, heat, and momentum balances for the process steps. Multicomponent adsorption equilibria, kinetics, and heat for the system of interest form the key fundamental input variables for the design.[11,12] Bench- and pilot-scale process performance data are generally needed to confirm design calculations.

Table 1 Key commercial applications of adsorption technology

Gas separation
Gas drying
Trace impurity removal
Air separation
Carbon dioxide–methane separation
Solvent vapor recovery
Hydrogen and carbon dioxide recovery from steam-methane reformer off-gas
Hydrogen recovery from refinery off-gas
Carbon monoxide–hydrogen separation
Alcohol dehydration
Production of ammonia synthesis gas
Normal–isoparaffin separation
Ozone enrichment
Liquid separation
Liquid drying
Trace impurity removal
Xylene, cresol, cymene isomer separation
Fructose–glucose separation
Fatty chemicals separation
Breaking azeotropes
Carbohydrate separation
Environmental separation
Municipal and industrial waste treatment
Ground and surface water treatment
Air pollution control
VOC removal
Mercury vapor removal
Bioseparation and pharmaceutical separation
Recovery of antibiotics
Purification and recovery of enzymes
Purification of proteins
Recovery of vitamins
Separation of enantiomers of racemic compounds
Removal of micro-organisms
Home medical oxygen production
Electronic gas purification
Production of ultrahigh-purity N_2, Ar. He, H_2, O_2
Purification of fluorinated gases NF_3, CF_4, C_2F_6, SiF_4
Purification of hydrides NH_3, PH_3, ASH_3, SIH_4, Si_2H_6

ADSORBENT MATERIALS

A key factor in the development of adsorption technology for the fluid separation has been the availability of appropriate adsorbents. The most frequently used categories include crystalline materials like zeolites, and amorphous materials like activated carbons, silica and alumina gels, polymeric sorbents, and ion-exchange resins. These materials exhibit a large spectrum of pore structures (networks of micro- and mesopores of different shapes and sizes) and surface chemistry (degrees of polarity), which provide a large choice of core adsorptive properties (equilibria, kinetics, and heat) to be utilized in the design of the separation processes. Table 2 lists some of the physical properties of common adsorbents.

The microporous alumino-silicate zeolites (Types A, X, and mordenite are frequently used) provide a variety of pore openings (3–10 Å), cavity and channel sizes, and framework Si/Al ratios. They are also available in various cationic exchanged forms (Na, K, Li, Ag, Ca, Ba, Mg), which govern their pore openings and cationic adsorption site polarities. They are highly hydrophilic materials and must be dehydrated before use. The amorphous adsorbents contain an intricate network of micropores and mesopores of various shapes and sizes. The pore size distribution may vary over a wide range. The activated carbons and the polymeric sorbents are relatively hydrophobic in nature. The silica and alumina gels are more hydrophilic (less than zeolites) and they must also be dehydrated before use.

Commercial adsorbents are generally produced in bound forms (0.5–6.0 mm diameters) in regular particle shapes (beads, pellets, extrudates, granules, etc.). The purpose is to reduce pressure drops in adsorbers. Clay, alumina, polymers, pitch, etc. are used as binders, which typically constitute 10–20% (by weight) of the final product. The binder phase usually contains a network (arteries) of meso- and macropores (0.5–50.0 μm diameters) to facilitate the transport of the adsorbate

Table 2 Physical properties of some adsorbents

molecules from the bulk fluid phase to the adsorption sites (within zeolite crystals and micropores of amorphous adsorbents) and vice versa. Adsorption of fluid molecules on the binder material is generally very weak. Fig. 2 shows a schematic drawing of a bound zeolite pellet depicting the pathways for transport of the adsorbate molecules.

The vast majority of fluid separation by adsorption is affected by the thermodynamic selectivity of the adsorbent for certain components of the fluid mixture over others. Physisorption is the dominant mechanism for separation. Thus, it is governed by the surface polarity of the adsorbent and the polarizability and permanent polarity of the adsorbate molecules. All adsorbate molecules, in this case, have access to the adsorption sites. The separation can also be based on a kinetic selectivity by the adsorbent where certain molecules of the fluid mixture diffuse into the adsorbent pores faster than the others because of their relative size differences. Size or steric exclusion of certain components of a fluid mixture from entering the adsorbent pores (typically for zeolites) is also possible. The last case is known as ''molecular sieving.'' Adsorbents may be energetically homogenous, containing adsorption sites of identical adsorption energy (heat of adsorption), or energetically heterogenous, containing a distribution of sites of varying energies. The cause of adsorbent heterogeneity is generally physicochemical in nature. It is created by a distribution of micro- and mesopores of different sizes and shapes within the adsorbent particle as well as by a distribution of adsorption sites of different surface chemistry and polarity within the micropores.

An adsorbent is often tailor-made to suit a separation need or a process can be designed to best fit the properties of an adsorbent. Special adsorbents are also available for specific applications (e.g., removal of mercury vapor, drying of reactive fluids, resistance to acids, etc). More recently, adsorbents have been produced that use reversible chemisorption as the mechanism for gas separation.[13] Creation of new adsorbents and modification of existing adsorbents continue to be an active area of research and development.

KEY ADSORPTIVE PROPERTIES FOR SEPARATION

All practical adsorptive separation processes are carried out using a stationary packed bed (adsorber) of the adsorbent particles. Each particle is subjected to the adsorption, the desorption, and the complementary

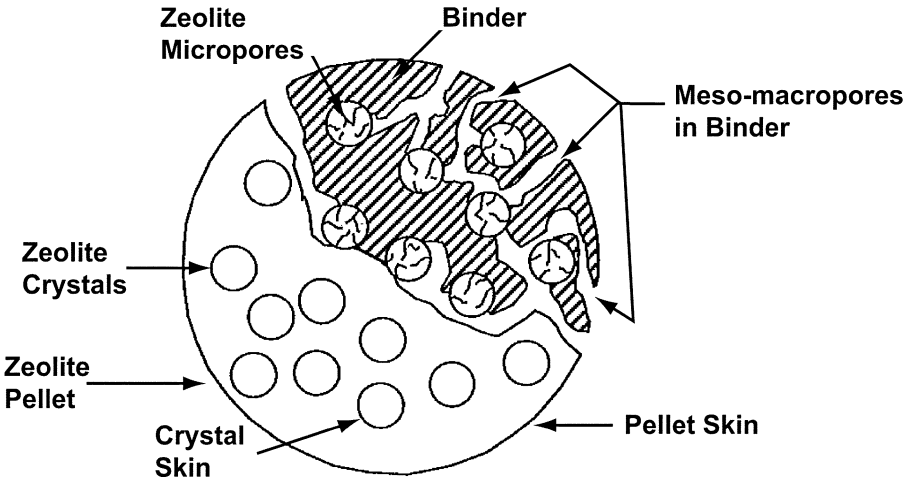

Fig. 2 Schematic drawing of a bound adsorbent particle.

steps of the process in a cyclic fashion. The ad(de)-sorption characteristics exhibited by the particle during different periods of the cycle are governed by the multi-component adsorption equilibria, kinetics, and heat for the fluid mixture of interest under the local conditions (e.g., fluid phase pressure, temperature and composition, adsorbate loadings in the particle, and its temperature) that the particle experiences. As these conditions can vary over a wide range during a process cycle, it is imperative that those adsorptive properties be accurately known over that range for reliable process design.

ADSORPTION EQUILIBRIA

Adsorption equilibria determine the thermodynamic limits of the specific amounts of adsorption (mol/g) of a pure gas or the components of a fluid mixture (gas or liquid) under a given set of conditions [pressure (P), temperature (T), and mole function (y_i or x_i) of component i] of the bulk fluid phase. The simplest way to describe adsorption equilibria of pure gas i is in the form of adsorption isotherms where the amount adsorbed (n_i^0) is plotted as a function of gas pressure (P) at a constant temperature (T). The pure gas adsorption isotherms can have various shapes (Types I–V) by Brunauer classification depending on the porosity of the adsorbent (microporous, mesoporous, or nonporous) and the system temperature (below or above the critical temperature of the adsorbate).[9] However, the most common isotherm shape is Type I, which is depicted by most microporous adsorbents of practical use. These isotherms exhibit a linear section in the very low-pressure region (Henry's law region) where the amount adsorbed is proportional to the gas pressure [$(n_i^0) = K_i P$]. The proportionality constant is called Henry's law constant (K_i), which is a function of temperature only. The amount adsorbed monotonically increases with increasing pressure beyond the Henry's law region with a progressively decreasing isotherm slope and finally the amount adsorbed asymptotically approaches the saturation adsorption capacity (m_i) of the adsorbate. Figs. 3A and 3B show examples of Type I isotherms for adsorption of pure N_2 and pure O_2, respectively, on various zeolites at 25°C.[2] The figures demonstrate that N_2 is more strongly adsorbed than O_2 on all zeolites and their adsorption characteristics are significantly affected by the structure of the zeolite, as well as by the nature of the cation present in them. The LSX zeolites in Fig. 3 represent X zeolite structure with low Si/Al ratio. The amounts adsorbed of a pure gas at any given pressure decrease with increasing temperature because of the exothermic nature of the adsorption process.

The equilibrium amounts adsorbed of component i from a binary gas mixture (n_i) are generally described as functions of gas phase mole fractions (y_i) at a constant system temperature (T) and total gas pressure (P). An example is given in Fig. 4 for adsorption of binary N_2–O_2 mixtures on Na–mordenite at various temperatures where the total gas pressure was 1.0 atm.[2] These binary isotherm shapes are typical for Type I adsorption systems on microporous adsorbents.

The relative adsorption between components i and j of a gas mixture is expressed in terms of the selectivity of adsorption ($S_{ij} = n_i y_j / n_j y_i$). Component i is more selective than component j if $S_{ij} > 1$. The thermodynamic selectivity decreases with increasing T for any given values of n_i. For adsorption on a homogenous adsorbent at constant T, S_{ij} can be constant, increase, or decrease with adsorbate loading depending on the size differences between the molecules of components

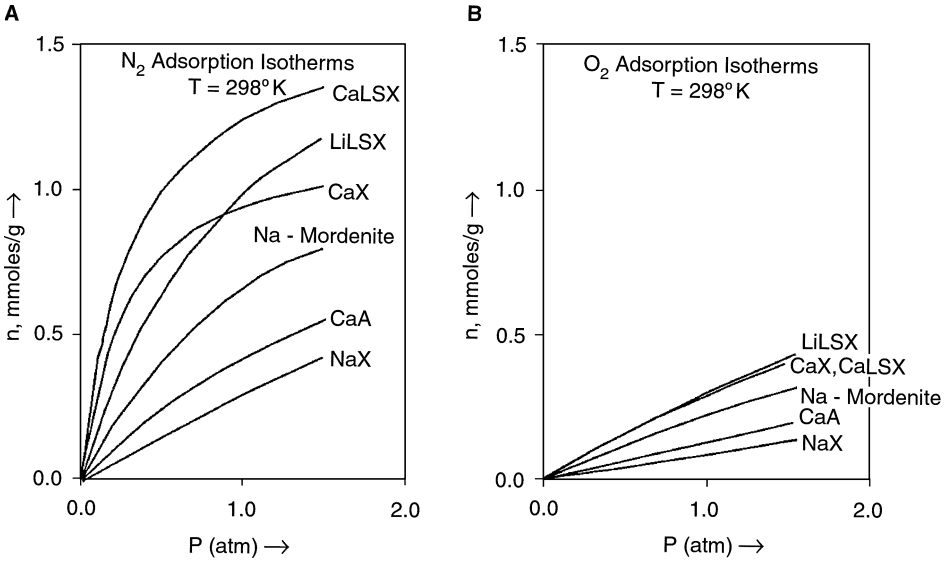

Fig. 3 Pure gas adsorption isotherms for (A) nitrogen and (B) oxygen on various zeolites.

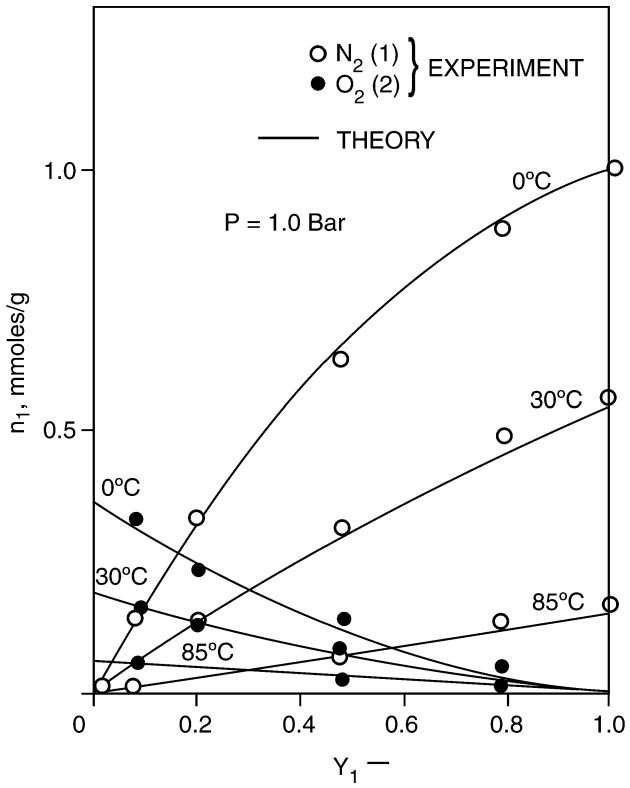

Fig. 4 Binary gas adsorption isotherms for nitrogen (1) and oxygen (2) mixtures on sodium mordenite.

i and j.[14] For adsorption on a heterogenous adsorbent, S_{ij} generally decreases with increasing adsorbate loading.[2] Table 3 gives a list of Henry's law selectivity ($S_{ij}^* = K_i/K_j$) for several binary gas mixtures at 30°C on a zeolite and an activated carbon.[2] The first-mentioned gas of a pair is the more selectively adsorbed component.

Separation of a gas mixture by a time dependent kinetic selectivity [$S_{ij}(t) = n_i(t)y_j/n_j(t)y_i$] has also been used in practice when there is a difference in the rates of adsorption of the components of the gas mixture.

Table 3 Selectivities of binary gas mixtures

Gas mixture	5A Zeolite	BPL Carbon
CO_2–CH_4	195.6	2.5
CO_2–CO	59.1	7.5
CO_2–N_2	330.7	11.1
CO_2–H_2	7400.0	90.8
CO–CH_4	3.3	0.33
CO–N_2	5.6	1.48
CO–H_2	125.0	12.1
CH_4–N_2	1.7	4.5
CH_4–H_2	37.8	36.6
N_2–H_2	22.3	8.2

$n_i(t)$, in this case, is the amount of component i adsorbed at time t.

Numerous models have been developed to describe pure and multicomponent gas adsorption on porous adsorbents. The analytical models are, however, most useful for process design. A few analytical models for Type I adsorption systems, which are thermodynamically consistent, are given below:[2]

$$\text{Langmuir:} \quad b_iPy_i = \theta_i/(1 - \theta_i) \tag{1}$$

$$\text{Multisite Langmuir:} \quad b_iPy_i = \theta_i \Big/ \left(1 - \sum \theta_i\right)^{a_i} \tag{2}$$

$$\text{Martinez–Basmadjian:} \quad b_iPy_i = \left\{\theta_i \Big/ \left(1 - \sum \theta_i\right)^{a_i}\right\} \exp\left(-\sum a_i w_i \theta_i\right) \tag{3}$$

$$\text{Toth:} \quad b_iPy_i = \theta_i \Big/ \left\{1 - \left(\sum \theta_i\right)^{k}\right\}^{1/k} \tag{4}$$

The frequently used Langmuir model describes adsorption of equal-sized adsorbates ($m_i = m_j$) on an energetically homogenous adsorbent. The multisite Langmuir model is an extension to include the effects of dissimilar adsorbate sizes ($m_i \neq m_j$). The Martinez–Basmadjian model is a further extension to include lateral interactions in the adsorbed phase. The Toth model is developed to describe adsorption of equal-sized molecules on an energetically heterogenous adsorbent. The variables of Eqs. (1)–(4) are the fractional coverage of component i of the gas mixture ($\theta_i = n_i/m_i$) at P, T, and y_i, the number of adsorption sites occupied by the adsorbate type i (a_i), the energy of lateral interactions between i molecules in the adsorbed phase (w_i), the gas–solid interaction parameter for component i (b_i), and the adsorbent heterogeneity parameter for all adsorbates ($k < 1$). The temperature coefficient of the parameter b_i is given by:

$$b_i = b_i^0 \exp(q_i^*/RT) \tag{5}$$

where b_i^0 is a constant. q_i^* is the isosteric heat of adsorption of pure gas i in the Henry's law region. R is the gas constant. The pure gas adsorption isotherms (θ_i^0 vs. P) for these models can be obtained by setting $y_i = 1$.

The extent of specific equilibrium adsorption of component i from a liquid mixture having mole fraction x_i for that component is expressed in terms of a variable called the Gibbsian surface excess [$n_i{}^e$ (mol/g)], which is related to the actual amounts adsorbed by[15]

$$n_i^e = n_i - \left(\sum n_i\right)x_i \tag{6}$$

The surface excess of component i is equal to its actual amount adsorbed ($n_i^e \sim n_i$) only when $x_i \ll 1$ and the

component i is very selectively adsorbed ($S_{ij} \gg 1$) over other components of the mixture.[15] The binary liquid phase surface excess adsorption isotherm (n_1^e vs. x_1) at a constant temperature (pressure is not a variable) on a microporous adsorbent is often U-shaped, as shown in Fig. 5A. Component 1 is selectively adsorbed if $n_1^e > 0$. For adsorption of a dilute solute from a liquid mixture, on a microporous solid, the excess isotherm is similar in shape as Type I isotherm for vapor adsorption (as shown in Fig. 5B).

Numerous analytical models have also been developed for binary liquid phase surface excess isotherms. A model equation that accounts for adsorbate size differences, bulk liquid phase nonideality, as well as a simplified description of adsorbent heterogeneity is given below:[16]

$$n_1^e = \frac{m_1}{(S_{0H} - S_{0L})}\left\{\frac{x_2}{a_1}\left[\left(\frac{S_H}{S_{0H}}\right)^{1/(\beta-1)} - \left(\frac{S_L}{S_{0L}}\right)^{1/(\beta-1)}\right] + \frac{a_2}{a_1(\beta-1)}\left(\frac{S_{0H}}{S_H} - \frac{S_{0L}}{S_L}\right)\right\} \quad (7)$$

$$\left(\frac{S_H}{S_{0H}}\right) = (S_H a_1 + a_2)^{(\beta-1)/\beta}; \qquad \left(\frac{S_L}{S_{0L}}\right) = (S_L a_1 + a_2)^{(\beta-1)/\beta} \quad (8)$$

where the variable $\beta = (m_1/m_2)$, a_i is the activity of component i in the bulk liquid phase, and S_{0L} and S_{0H} are the selectivities of adsorption of component 1 over component 2 at the limit of $x_1 \rightarrow 0$ at the lowest and the highest energy sites of the adsorbent.

HEAT OF ADSORPTION

The pertinent thermodynamic variable to quantitatively describe the thermal effects in the exo(endo) thermic gas ad(de)sorption process is called the isosteric heat of adsorption.[17] The isosteric heat of adsorption of component i of an ideal gas mixture (q_i) at adsorbate loading of n_i and temperature T is given by the following thermodynamic relationship:[17]

$$q_i(n_i) = RT^2\left\{\frac{\delta \ln(Py_i)}{\delta T}\right\}_{n_i} \quad (9)$$

Eq. (9) is frequently used to obtain the isosteric heat of adsorption of a pure gas i (q_i^0) as a function of n_i^0 and T from measured isotherms at different temperatures (y_i is equal to unity in that case). Estimation of isosteric heat of adsorption of component i of a gas mixture by using Eq. (9) is, however, not practical and they must be obtained by calorimetric measurements. In the absence of lateral interactions, the isosteric heat of adsorption of a pure gas on an energetically homogenous adsorbent is independent of adsorbate loadings. It remains constant at its value at the Henry's law region (q_i^*) at all coverages. The presence of lateral interactions between adsorbed molecules (pronounced at higher coverages) can increase q_i^0 with increasing n_i^0. The isosteric heat decreases with increasing adsorbate loading when the adsorbent is energetically heterogenous. The isosteric heat is generally a very weak function of T. Fig. 6 shows several calorimetrically measured examples of these behaviors for adsorption of pure SF_6 on various micro- and mesoporous adsorbents.[18] The isosteric heat of adsorption of a component of a gas mixture is equal to that of the pure gas for adsorption on a homogenous adsorbent.

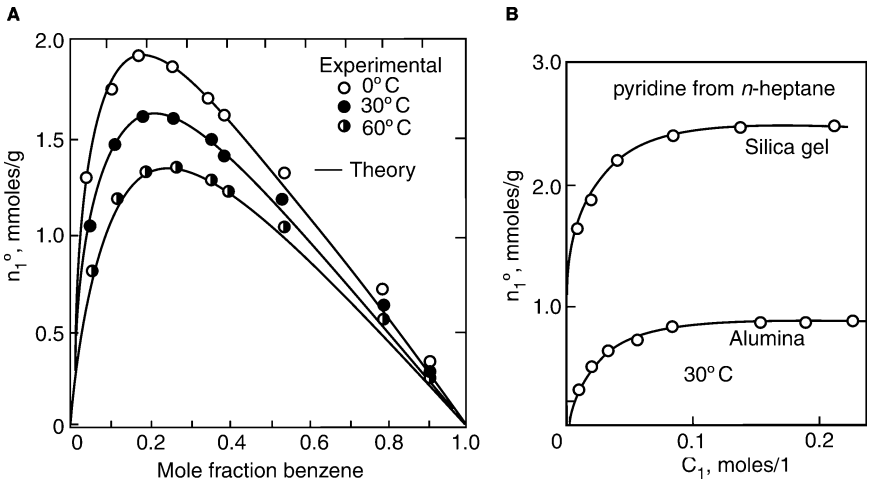

Fig. 5 Binary surface excess isotherms for adsorption of liquid mixtures: (A) benzene (1) + cyclohexane (2) on silica gel and (B) pyridine (1) + n-heptane (2) on silica gel and alumina.

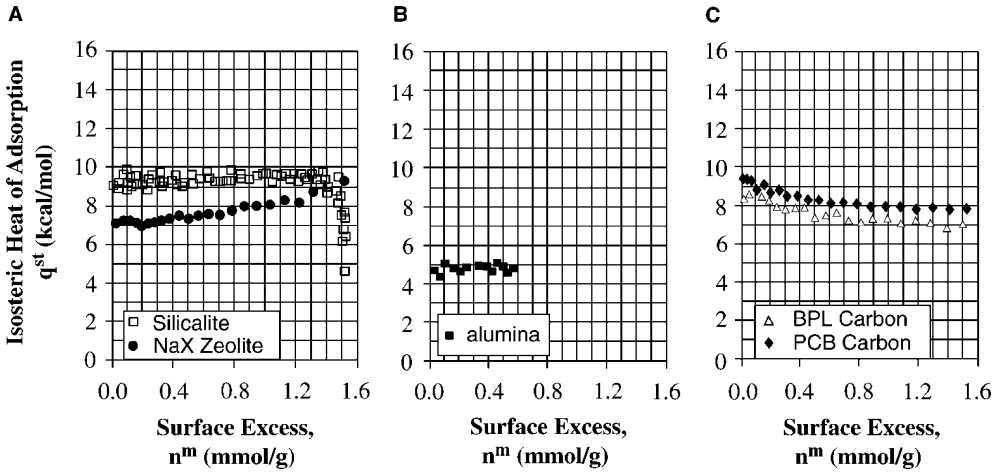

Fig. 6 Isosteric heat of pure SF_6 on various absorbents: (A) zeolites, (B) alumina, and (C) activated carbons.

However, the component isosteric heat of a mixture can be substantially different from that of the pure gas at the same loadings when the adsorbent is energetically heterogenous.[17] Furthermore, the dependence of component isosteric heat on the adsorbate loadings can be very complex in that situation.[17]

HEAT OF IMMERSION

The thermodynamic property to quantify the heat effects for ad(de)sorption of a liquid mixture is the heat of immersion. Fig. 7 shows examples of heat of immersion of binary benzene–cycloxane mixtures on two activated carbons at 30°C.[15] The corresponding surface excess isotherms are U-shaped (e.g., see Fig. 5A). Benzene is the more selectively adsorbed species. The

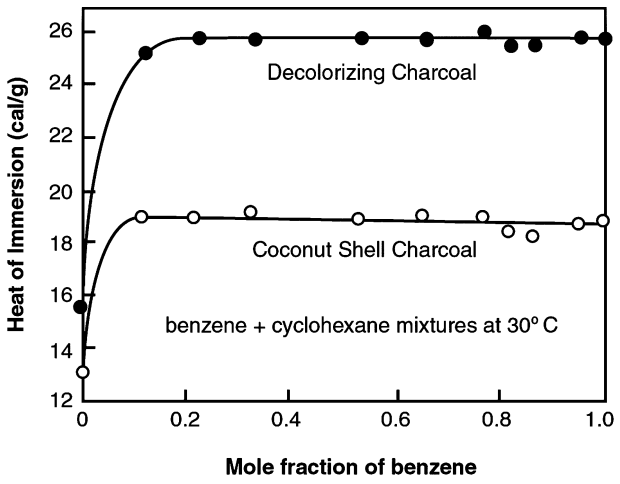

Fig. 7 Heat of immersion of binary liquid mixtures of benzene (1) + cyclohexane (2) on activated carbons.

temperature coefficients of liquid phase adsorption isotherms are generally much smaller than those for gas phase adsorption. The temperature changes in a liquid phase adsorber because of the ad(de)sorption processes are also small owing to the high heat capacity of the liquid.

ADSORPTION KINETICS

The actual kinetics of the ad(de)sorption process is generally very fast (in the order of microseconds). However, a significant resistance may exist for transfer of the adsorbate molecules from the bulk fluid phase to the adsorption sites inside the micropores of the adsorbent (see Fig. 2). For gas adsorption, these resistances may be caused by 1) molecular diffusion through a fluid film outside the adsorbent particles (for mixtures only); 2) Knudsen diffusion through the meso- and macropores of the adsorbent and the binder material in parallel with surface diffusion of adsorbed molecules on the walls of those pores (if any); and 3) activated (hopping) diffusion of adsorbed molecules inside the micropores. The same resistances exist for adsorption of liquid mixtures except that the flow through the meso-macropores of the adsorbent and the binder is controlled by molecular and surface diffusion through liquid filled pores. Additional mass transfer resistance called ''skin resistances'' at the surface of the adsorbent particles or zeolite crystals has also been observed.[2] Some or all of these processes are strongly influenced by the local fluid phase concentration and temperature within the adsorbent particle.

The magnitudes of gas diffusivities by different mechanisms follow the order: meso-macropore gas diffusivity (D_p) $\gg$ surface diffusivity (D_s) in those pores $\geq$ micropore diffusivity (D_m). For example, D_p

and D_s for adsorption of water vapor into the mesopores of an activated alumina sample were ~5–10 × 10^{-2} cm^2/sec and ~3 × 10^{-6} cm^2/sec, respectively.[4] The micropore diffusivity of water vapor into the crystals of NaA zeolite was ~1 × 10^{-6} cm^2/sec.[4]

The diffusivity of a liquid adsorbate through the meso-macropores is much slower than that for a gas. For example, the diffusivity of bulk liquid phase water from ethanol into an alumina sample was ~6 × 10^{-7} cm^2/sec.[4]

The time constant for meso-macropore diffusion into an adsorbent particle of radius R_p is given by (D_p/R_p^2). The time constant for micropore diffusion into a pore (having a characteristic diffusional distance of R_m) is given by (D_m/R_m^2). Because R_m (1–2 μm) is typically much smaller than R_p (1–2 mm), the meso-macropore diffusion generally controls the overall mass transfer into a practical adsorbent particle, even though $D_m \ll D_p$. An exception will be the case where the diameter of the adsorbate molecule is very close to that of the micropore, so that D_m is extraordinarily small, and the micropore diffusion becomes the controlling mechanism. Table 4 shows the micropore diffusivities of various gases in the Henry's law region into the crystals of several zeolites at 300 K.[2]

The table shows the remarkable decrease in the micropore diffusivity of a gas when its molecular diameter approaches that of the zeolite pore. The temperature coefficients of D_s and D_m are given by the Arrhenius relationship [D_s, $D_m = D^0 \exp(-E/RT)$] because these diffusions are activated processes. E is the activation energy for the diffusion process and D^0 is a constant. These diffusivities can also be complex functions of adsorbate loadings and compositions.[19]

The most rigorous formulation to describe adsorbate transport inside the adsorbent particle is the chemical potential driving force model. A special case of this model for an isothermal adsorption system is the Fickian diffusion (FD), model which is frequently used to estimate an effective diffusivity for adsorption of component i (D_i) from experimental uptake data for pure gases.[2,19] The FD model, however, is not generally used for process design because of mathematical complexity. A simpler analytical model called linear driving force (LDF) model is often used.[20] According to this model, the rate of adsorption of component i of a gas mixture into an adsorbent particle of radius R is given by:[11]

$$\frac{d\bar{n}_i}{dt} = k_{ii}(\bar{n}_i^* - \bar{n}_i) + \sum k_{ij}(\bar{n}_j^* - \bar{n}_j) \qquad (10)$$

where $\bar{n}_i$ is the average adsorbate loading of component i in the particle at time t. The variable $\bar{n}_i^*$ represents the adsorbate loading of component i that would be in equilibrium with the superincumbent gas phase conditions at time t. k_{ii} and k_{ij} are straight and cross mass transfer coefficients for component i. Further simplifications are often made by assuming that $k_{ij} = 0$ and k_{ii} is a function of T only. The relation between k_{ii} and D_i is generally given by $K_{ii} = \Omega(D_i/R^2)$, where Ω is a constant.[20] A value of $\Omega = 15$ is often used even though other values are also possible.[20] A parallel formulation called the surface excess linear driving force (SELDF) model for describing adsorption kinetics from liquid mixtures using Gibbsian surface excess as the variable has also been used successfully.[4]

Table 5 shows examples of LDF mass transfer coefficients for adsorption of several binary gas mixtures on BPL activated carbon particles (6–16 mesh) at ~23–30°C.[21] The data show that the mass transfer coefficients are relatively large for these systems. There is a scarcity of multicomponent adsorption equilibria, kinetics, and heat data in the published literature. This often restricts extensive testing of theoretical models for prediction of multicomponent behavior.

DESCRIPTION OF SELECTED ADSORPTIVE SEPARATION PROCESSES

Adsorption has become the state of the art technology for many separation applications as listed in Table 1. The more prolific areas include:

a. Drying of gaseous and liquid mixtures.
b. Production of oxygen and nitrogen enriched gases from air.
c. Production of ultrapure hydrogen from various gas sources.
d. Separation of bulk liquid mixtures where distillation is not convenient.

Table 4 Examples of pure gas diffusivities into zeolites at 300 K[a]

Gas	Kinetic diameter (Å)	NaA Zeolite (4A) (m^2/sec)	Na-CaA Zeolite (5A) (m^2/sec)	Nax Zeolite (13X) (m^2/sec)
N_2	3.70	3.1 × 10^{-14}	1.1 × 10^{-10}	Fast
Kr	3.65	1.2 × 10^{-17}	—	—
CH_4	3.76	1.2 × 10^{-15}	6.0 × 10^{-10}	—

There has been extensive research and development in all of these areas during the last 30 yr. For example, topics (a)–(c) alone have generated more than 600 U.S. patents during the period 1980–2000.[1] They have been assigned to 160 different corporations around the world. For the sake of brevity, only a selected few commercial processes will be discussed here.

Adsorptive Drying

Both TSA and PSA processes are commercially used for removal of trace or dilute water contamination from a gas. They are commercially designed to handle 1–40,000 ft^3 of feed gas per minute. The basic steps of a conventional TSA process consists of: 1) flowing the contaminated gas over a packed bed of a desiccant (silica gel, alumina, zeolite) at a near-ambient temperature and withdrawing a dry product gas until the moisture concentration in the product gas rises to a preset level; 2) heating the adsorbent to ~150–300°C by flowing a hot dry gas countercurrently through the dbed and rejecting the water laden effluent gas; and 3) cooling the bed to feed gas temperature by countercurrently flowing a dry gas through the bed at feed gas temperature while rejecting the effluent gas. The cycle is then repeated. A part of the dry gas (~10–30%) produced in step 1 is generally used to supply the gas for steps 2 and 3. The effluent gas from step 3 is often heated to supply the gas for step 2. Fig. 8A is a schematic diagram of a three-column TSA gas drying unit. The total cycle time (all steps) for TSA processes generally varies between 2 and 8 hr. A typical dynamic water removal capacity of an alumina dryer is ~5–15% by weight. Product gas dew points of less than −40°C can be easily obtained. Many different process modifications like thermal pulsing, elimination of the cooling step, lower temperature regeneration, etc. are also used for decreasing the costs of drying.[4]

The TSA dryers for liquid mixtures use similar process steps to those used for gas dryers except that the adsorbers are first drained to remove the void liquid before they are heated countercurrently using a hot gas. Heating vaporizes the adsorbed water as well as liquid films adhering to the adsorbent particles. The hot effluent gas is cooled to condense out the components of the feed liquid mixture. The adsorber is then cooled by countercurrently flowing a cold gas and refilled with dry liquid before starting a new cycle.[4]

The basic steps of a conventional PSA gas drying process (Skarstrom cycle) consists of: 1) adsorption of water vapor from the feed gas by flowing the gas over a desiccant bed (silica gel, alumina, zeolite) at an elevated pressure (say 5–15 atm) and withdrawing a dry product gas at feed pressure; 2) countercurrently depressurizing the adsorber to near-ambient pressure and venting the effluent; 3) countercurrently purging the adsorber with a part of the dry gas produced by step 1 at near-ambient pressure while venting the effluent; and 4) countercurrently pressurizing the adsorber with a part of the product gas from step 1. Adsorption at a relatively lower feed gas pressure (1.3–1.7 atm) and desorption under vacuum (both depressurization and purge steps) are also practiced. Fig. 8B is a schematic diagram of a two-bed PSA dryer. The process can be used to obtain a very dry product (say −60°C dew point). A typical process uses ~15–30% of the dry product gas as purge. The total cycle times for PSA processes generally vary between 2 and 6 min.[4]

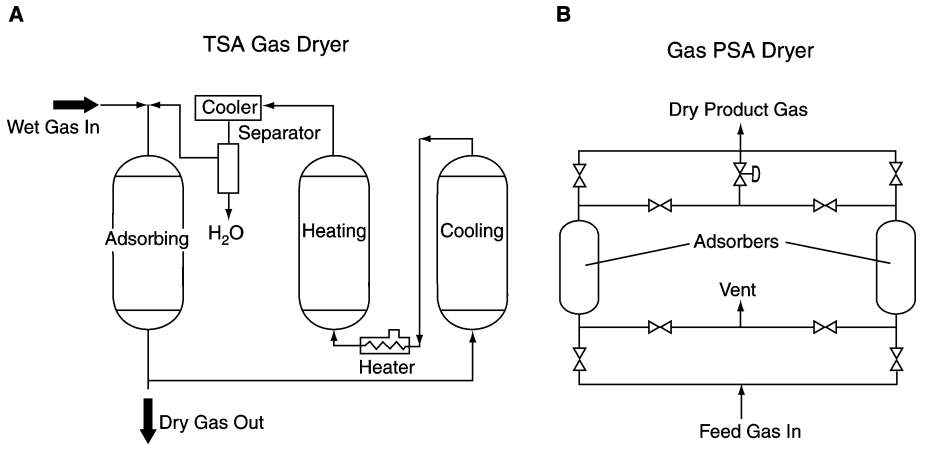

Fig. 8 Schematic drawings of (A) three-column TSA and (B) two-column PSA processes.

Air Fractionation

A large variety of PSA process concepts have been commercialized for: 1) production of 23–95 mol% oxygen using a N_2 selective (thermodynamic) zeolite; 2) production of 99+ mol% nitrogen using an O_2 selective (kinetic) carbon molecular sieve; and 3) simultaneous production of 90+ mol% O_2 and 98+ mol% N_2 using a N_2 selective zeolite from ambient air. Some of these concepts are called vacuum swing adsorption (VSA) because the final desorption pressure is subatmospheric. Commercial units are designed in the size range of 0.012–100 tons of oxygen per day (TPD).[2]

A VSA process for production of 90% O_2 from air using a LiX zeolite uses the cyclic steps of: 1) pressurizing the adsorber from an intermediate pressure level (P_I) to the final adsorption pressure level of P_A ($\sim$1.43 atm) with compressed air; 2) flowing compressed air feed at P_A through the adsorber and producing the 90% O_2 enriched product gas; 3) countercurrently depressurizing the adsorber to near-ambient pressure and venting the effluent gas; 4) countercurrently evacuating the adsorber to a vacuum level of P_D ($\sim$0.34 atm) and countercurrently purging the adsorber with a part of the O_2 product gas from step 2 at that pressure while venting the effluent gas; and finally (5) countercurrently pressurizing the adsorber from P_D to P_I using a part of the product gas. The cycle is then repeated.[22] Using a total cycle time of 70 sec, the O_2 productivity by the process, in terms of bed size factor (BSF), was 830 lb of zeolite per TPD of oxygen. The total power requirement was 11.6 kW/TPD when the product O_2 gas was delivered at a pressure of 6.45 atm by recompression.[22]

The LiX zeolite is currently favored for O_2 production. Table 6 demonstrates its superiority over other zeolites for making 90 mol% O_2 from air using a specific VSA cycle operating between final adsorption and desorption pressures of 1.48 and 0.25 atm, respectively.[23]

The Carbon Molecular Sieves (CMS) contain constricted pore mouths that permit the slightly smaller O_2 molecules to diffuse into the pores of the carbon faster than the N_2 molecules from air. This produces an O_2 enriched adsorbed phase based on kinetic selectively when the CMS is contacted with air for a short period of time. The material has practically no thermodynamic selectivity for either gas.[24] A simple four-step PSA process using a CMS consists of: 1) passing compressed air into the adsorber to pressurize it to P_A, and then withdrawing a N_2 enriched product gas at that pressure; 2) connecting the adsorber with another adsorber that has completed step 3 below, to pressure equalize the adsorbers; 3) countercurrently depressurizing the adsorber to near-ambient pressure and venting the O_2 enriched gas, and finally 4) pressure equalizing the adsorber with the companion adsorber, which has completed step 1. The cycle is then repeated. Using a feed air pressure of $\sim$8.1 atm ($=P_A$), the process could produce a 99.0 mol% N_2 product gas with a N_2 recovery of 49.4% from the feed air. The N_2 productivity was $\sim$92 ft^3/hr per cubic foot of adsorbent.[24] The O_2 enriched waste gas contained 33.8% O_2. The N_2 productivity and recovery were reduced to 73% and 39.2%, respectively, when its purity was raised to 99.5 mol%. Other process cycles have been designed using CMS adsorbents to raise the N_2 product gas purity above 99.9 mol%.[25]

Table 6 Comparative performance of various zeolites for O_2 production by a VSA process

Zeolite	BSF	Energy of separation
NaX	1.00	1.00
CaX	1.28	1.78
LiX	0.51	0.88

Production of Hydrogen

The most common industrial method to make ultrapure hydrogen is by steam-methane reforming (SMR) using a catalyst at the temperature 890–950°C. The reformed gas is then subjected to a high temperature water gas shift (WGS) reaction at 300–400°C. The WGS reactor effluent typically contains 70–80% H_2, 15–25% CO_2, 1–3% CO, 3–6% CH_4, and trace N_2 (dry basis), which is fed to a PSA system at a pressure of 8–28 atm and a temperature of 20–40°C for production of an ultrapure (99.99+ mol%) hydrogen gas at the feed pressure. Various PSA systems have been designed for this purpose to produce 1–120 million cubic feet of H_2 per day.

A popular PSA cycle called polybed process consists of 11 cyclic steps.[26] They include: 1) passing the feed gas at pressure P_F through a packed adsorbent column and withdrawing the high-purity H_2 product gas; 2) cocurrently depressurizing the adsorber from pressure P_F to P_I while producing a stream of essentially pure H_2; 3) further cocurrently depressurizing the adsorber from pressure P_I and P_{II} and withdrawing another stream of H_2 enriched gas; 4) even further depressurizing the adsorber cocurrently from pressure P_{II} and P_{III} and again withdrawing a stream of H_2 enriched gas; 5) countercurrently depressurizing the adsorber from pressure P_{III} to a near-ambient pressure (P_D) and venting the effluent gas; 6) countercurrently purging the adsorber with a stream of essentially pure H_2 produced by a companion adsorber undergoing step 4; 7) countercurrently pressurizing the adsorber from P_D to P_{II} by introducing the effluent gas from

another adsorber carrying out step 3; 8) further pressurizing the adsorber countercurrently from pressure P_{II} and P_I using the gas produced by another adsorber undergoing step 2; and 9) finally pressurizing the adsorber countercurrently from pressure P_I to P_F using a part of the product gas produced by another adsorber carrying out step 1. The cycle is then repeated. Increasing the pressure ratio between the feed gas and the purge gas (P_F/P_D) generally improves the separation performance of the PSA process by: 1) providing higher specific adsorption capacities for the selectively adsorbed components of the feed gas during the adsorption step (thus reducing adsorbent inventory) and 2) lowering the quantity of the purge gas required for adsorbent regeneration (thus increasing product recovery). However, increased feed gas pressure also increases the void gas quantity inside the adsorber at the end of the adsorption step, which: 1) increases the amount of adsorbent needed to contain the impurities during the subsequent cocurrent depressurization steps and 2) increases product loss during the countercurrent depressurization step. Consequently, there is an upper feed gas pressure limit (typically <40 atm) for optimum operation of the PSA cycle.

The most distinguishing feature of the polybed process is that step 1 is terminated when there is a substantial adsorption capacity left for the feed gas impurities inside the column so that these impurities are removed from the expanding void gases in steps 2–4 to produce high-purity H_2 effluents. The adsorbers are generally packed with a layer of an activated carbon at the feed end primarily for selective removal of H_2O and CO_2. A layer of 5A zeolite at the product end removes any remaining CO, CH_4, and N_2. These adsorbents are chosen due to the ease of desorption of the impurities from them. Fig. 9A shows a schematic diagram of a polybed system containing nine parallel adsorbers. Using a total cycle time of 13.3 min, the polybed process could produce a 99.999% pure H_2 product from a WGS reactor effluent gas at 20.7 atm and 21°C with a H_2 recovery of 86.0%. The feed processing capacity was ~35 ft^3 of feed gas per cubic foot of total adsorbent in the system/cycle.[26]

Pressure swing adsorption processes are also designed to produce high-purity (99.95+ %) H_2 products from refinery-off gases containing H_2 (65–90%) and C_1–C_5 hydrocarbon impurities with high H_2 recoveries (~86+ %). Silica gel and activated carbons are used as adsorbents.[27]

Separation of Bulk Liquid Mixtures

A variety of simulated moving bed (SMB) processes has been commercialized for adsorptive separation of bulk liquid mixtures where distillation is not cost-effective. They are designed to process 100–120,000 tons of bulk chemicals per year. Key examples include separation of: 1) *n*-paraffins from branched and cyclic compounds; 2) olefins from paraffins; 3) xylene isomers; 4) glucose–fructose mixture; and 5) enantiomers of racemic compounds. The SMB concept is based on the principles of liquid phase chromatography. It uses a stationary bed of an adsorbent with multiple inlet and outlet ports along its length as shown by Fig. 9B. Continuous countercurrent flow of the solid and the liquid phases inside the adsorber is mimicked by periodically moving the feed introduction and product withdrawal points to and from the adsorber using a rotary valve (RV). A weakly adsorbed desorbent liquid (D) is continuously circulated through the column with a pump. The pump flow rate is periodically changed with the change in the position of the RV. The process splits a feed liquid mixture (A + B) into two easy to separate liquid mixtures (A + D and B + D), which can then be further separated by distillation, if needed. For example, an SMB process could separate a *n*-paraffin + *n*-olefin feed mixture of C_{11}–C_{14} hydrocarbons containing ~9.0 wt% olefins to produce an olefin enriched stream containing ~96.2% olefins with an olefin recovery of ~94.0%. The paraffin enriched stream contained ~98.5 wt%

paraffins. A hydrocarbon mixture of lower boiling range was used as the desorbent liquid.[6] The preferred adsorbent was NaX zeolite (caustic treated).[3,6]

EMERGING ADSORPTIVE SEPARATION PROCESSES

Design of new adsorptive process cycles using new (or modified) and existing adsorbents continues to grow. The following areas have attracted considerable attention in recent years.

Rapid PSA Cycles

The concept involves the use of faster cycle times (seconds) than those for conventional PSA cycles (minutes) to increase the productivity rate (volume of product gas/volume of adsorbent/hour) by several folds. This is achieved by operating an existing PSA cycle faster using modified hardware or by designing new process cycles using conventional hardware. An example of the latter case is a rapid PSA (RPSA) process for production of ~27.5% O_2 from air.[2] It uses multiple layers of a N_2 selective zeolite stacked in a single adsorber vessel. The layers are cyclically subjected to: 1) simultaneous air pressurization and adsorption and 2) simultaneous depressurization and back purging with O_2 product gas. Using a total cycle time of 10 sec, the O_2 productivity could be raised to ~2300 ft^3/hr per cubic foot of adsorbent with an O_2 recovery of ~64%. This productivity is an order of magnitude higher than conventional PSA processes.[2]

Radial and Rotary Bed Adsorbers

The maximum permissible gas flow rate through a conventional packed bed adsorber is governed by pressure drop, local fluidization, and channeling within the column. Radial bed adsorbers are designed to circumvent some of these problems. The adsorbent is placed in an annular section between two coaxial cylindrical chambers with perforated walls, and the gas flows radially through the arrangement. Fig. 10A is a schematic drawing of a radial bed adsorber.[28] The adsorber allows lower pressure drops, faster cycle times, higher throughputs, and elimination of fluidization, but they are more expensive to build. Radial beds have been used for both PSA and TSA processes.

The rotary bed adsorber (also called adsorption wheel) is designed to provide a truly continuous TSA system.[29] It uses a shallow wheel-shaped adsorption bed that continuously turns about an axis inside a fixed supporting frame. A section of the wheel is used to adsorb impurities from a feed gas while the other section is used to thermally regenerate the adsorbent. Fig. 10B is a schematic drawing of the adsorption wheel arrangement. The adsorbent is made from a

CH_4	35–50	47–55
H_2	14–30	—

honeycomb-shaped alumina substrate, which can be coated with layers of different adsorbents. The rotary adsorber has been designed for dehumidification of gases, solvent vapor recovery, volatile organic compounds (VOC) removal, gas deodorization, etc.

Hybrid Gas Separation Using Adsorption

Hybrid concepts combining the principles of selective adsorption with those of membrane technology and reaction engineering have been developed to enhance the overall separation or reaction efficiency.[10] Two examples are given below.

Nanoporous Carbon Membrane

The nanoporous carbon membrane consists of a thin layer (<10 μm) of a nanoporous (3–7 Å) carbon film supported on a meso-macroporous solid such as alumina or a carbonized polymeric structure. They are produced by judicious pyrolysis of polymeric films. Two types of membranes can be produced. A molecular sieve carbon (MSC) membrane contains pores (3–5 Å diameters), which permits the smaller molecules of a gas mixture to enter the pores at the high-pressure side. These molecules adsorb on the pore walls and then they diffuse to the low-pressure side of the membrane where they desorb to the gas phase. Thus, separation is primarily based on differences in the size of the feed gas molecules. Table 7 gives a few examples of separation performance of MSC membranes.[30] Component 1 is the smaller component of the feed gas mixture.

The pores of a selective surface flow (SSF) membrane are large enough (6–7 Å) to permit all molecules of a gas mixture to enter the pores. However, the larger and more polar molecules are selectively adsorbed at the high-pressure side. Then, they selectively diffuse on the pore walls to the low-pressure side, where they desorb into the gas phase. The adsorbed molecules also block the passage of smaller molecules through the void space within the pores. Thus, separation is primarily based on selective adsorption and surface diffusion. One key advantage of the SSF membrane is that the smaller molecules of the feed gas mixture (often the desired species) are enriched in the high-pressure side, which reduces subsequent recompression, if needed. The membrane can be used to enrich H_2 from mixtures with C_1–C_4 hydrocarbons, separate H_2 and CH_4 from H_2S, and dehumidify a gas stream at moderate feed gas pressures.[30] Table 8 shows an example of the performance of an SSF membrane in treating a refinery waste gas (pressure ~3.5 atm) where a hydrogen recovery of 60% was achieved.[30]

Simultaneous Adsorption and Reaction

The concept is based on Le Chatelier's principle that the conversion of an equilibrium controlled reaction as well as the rate of the forward reaction can be significantly enhanced by selectively removing one of the reaction products from the reaction zone. A selective adsorbent can be used for this purpose by mixing it with the catalyst in a reactor. The adsorbent, however, must be periodically regenerated. Such concepts are often called ''pressure swing reactors'' when the principles of PSA are used for regeneration.[10] One example is a cyclic process called sorption enhanced reaction process (SERP), which was developed for producing H_2 by SMR ($CH_4 + 2H_2O \leftrightarrow CO_2 + 4H_2$) using an admixture of a conventional SMR catalyst and a novel chemisorbent (K_2CO_3 promoted hydrotalcite) for selective removal of CO_2 from the reaction zone. The process used steam purge under vacuum for regeneration of the chemisorbent. The process could directly produce an essentially CO_x-free H_2 product containing ~95% H_2 and 5% CH_4 at a feed pressure of ~26 psia using a H_2O/CH_4 ratio of 6 : 1 as feed. A CH_4 to H_2

Table 9 Performance of SERP concept for H_2 production[a]

	Product composition (dry)				
	H_2	CH_4	CO_2	CO	Conversion (%)
SERP concept	94.4%	5.6%	40 ppm	<30 ppm	73.0
Conventional SMR	67.2%	15.7%	15.9%	1.2%	52.6

[a]$T = 490°C$, $P = 26.1$ psia, $H_2O/CH_4 = 6.1$.

conversion of ~73% could be achieved at a reaction temperature of only ~500°C, which was much lower than the temperature of a conventional SMR reaction (~850°C). Table 9 describes the pilot test performance of the SERP concept.[13] It also shows the equilibrium limitation of an SMR reactor operated without using the concept. The advantages are obvious.

CONCLUSIONS

The range of applications for gas and liquid separation and purification by adsorption is large and growing. The strong research and development activity in this area is facilitated by the flexibility of practical adsorptive process designs such as pressure and thermal swing adsorption, and SMB adsorption, as well as by the availability of a large spectrum of new and old micro- and mesoporous adsorbents.

The fundamental adsorptive properties governing the performance of the separation processes are the multicomponent equilibria, kinetics, and heat. A large volume of data, as well as models to describe them, exist in the published literature only for adsorption of pure gases and binary liquid mixtures. Binary gas adsorption data are sporadic. Multicomponent data are rare. Existence of adsorbent heterogeneity can introduce severe complexity in the multicomponent adsorption behavior.

Despite these limitations, adsorption has become the state of the art technology for many commercial separations. Examples include: 1) gas and liquid drying; 2) production of oxygen and nitrogen enriched air; 3) hydrogen purification; and 4) several bulk liquid phase separations of close boiling compounds. Emerging topics on adsorption research and development include: 1) rapid pressure swing adsorption; 2) novel adsorber configurations; 3) adsorbent membranes; and 4) simultaneous reaction and adsorption.

Advanced Oxidation

Sangchul Hwang
Department of Civil Engineering and Surveying, University of Puerto Rico, Mayagüez, Puerto Rico

INTRODUCTION

Chemical oxidation technologies are defined as the processes that use oxidizing agents to degrade or transform complex hazardous chemicals to simpler nontoxic ones. Advanced oxidation processes (AOPs) constitute, in general, the generation and the use of hydroxyl radicals ($^{\bullet}OH$) to oxidize hazardous chemicals, which are otherwise very recalcitrant to conventional oxidation processes.

Advanced oxidation processes have been used for the treatment of drinking water, wastewater, and soil/groundwater contaminated with unwanted and hazardous substances. The processes are, in general, based on the generation and the use of highly reactive hydroxyl radicals ($^{\bullet}OH$) that react indiscriminately with many organic and inorganic substances. This entry provides the readers with an overview of such AOPs in terms of fundamentals of the reaction mechanisms and their application to drinking water, wastewater, and soil/groundwater treatment processes.

REDUCTION AND OXIDATION

This section includes a brief technical discussion on the fundamentals related to the basic reduction and oxidation reactions.

Redox Reaction

A reduction and oxidation (redox, hereafter) reaction is an electron transfer reaction between an oxidizing agent and a reducing agent. Oxidizing agents (oxidants) are substances that cause oxidation, whereas reducing agents (reductants) are those that cause reduction. Losing an electron is oxidation and gaining an electron is reduction. Hence, oxidizing agents gain electrons or are reduced and reducing agents lose electrons or are oxidized. Oxidation state is a measure of the charge on an atom in any chemical substance. More information on the oxidation state of the substance is addressed in the following section.

A redox reaction can be separated into a reduction half-reaction and an oxidation half-reaction. In each of these reactions, the number of electrons lost or gained is equal to the change in oxidation state of the oxidized or reduced substances. Also, both reactions are needed to be properly balanced.[1,2]

Electrode Potential

The power of an oxidant or a reductant is measured by the electrode potential of the substance.[3] Under standard conditions, the electrode potential is defined as the standard electrode potential, E°. Standard conditions are the cases at 25°C, 1 atm pressure, and unit activity of all species. Table 1 lists the values of E° for some chemical oxidants used in water and wastewater treatment processes.

The standard free energy ΔG° is defined as follows:

$$\Delta G^{\circ} = -nFE^{\circ} = -RT \ln K \quad (1)$$

where n is the number of electrons transferred in the redox reaction, F is Faraday's constant (23,062.4 ± 0.3 cal/V/eq), R is the gas constant (1.9872 cal/deg/mol), and T is the absolute temperature (K). For example, when water containing manganese ions is ozonated under acidic conditions at 25°C, a reduction half-reaction and an oxidation half-reaction can be written, respectively, as follows:

$$5[O_3 + 2H^+ + 2e^- \rightarrow O_2 + H_2O] \quad (2)$$

$$2\left[Mn^{2+} + 4H_2O \rightarrow MnO_4^- + 8H^+ + 5e^-\right] \quad (3)$$

Consequently, the net redox reaction for such conditions is as follows:

$$5O_3 + 2Mn^{2+} + 3H_2O \rightarrow 2MnO_4^- + 6H^+5O_2 \quad (4)$$

For the first reduction half-reaction [Eq. (2)] E° is found to be 2.07 V, and for the second oxidation half-reaction [Eq. (3)] the value is obtained to be (−)1.49 V by reversing the sign of the E° value for the reduction half-reaction of permanganate under acidic conditions.[1,2] Therefore, the value of E° for the net redox reaction is the sum of two values [2.07 + (−)1.49 = 0.58 V]. The values of ΔG° and K of the net redox reaction are calculated from Eq. (1) to be (−)133 kcal/mol and 5×10^{97}, respectively, indicating that the reaction is very favored thermodynamically.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120008088

Table 1 Standard electrode potentials for selected chemical oxidants

Oxidants	Standard electrode potentials (V)
Chloride	1.36
Hypochlorous acid	1.49
Permanganate	1.68
Hydrogen peroxide	1.78
Ozone	2.07
Hydroxyl radical	2.78

(From Refs.[1,2].)

At conditions where the thermodynamic activities of all substances are not unity (i.e., nonstandard conditions), such concentration effects on redox potential are expressed by the Nernst equation as follows:

$$E = E^\circ - \frac{RT}{nF} \ln \frac{a_{red}}{a_{ox}} \quad (5)$$

where a_{red} and a_{ox} represent the chemical activities of all of the species that appear on the reduced side and the oxidized side, respectively, in the redox reaction.

Analogous to pH, it is convenient to express the activity of electron as pE because electron activities may vary many orders of magnitude. In this sense, the value of pE (pE° if at standard conditions) is defined as follows:

$$pE^\circ = -\log(a_{e^-}) = \frac{E^\circ/2.303RT}{F} = \frac{E^\circ}{0.0591} \quad (6)$$

where a_{e^-} is the activity of electron in solution. Accordingly, if the electron activity were increased by a factor of 10, the pE value would be changed by (−)1.0. For example, if E° (or pE°) for Eqs. (2), (3), or (4) is positive, the reaction will proceed to the right direction as written because ΔG° becomes negative. The greater the positive value of E° or pE°, the greater the tendency of the reaction to proceed.

FUNDAMENTALS OF AOP

The use of chemical reagents with high oxidizing potential is the most effective way of oxidizing substances. The most highly oxidizing reagent available is the hydroxyl radical ($^\bullet$OH). In this regard, most AOPs are performed in conjunction with the generation of $^\bullet$OH to initiate oxidations.

A radical is a compound containing an atom with a single unpaired electron.[4] Structurally, $^\bullet$OH is a highly reactive radical because of its orbital characteristics. The four outermost orbitals of $^\bullet$OH have only seven electrons so that it has a great tendency to gain the eighth one to form the stable state. In the presence of an organic contaminant(s), $^\bullet$OH can abstract a hydrogen atom, thereby provoking contaminant oxidation. Such abstraction reaction is thermodynamically favored strongly, releasing about 119 kcal/mol of energy:

$$^\bullet OH + {}^\bullet H \rightarrow H_2O \quad \Delta H = (-)119\,\text{kcal/mol} \quad (7)$$

where ΔH is the enthalpy of the reaction. If the reaction has a negative ΔH, the reaction releases the heat of the reaction (i.e., exothermic reaction). Conversely, if the reaction has a positive ΔH, it is called an endothermic reaction.

The required dissociation energy (i.e., ΔH for breaking bond) for a C–H bond ranges from 80 to 104 kcal/mol, depending on the C–H location from which H is abstracted. In this regard, ΔH for the chemical oxidation via H abstraction by $^\bullet$OH is negative so that the reaction is energetically permitted.[4]

In this section, brief fundamental reaction mechanisms for each AOP are addressed. Included as AOPs are individual and combinational processes in the use of ultraviolet (UV) irradiation, catalyzed titanium dioxide oxidation, Fenton's reagent oxidation, ozonation, peroxone oxidation, and permanganate oxidation.

Photochemical Oxidation

Ultraviolet and visible lights have sufficient energy to alter the electronic configuration of a molecule that is known to be at its ground state. When a molecule absorbs light of energy $h\nu$, one of the two electrons with opposite spin occupying the same orbital can be promoted to a vacant orbital of higher energy. This phenomenon is called electron transition, allowing the molecule to be in an excited state. In some cases, the promoted electron maintains a spin opposite to that of its former partner, resulting in an excited singlet state. At other times, a spin is reversed, leading to an excited triplet state.[4,5]

The relative energies of the ground and excited states are depicted in Fig. 1. The easiest electronic transition is the excitation of a nonbonded electron (n) into a π antibonding orbital (i.e., $n \rightarrow \pi^*$ transition). The other one is excitation from a π bonding orbital to a π antibonding orbital (i.e., $\pi \rightarrow \pi^*$ transition). Excitation of an electron from a σ bonding molecular orbital to a σ antibonding orbital (i.e., $\sigma \rightarrow \sigma^*$ transition) is impractical. This is, for example, because in dilute aqueous solutions the solvent is present at much greater concentrations and would absorb most of the light.[4,5]

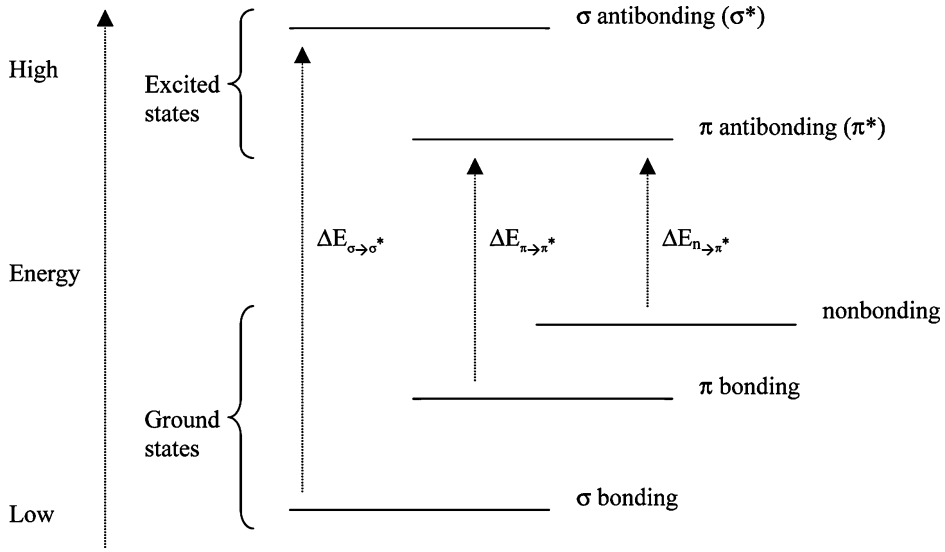

Fig. 1 The relative energies of the ground and excited states.

In general, a molecule in the ground state X absorbs $h\nu$ to produce an excited state Y^* or Z^* as follows:

$$X \xrightarrow{h\nu} Y^* \rightarrow \text{products} \quad (8)$$

$$Y^* \rightarrow Z^* \quad (9)$$

$$Z^* \rightarrow \text{products or X} \quad (10)$$

Typical reactions of excited states include rearrangement, abstraction, addition, and cleavage reactions.

Photocatalyzed Titanium Dioxide Oxidation

Titanium dioxide (TiO_2) has been the most commonly applied photocatalyst because of its chemical stability and low toxicity. The decomposition of organic contaminants in TiO_2 suspensions is initiated by photogenerated electron/hole pairs as follows:[6,7]

$$TiO_2 \xrightarrow{h\nu} TiO_2(e^- + h^+) \quad (11)$$

The holes (h^+) react with electron donors (H_2O and OH^-) or are adsorbed to TiO_2 to produce $^{\bullet}OH$ [Eq. (12)]. At the same time, dioxygen molecules react with the electrons to yield superoxide radical anions ($^{\bullet}O_2^-$) [Eq. (13)], which are in turn protonated to generate hydroperoxy radicals ($HO_2^{\bullet}$) [Eq. (14)].

$$h^+ + H_2O \text{ (or } OH_{surface}^-) \rightarrow {}^{\bullet}OH + H^+ \quad (12)$$

$$O_2 + e^- \rightarrow {}^{\bullet}O_2^- \quad (13)$$

$$^{\bullet}O_2^- + H^+ \rightarrow HO_2^{\bullet} \quad (14)$$

The surface of TiO_2 exhibits the positive charge because of an excess of protons from H_2O or in an acidic solution. In this regard, $^{\bullet}OH$ photogenerated on the TiO_2 surface acts as the major oxidant for the negatively charged contaminants that are attracted to the TiO_2 surface via coulombic forces. Contaminants can also be oxidized at the solution bulk phase as follows:

$$^{\bullet}OH + \text{compounds} \rightarrow \text{products} \quad (15)$$

Oxidation in Use of Hydrogen Peroxide

The simplest way for the $^{\bullet}OH$ generation is the direct photochemical cleavage of H_2O_2 as follows:[8]

$$H_2O_2 \xrightarrow{h\nu} 2{}^{\bullet}OH \quad (16)$$

However, the above theoretical amount of $^{\bullet}OH$ quantum yield can be reduced to about 0.5 because of the radical–radical recombination [Eq. (17)] and other scavenging compounds, such as H_2O_2 itself [Eq. (18)] and bicarbonate ions (HCO_3^-) [Eqs. (19–21)]

$$^{\bullet}OH + {}^{\bullet}OH \rightarrow H_2O_2 \quad (17)$$

$$^{\bullet}OH + H_2O_2 \rightarrow H_2O + HO_2^{\bullet} \quad (18)$$

$$^{\bullet}OH + HCO_3^- \rightarrow CO_3^{-\bullet} + H_2O \quad (19)$$

$$^{\bullet}OH + CO_3^{2-} \rightarrow CO_3^{-\bullet} + OH^- \quad (20)$$

$$CO_3^{-\bullet} + H_2O_2 \rightarrow HCO_3^- + {}^{\bullet}O_2^- + H^+ \quad (21)$$

Another common method of generating $^{\bullet}OH$ for the oxidation of organic compounds is via Fenton's reagent. Fenton's reagent oxidation involves the decomposition of hydrogen peroxide in the presence

of reduced iron salts into $^{\bullet}OH$.[9] Hydrogen peroxide (H_2O_2) reacts with ferrous iron (Fe^{2+}) to yield $^{\bullet}OH$ and ferric iron (Fe^{3+}) [Eq. (22)]; Fe^{3+} is reduced back to Fe^{2+} via reaction with H_2O_2 [Eq. (23)], the superoxide radical ($^{\bullet}O_2^-$) [Eq. (24)], or the perhydroxyl radical ($HO_2^{\bullet}$) [Eq. (25)], which is the protonated form of $^{\bullet}O_2^-$ ($pK_a = 4.8$). The primary reactions are as follows:

$$H_2O_2 + Fe^{2+} \rightarrow Fe^{3+} + OH^- + {}^{\bullet}OH \quad (22)$$

$$H_2O_2 + Fe^{3+} \rightarrow Fe^{2+} + {}^{\bullet}O_2^- + 2H^+ \quad (23)$$

$$^{\bullet}O_2^- + Fe^{3+} \rightarrow Fe^{2+} + O_2 \quad (24)$$

$$HO_2^{\bullet} + Fe^{3+} \rightarrow Fe^{2+} + HO_2^- \quad (25)$$

Hydroxyl radicals are highly reactive and are involved in nonspecific reactions with a wide range of compounds.[10] These reactions involve moderate to moderately high second-order reaction rate constants (10^7–$10^9\,M^{-1}\,sec^{-1}$) between the radical and compounds as shown in Table 2 and represent a promising option for the remediation of hazardous chemicals.[11] Fenton's reagent remediation is discussed in detail later in this entry.

Ozonation

Ozone (O_3) can directly oxidize organic compounds. Typical direct ozonation involves the insertion of the O_3 molecule into unsaturated carbon–carbon bond, resulting in the formation of an ozonide. This direct mechanism is very selective. The other mode of oxidation is through the reaction with $^{\bullet}OH$, which is generated via several O_3-based reactions.[12]

Ozone is very unstable in water with the half-life being in the range of seconds to hours. This is because the bonds that hold the O atoms together in O_3 molecule are very weak. The stability of ozone is largely dependent on the pH of the water. In fact, hydroxide ions play an important role and accelerate the O_3 decomposition as follows:

$$O_3 + OH^- \rightarrow HO_2^- + O_2 \quad (26)$$

$$O_3 + HO_2^- \rightarrow {}^{\bullet}O_2^- + {}^{\bullet}OH + O_2 \quad (27)$$

$$O_3 + {}^{\bullet}O_2^- \rightarrow {}^{\bullet}O_3^- + O_2 \quad (28)$$

Table 2 Rate constants for $^{\bullet}OH$ reactions with selected environmental contaminants

Reactants	Rate constants ($M^{-1}sec^{-1}$)
Benzene	7.8×10^9
2-Chlorophenol	1.2×10^{10}
Naphthalene	5×10^9
Nitrobenzene	3.9×10^9
Phenol	6.6×10^9
Tetrachloroethylene	2.6×10^9
Toluene	3.0×10^9
Trichloroethylene	4.2×10^9
Vinyl chloride	1.2×10^{10}

(From Ref.[10].)

Peroxone Oxidation

Ozone decomposition can be accelerated by the addition of H_2O_2. The reaction between H_2O_2 and O_3 is known to produce the $^{\bullet}OH$. This reaction is called peroxone.[13] The formation of the $^{\bullet}OH$ during peroxone oxidation is as follows:

$$H_2O_2 + H_2O \rightarrow HO_2^- + H_3O^+ \quad (29)$$

$$O_3 + HO_2^- \rightarrow HO_2^{\bullet} + {}^{\bullet}O_3^- \quad (30)$$

$$HO_2^{\bullet} \rightarrow H^+ + {}^{\bullet}O_2^- \quad (31)$$

$$O_2^{\bullet -} + O_3 \rightarrow {}^{\bullet}O_3^- + O_2 \quad (32)$$

$$^{\bullet}O_3^- + H^+ \rightarrow HO_3^{\bullet} \quad (33)$$

$$HO_3^{\bullet} \rightarrow O_2 + {}^{\bullet}OH \quad (34)$$

As such, the peroxone process results in the formation of $^{\bullet}OH$ through the reaction of O_3 with H_2O_2. A difference between the ozonation and peroxone process is that the former relies mainly on the direct oxidation by O_3, whereas the latter depends primarily on the oxidation with $^{\bullet}OH$. The O_3 residual in the peroxone process is short-lived because the O_3 decomposition is accelerated by the addition of H_2O_2, leading to a more reactive and faster oxidation in the peroxone process compared to the ozonation.

Permanganate Oxidation

Oxidation of organic chemicals using permanganate (MnO_4^-, either as potassium permanganate, $KMnO_4$ or sodium permanganate, $NaMnO_4$) involves, in general, direct electron transfer rather than free radical processes. The primary redox reactions for

permanganate are pH-dependent as follows:[14]

$$MnO_4^- + 8H^+ + 5e^- \rightarrow Mn^{2+} + 4H_2O \quad (\text{for pH} < 3.5) \tag{35}$$

$$MnO_4^- + 2H_2O + 3e^- \rightarrow MnO_2(s) + 4OH^- \quad (\text{for } 3.5 < \text{pH} < 12) \tag{36}$$

$$MnO_4^- + e^- \leftrightarrow MnO_4^{2-} \quad (\text{for pH} > 12) \tag{37}$$

The basic reactions involved in $KMnO_4$ oxidation in the presence of water are as follows:

$$RH_2 + 2KMnO_4 + 4H_2O \rightarrow ROH + 2MnO_2 + 2KOH \tag{38}$$

For example, the stoichiometric reaction for the complete destruction of trichloroethylene (C_2HCl_3) is as follows:

$$2KMnO_4 + C_2HCl_3 \rightarrow 2CO_2 + 2MnO_2 + 2K^+ + H^+ + 3Cl^- \tag{39}$$

Similar to the scavenging reactions in Fenton systems, in permanganate systems, there is a background oxidant demand that imposes a demand on the permanganate ion, which in turn reduces process efficiency. This demand, resulting from reaction with a wide range of reduced, naturally occurring chemical species, can often be greater than the demand imposed by the target contaminant to be oxidized. Permanganate is more expensive ($KMnO_4$—\$1.40/lb, \$162/1000 eq; $NaMnO_4$—\$5.95/lb, \$620/1000 eq) than H_2O_2 (\$0.26/lb; \$39/1000 eq). For further information on principles and practices of permanganate oxidation, the readers are highly recommended to refer to Ref.[14].

APPLICATION OF AOP

This section provides brief examples of the application of AOPs to the treatment of drinking water, wastewater, and soil/groundwater contaminated with unwanted and/or hazardous materials.

Drinking Water Treatment

The application of O_3 in drinking water treatment is prevalent because of its capability of disinfection and oxidation.[15] Ozone, as a disinfectant, is unstable in water and undergoes reactions with water components, whereas O_3 decomposes to $^{\bullet}OH$ so that advanced oxidation occurs. Unfortunately, undesired oxidation/disinfection by-products (DBPs) can be formed from the reaction of O_3 and $^{\bullet}OH$ with water matrix components. Such organic and inorganic DBPs can be treated with a subsequent treatment process, such as biological filtration. Care should be taken during ozonation of bromide-containing waters, which forms bromate that is not degraded by biological means. In addition, micro-organisms such as *Cryptosporidium parvum* oocysts are so resistant against disinfection that higher O_3 exposures are required and in turn more DBPs are formed.[11]

In an attempt to remove arsenic from potable municipal water and groundwater, Krishna et al. employed the treatment with Fenton's reagent followed by passing through iron scrap.[16] Their results indicated that the two-stage approach was capable of removing 2.5 mg/L arsenic to lower than the United States Environmental Protection Agency's (USEPA) guideline value of 10 μg/L.

Wastewater Treatment

Arslan et al. have investigated the AOPs for the treatment of reactive dye wastewater.[7] The investigators found that all investigated AOPs (e.g., UV/H_2O_2, photo-Fenton, UV/TiO_2) were capable of completely decolorizing and partially mineralizing the dye wastewater within 1 hr. Among those processes, photo-Fenton oxidation achieved the highest removal efficiency.

Wanpeng et al. have also applied a Fenton reagent oxidation for the treatment of a dye H-acid containing wastewater.[17] These investigators found that the process not only removed chemical oxidant demand effectively, but also improved the biodegradability by combining with the coagulation process.

Using a batch recycle mode, oily wastewater was treated in the photoassisted advanced oxidation systems.[18] Their results indicated that UV/H_2O_2 oxidized oily compounds into organic acids with the efficiency being greater at acidic pH. The oxidation rate was enhanced in the presence of Fe^{3+}.

Ozone, H_2O_2, and UV irradiation were applied separately and in all possible combinations for the treatment of textile wastewater.[19] Among the investigated AOPs, the most effective system was the simultaneous use of all three agents (i.e., $O_3/UV/H_2O_2$). Effective performance was also achieved in combined treatment O_3/H_2O_2. The authors pointed out that it was advisable to assess the costs of different AOPs to make practical comparison among the treatment schemes.[19]

Soil and Groundwater Treatment

One of the commonly used methods of treating soil and groundwater contaminated with hazardous

materials is the use of catalyzed hydrogen peroxide in the presence of iron species (i.e., Fenton's reagent oxidation). Watts et al. applied a higher H_2O_2 concentration than would be stoichiometrically required to oxidize pentachlorophenol (PCP) in soil systems to enhance mineralization.[20] With a pH of 2–3 being an optimum parameter, they achieved a rapid decrease in both PCP and total organic carbon contents within 24 hr.

Photochemical oxidation processes have also been used for the remediation of contaminated soil and groundwater environments. For example, Lewis et al. documented a field evaluation of the UV/oxidation technology ($UV/O_3/H_2O_2$) to treat volatile organic contaminants in groundwater.[21] Greater than 90% removal efficiency was reported for most contaminants.

Another AOP commonly used in in situ oxidation of contaminants in soil and groundwater environments is the permanganate oxidation. Although the process is active at most environmental pHs [Eq. (36)], Eqs. (36), (38), and (39) also indicate that manganese dioxide (MnO_2) is formed as a reaction by-product. Under most environmental conditions (pH 3.5–12), MnO_2 is present as a precipitate, i.e., $MnO_2(s)$. Under some conditions where background oxidant demand is high and large volumes and concentrations of MnO_4^- are needed, accumulation of large quantities of $MnO_2(s)$ in the subsurface can have negative consequences. For example, $MnO_2(s)$ encrustment on dense nonaqueous phase liquids (DNAPLs) may interfere with mass transfer of DNAPL components to the aqueous phase. Permeability reductions in the porous media may result from the formation of $MnO_2(s)$ on the well screen, sand/gravel pack, or aquifer material. Permeability loss can also result from the ion exchange of Na^+ or K^+ for divalent cations in the aquifer matrix. Undesirable reaction by-products may result from the oxidation and mobilization of metals or from the heavy metal content of the MnO_4^- product itself. Finally, there is a secondary drinking water standard established by the USEPA for manganese (0.05 mg/L) based on color, staining, and taste. Manganese imparts a black to brown color to water, can cause black staining on almost everything but glass, and imparts a bitter metallic taste.

Advanced Oxidation Processes as Pretreatment for Biological Treatment

Because of the presence of biorefractory materials, the efficiency of the biological treatments is often hampered. In general, AOP could reduce the toxicity that would otherwise detrimentally affect the biological processes. Additionally, AOP could transform biorefractory materials to more biodegradable compounds.[22,23]

As such, the use of AOP as pretreatment for the biological processes is promising. However, it should be noted that there is a great necessity to improve our understanding of such combined chemical and biological systems. This is because, for example, excess hydrogen peroxide concentration may show toxicity to the micro-organisms, and the by-products produced in the advanced oxidation process may sometimes be toxic to the micro-organisms as well.

FENTON'S REAGENT OXIDATION

This section introduces unconventional reaction mechanisms and the results of Fenton's reagent oxidation.

Hydroxyl-Radical-Independent Fenton Remediation

As mentioned earlier, the classical Fenton reagent oxidation constitutes the generation of $^{\bullet}OH$ as follows:[9]

$$H_2O_2 + Fe^{2+} \rightarrow Fe^{3+} + OH^- + {}^{\bullet}OH \qquad (22)$$

However, because of the small rate constant of the above Fenton reaction ($<10^2\,M^{-1}\,sec^{-1}$), the oxidation of Fe^{2+} by $^{\bullet}O_2^-$ [Eq. (40)] may completely overshadow the Fenton reaction and may have a significant role because of its much higher rate constant ($\sim 10^7\,M^{-1}\,sec^{-1}$).

$$^{\bullet}O_2^- + Fe^{2+} \rightarrow Fe^{3+} + H_2O_2 \qquad (40)$$

In Fe^{2+}-aerobic condition, an iron–oxygen complex, perferryl ion can be produced as an intermediate as follows:

$$Fe^{2+} + O_2 \leftrightarrow \left[\left(Fe^{2+}{-}O_2\right) \leftrightarrow \left(Fe^{3+}{-}{}^{\bullet}O_2^-\right)\right] \leftrightarrow Fe^{3+} + {}^{\bullet}O_2^- \qquad (41)$$

A common representation of perferryl ion is $Fe^{5+}{=}O$, with the formal charge of iron as (+)5. Its high electron affinity may replace $^{\bullet}OH$ as the oxidant.

Another iron–oxygen complex can be ferryl ion as follows:

$$^{\bullet}O_2^- + Fe^{3+} \rightarrow Fe^{2+} + O_2 \qquad (24)$$

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{2+}O + H_2O \qquad (42)$$

$$Fe^{2+} + \left(Fe^{2+}{-}O_2\right) \rightarrow \left(Fe^{2+}{-}O_2{-}Fe^{2+}\right) \rightarrow \left(2Fe^{2+}{-}O\right) \qquad (43)$$

A common representation of ferryl ion is $Fe^{4+}{=}O$ or $Fe^{2+}{-}O$, with the formal charge of iron (+)4. Like perferryl ion, the high electron affinity of ferryl ion may also replace $^{\bullet}OH$ as the oxidant.

A chelating agent diethylenetriaminepentaacetic acid (DTPA) inhibits the reduction of Fe^{3+} by $^{\bullet}O_2^-$ [i.e., prevents the reaction in Eq. (24) from going to the right]. In comparison, ethylenedinitrilotetraacetic acid (EDTA) stimulates the reduction of Fe^{3+} by $^{\bullet}O_2^-$ [Eq. (44)]. Hence, DTPA and EDTA reduce and enhance the Fenton reaction, respectively [Eq. (22)].[24]

$$(Fe^{3+}-EDTA) + {}^{\bullet}O_2^- \rightarrow O_2 + (Fe^{2+}-EDTA) \quad (44)$$

$$H_2O_2 + Fe^{2+} \rightarrow Fe^{3+} + OH^- + {}^{\bullet}OH \quad (22)$$

Effect of pH on Fenton's Reagent Oxidation

Reaction pH has been observed to significantly influence the degradation of organic contaminants. In most cases, the optimum pH has been at 3.[20] At lower pH (i.e., pH < 2.5), the rate and extent of oxidation can decrease because of several reasons: (1) $[Fe(II)(H_2O)]^{2+}$ is formed, which reacts with H_2O_2 more slowly and therefore $^{\bullet}OH$ is produced less; (2) hydrogen ions can scavenge $^{\bullet}OH$; and (3) the reaction of Fe^{3+} with H_2O_2 is inhibited and therefore less Fe^{2+} is available for $^{\bullet}OH$ production.[10,11]

Despite pH 3 being recommended as the operating pH, the percentage of Fenton destruction of 2-methylnaphthalene, *n*-hexadecane, and diesel fuel was higher at pH 7 than at pH 2.[20,25] Beltran et al. also documented enhanced Fenton oxidation rates for polycyclic aromatic hydrocarbons (PAHs) at pH 7 than at pH 2.[26]

At pH higher than 8, Fe^{3+} exists mostly as hydroxy complexes like $FeOH^{2+}$ or $Fe(OH)_2^-$ or as insoluble Fe_2O_3 or $Fe(OH)_3$. In addition, because the oxidation rate of Fe^{2+} with oxygen is proportional to the square of the OH^- concentration [i.e., $(C_{OH^-})^2$], while that with H_2O_2 is only proportional to C_{OH^-}, the formation of Fe^{3+} complexes or hydroxides is favored at high pH and $^{\bullet}OH$ generation through the initiation reaction Eq. (22) or (45) reduces. In this regard, even slower and worse Fenton oxidation of PAHs was achieved at pH 10 or higher than pH 7.[26]

$$H_2O_2 + Fe^{2+} \rightarrow Fe^{3+} + OH^- + {}^{\bullet}OH \quad (22)$$

$$H_2O_2 + Fe(OH)^+ \rightarrow Fe(OH)_2 + 2{}^{\bullet}OH \quad (45)$$

Effect of Fe Source on Fenton's Reagent Oxidation

Grigoropoulou and Philippopoulos reported that ferric salts [$Fe_2(SO_4)_3$ and $FeCl_3$] provided better oxidation rates of phenolic compounds than ferrous ones [$FeSO_4$ and $Fe(NH_4)_2(SO_4)_2$], and the nature of the anions present did not affect the reaction rates.[27] However, the use of iron salts has been limited mainly because of formation of amorphous ferric hydroxide precipitate at neutral and high pH values at the concentrations required for effective Fenton oxidation.

Recent studies have showed that catalytic chemical oxidation can also occur by the interaction of H_2O_2 with iron oxide minerals, such as goethite (α-FeOOH). In model subsurface systems using goethite, Watts et al. reported an enhanced H_2O_2 decomposition and nitrobenzene oxidation at pH 7 than lower pHs.[28] In a heterogeneous Fenton-like reduction, Gurol and Lin reported a lack of the pH effect in the range of 5–9 on chlorobutane oxidation, although the decomposition rate of H_2O_2 was enhanced with increasing pH.[29]

Iron oxide surface can coordinate with protons and hydroxide ions to form different surface groups.[29]

$$\equiv Fe^{III}OH_2^+ \leftrightarrow \equiv Fe^{III}OH + H^+ \quad \left(pK_{a1}^S\right) \quad (46)$$

$$\equiv Fe^{III}OH \leftrightarrow \equiv Fe^{III}O^- + H^+ \quad \left(pK_{a2}^S\right) \quad (47)$$

where $\equiv Fe^{III}OH$ is the surface site of iron oxides, and $\left(pK_{a1}^S\right)$ and $\left(pK_{a2}^S\right)$ are the surface acidity constants for iron oxides. The protonated surface sites of iron oxides (i.e., $\equiv Fe^{III}OH_2^+$) are expected to dominate at pH below $\left(pK_{a1}^S\right)$, whereas the deprotonated surface (i.e., $\equiv Fe^{III}O^-$) would dominate at pH higher than $\left(pK_{a2}^S\right)$. Accordingly, H_2O_2 reacts faster with the negatively charged, deprotonated surface sites than the positively charged, protonated sites. As such, the rate of H_2O_2 decomposition and, consequently, the rate of $^{\bullet}OH$ generation was accelerated at a higher pH at the surface, but this did not necessarily improve compound oxidation because of a lesser number of target compound molecules being held on the surface sites at a higher pH.[29]

From the viewpoint of electron transfer phenomena, the decomposition of H_2O_2 can provide electrons [Eq. (48)]. By gaining these electrons, Fe^{2+} are produced from the reductive dissolution of goethite under acidic conditions [Eq. (49)]. Hydroxyl radicals are therefore produced by the classical Fenton reaction [Eq. (22)].

$$H_2O_2 \rightarrow 2H^+ + O_2 + 2e^- \quad (48)$$

$$\alpha FeOOH + 3H^+ + e^- \rightarrow Fe^{2+} + 3H_2O \quad (49)$$

$$H_2O_2 + Fe^{2+} \rightarrow Fe^{3+} + OH^- + {}^{\bullet}OH \quad (22)$$

The presence of Fe^{2+} can also be attributed to the redox reaction between the intermediate species from the compound oxidation and the surface sites of

the goethite. The following is an example from the 2-chlorophenol (2CP) oxidation.

$$2CP + {}^{\bullet}OH \rightarrow H_2O + {}^{\bullet}R \quad (50)$$

$${}^{\bullet}R + \alpha FeOOH_{(s)} \rightarrow Fe^{2+} + {}^{\bullet}RO + \alpha FeOOH_{(s)} \quad (51)$$

$$H_2O_2 + Fe^{2+} \rightarrow Fe^{3+} + OH^- + {}^{\bullet}OH \quad (22)$$

Therefore, 2CP oxidation reaction is sustained through Eqs. (50), (51), and (22).

Versatile Fenton's Reagent Oxidation

As mentioned previously, $^{\bullet}OH$ is highly reactive and is involved in nonspecific reactions with a wide range of environmental contaminants. These reactions involve moderate to moderately high second-order reaction rate constants between radical and target contaminants and represent a promising option for the remediation of hazardous pollutants.[11]

Superoxide radical, Fe^{2+}, and the hydroperoxide anion (HO_2^-) are potential reducing agents and may facilitate reductive transformations of the contaminants. Therefore, in a treatment system generally perceived to be oxidative, contaminant transformation by reductive pathways may also occur. Indeed, reductive transformation of chloroaliphatic compounds has been reported.[30] However, the specific mechanisms and the environmental conditions in which they are facilitated have not been identified or optimized yet for contaminant transformation.

At many hazardous waste sites, codisposal of contaminants has occurred that require both reductive and oxidative transformations. Under this set of conditions, neither reductive nor oxidative transformations alone are sufficient to achieve the treatment objective. Rather than employing a complex sequence of oxidative and reductive technologies, or vice versa, the Fenton mechanism, if optimized, may be capable of addressing both treatment needs.

CONCLUSIONS

The fundamental mechanisms involved in advanced oxidations and the application of AOPs to the treatment of environmental contaminants have been introduced. As outlined earlier, AOPs are broadly defined as the processes that generate $^{\bullet}OH$ in sufficient quantities to oxidize hazardous contaminants. The generation of $^{\bullet}OH$ is generally accelerated by combining individual (advanced) oxidation processes (e.g., O_3/H_2O_2, UV/H_2O_2, UV/Fenton). Because AOPs hold great promise of oxidizing refractory organic contaminants, extensive research efforts have been conducted in application to the treatment of drinking water, wastewater, and soil and groundwater contaminated with recalcitrant hazardous substances. However, more research is still needed for better understanding and control of the AOPs, which will lead to an improvement of treatment efficiency and costs.

INTRODUCTION

The alkaline Zn/MnO_2 primary battery is one of the important aqueous electrolyte primary battery systems and has been widely and increasingly employed in consumer and industrial markets, since its commercialization in 1960. The total production volume of alkaline Zn-MnO_2 batteries approaches about 12 billion cells in 2001.[1] The alkaline Zn/MnO_2 battery can be regarded as a variant and new development of the traditional Leclanche cell, which consists of Zn anode, MnO_2 cathode and aqueous $NH_4Cl/ZnCl_2$ electrolyte. There are several major changes in the alkaline Zn/MnO_2 battery when compared with the Leclanche cell, which include electrolyte (change from acidic to alkaline, typically, ~30% concentrated KOH solution), the form of the cathode active material [change from chemical manganese dioxide (CMD) to electrolytic manganese dioxide (EMD) with higher purity], the form of the anode active material (change from zinc foil to zinc powder with large surface area), and the cell structure,[2–5] As a result of these changes, the alkaline Zn/MnO_2 battery demonstrates a number of advantages over the Leclanche cell, which include higher energy density, higher rate capability, longer shelf life or lower shelf-discharge rate, better dimensional stability,and others. Although these advantages are gained at the expense of higher initial cost for battery manufacture, they make the alkaline battery an attractive power source to replace at least in part the Leclanche battery. Today, alkaline Zn/MnO_2 batteries are being widely employed for various consumer products and electronic devices, such as toys, camera flash, light flash, radios, portable audio and video devices, and others.

CELL COMPONENTS AND CELL CHEMISTRY

Anode

The anode active material of the alkaline Zn/MnO_2 cell is zinc powder with median particle diameters of about 200 μm. Different from zinc foil used in Leclanche cells, zinc powders provide much higher surface area for the anode, which can carry substantially larger discharge current and, thus, effectively improves the battery rate capability. Actual anode is a compressed mixture of zinc powder, a polymer-based binder (such as polyacrylate or carboxymethyl cellulose) and the gelled electrolyte. The typical anode reaction in the concentrated KOH electrolyte can be described as follows:[6,7]

$$Zn + 4OH^- \rightarrow Zn(OH)_4^{2-} + 2e^- \quad (1)$$

It has been established that the actual anode reaction is more complicated and it takes place through the following mechanism: First, zinc is oxidized and reacts with hydroxide ions OH^- to form a transient intermediate zinc hydroxide $Zn(OH)_2$,[8] and then $Zn(OH)_2$ undergoes a dissolution process in the concentrated alkali solution to form zincate $Zn(OH)_4^{2-}$, namely,

$$Zn + 2OH^- \rightarrow Zn(OH)_2 + 2e^- \quad (2)$$

$$Zn(OH)_2 + 2OH^- \rightarrow Zn(OH)_4^{2-} \quad (3)$$

Although dissolved $Zn(OH)_4^{2-}$ can exist in concentrated KOH solutions at high concentrations, precipitation takes place with continuing discharge once $Zn(OH)_4^{2-}$ in the solution approaches a certain concentration in the alkaline electrolyte. Normally, ZnO is the precipitate in concentrated alkali solutions.[9] It is known that the solubility of ZnO in alkali solutions is only about one half of that of $Zn(OH)_2$,[10] and the overall reaction of the ZnO precipitation is as follows:

$$Zn(OH)_4^{2-} \rightarrow ZnO + H_2O + 2OH^- \quad (4)$$

This reaction takes place through a two-step mechanism: when $Zn(OH)_4^{2-}$ in the solution approaches a critical concentration at zinc surface

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007658

(exceeds saturation with respect to $Zn(OH)_2$), $Zn(OH)_2$ is formed:

$$Zn(OH)_4^{2-} \rightarrow Zn(OH)_2 + 2OH^- \quad (5)$$

Followed by a facile dehydration of $Zn(OH)_2$ in concentrated alkali solutions with ZnO being the precipitate, specially in the case of limited electrolyte:

$$Zn(OH)_2 \rightarrow ZnO + H_2O \quad (6)$$

In less concentrated alkali solutions, the rate of the dehydration decreases, and thus, $Zn(OH)_2$ becomes a main precipitate, especially in the case of excess electrolyte.[11]

Therefore, taking the ZnO precipitation reaction into account, one can describe the overall anode reaction of the alkaline Zn/MnO_2 cell as follows:

$$Zn + 2OH^- \rightarrow ZnO + H_2O + 2e^- \quad (7)$$

Cathode

The cathode active material of the alkaline Zn/MnO_2 battery is the EMD. Among various forms of MnO_2, gamma-MnO_2 is believed to be an active form. The EMD material has higher Mn content in its structure and higher purity, when compared with the CMD employed in Leclanche batteries, which helps reduce gassing and improve battery energy density. The actual cathode of the alkaline Zn/MnO_2 cell consists of EMD, carbon (usually graphite), binder, electrolyte, and selected additives. The cathode reaction at the first stage of the discharge is an one-electron transfer reaction to form manganese oxyhydroxide (MnOOH),[12] which can be described as follows:

$$MnO_2 + H_2O + e^- \rightarrow MnOOH + OH^- \quad (8)$$

At the second stage of the discharge, the produced MnOOH can be further reduced (discharged at a low discharge rate and a lower cut-off voltage) to Mn_3O_4:

$$3MnOOH + e^- \rightarrow Mn_3O_4 + OH^- + H_2O \quad (9)$$

which is equivalent to an additional 0.33 electron reduction per mole MnO_2.

Eq. (8) is a homogeneous proton-transfer reaction because MnOOH forms a solid solution with MnO_2, which results in a characteristic sloping discharge voltage profile for the first stage discharge of the alkaline Zn/MnO_2 cell, as shown in Fig. 1. Eq. (9) is a heterogeneous reaction because Mn_3O_4 has different structure from that of MnOOH, therefore, the voltage profile at this second discharge stage is quite flat. The further reduction of MnOOH is a complex process,

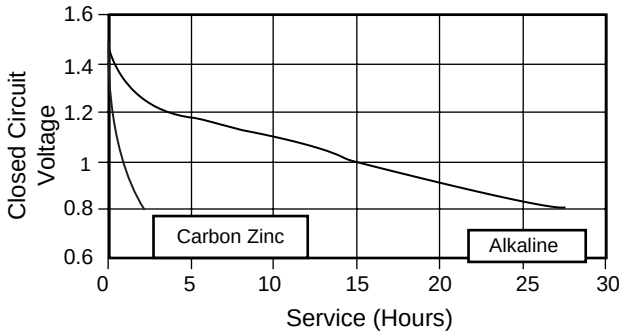

Fig. 1 Typical discharge curves of D size alkaline and carbon-zinc cells at high rate (500 mA). (From Ref.[14].) *(View this art in color at www.dekker.com.)*

and it is believed to place at least in part via the following reaction scheme:

$$MnOOH + H_2O + e^- \rightarrow Mn(OH)_2 + OH^- \quad (10)$$

A dissolution–precipitation mechanism for this reaction was proposed by Kozawa and Yeager.[13]

Cell Reactions

Combining both anode and cathode reactions, the overall cell reaction of the alkaline Zn/MnO_2 battery can be described as follows:

1. At the first stage of the discharge (one electron transfer per mole MnO_2):

$$2MnO_2 + Zn + H_2O = 2MnOOH + ZnO \quad (11)$$

2. The total cell reaction for 1.33 electron transfer per mole MnO_2:

$$3MnO_2 + 2Zn = Mn_3O_4 + 2ZnO \quad (12)$$

The open circuit voltage (OCV) of the alkaline Zn/MnO_2 cell is about 1.55 V at room temperature.

Electrolyte

Concentrated KOH aqueous solution (35–52%) is used for the electrolyte of the alkaline Zn/MnO_2 cell. Certain amount of ZnO is usually added into the electrolyte to suppress gassing process.[14] The electrolyte can be immobilized or gelled with addition of polymer materials, such as carboxymethyl cellulose. The major advantage of this electrolyte is that it has a high ionic conductivity, which helps improve battery rate

capability. In addition, this electrolyte is the source of water that acts as not only the solvent, but also as one of the reactants for the cell reactions, as discussed earlier.

Separator

Most commonly used separator materials for alkaline Zn/MnO_2 batteries are nonwoven polymers, such as cellulose, vinyl polymers, polyolefin, and others. The separator materials must be chemically stable in concentrated KOH solutions and electrochemically stable under both oxidizing and reducing conditions in the cell. In addition to its good electronic insulation, physical strength, and porous structure, good wettability to concentrated KOH solutions is especially crucial to provide a good ionic pathway for the battery operation.

Additives

In order to suppress or inhibit zinc corrosion and hydrogen evolution at zinc anode, a number of additives are selected and used for the anode. Because of its high over potential to the hydrogen evolution reaction, mercury is an effective gassing suppresser and used to be widely employed in alkaline Zn/MnO_2 batteries. In the case of using mercury as anode additive, zinc anode is usually amalgamated to certain level of mercury content. With increasing environmental concern on mercury, manufacturers of alkaline Zn/MnO_2 batteries have reduced mercury usage continuously and have developed mercury-free alkaline Zn/MnO_2 batteries, in which mercury is completely eliminated and the anode is made of zinc alloys with small amount of indium, bismuth, aluminum or calcium, instead. In addition, some organic additives have also been developed for the gassing inhibitor.

CELL CONSTRUCTION AND CELL DESIGN

There are two main cell constructions in consumer and industrial markets for alkaline Zn/MnO_2 batteries. The most common construction is the cylindrical cell, which is most widely being used for various industrial and consumer applications and it is generally categorized as D, C, AA, AAA sizes. Fig. 2 shows the cross-section of the typical construction of cylindrical cells. It is noted that the cylindrical steel can functions as both cathode current collector and the cell container. The inner surface of the can is usually plated with Ni or treated with conductive carbon coatings in order to improve contact with cathode mixture. On the other

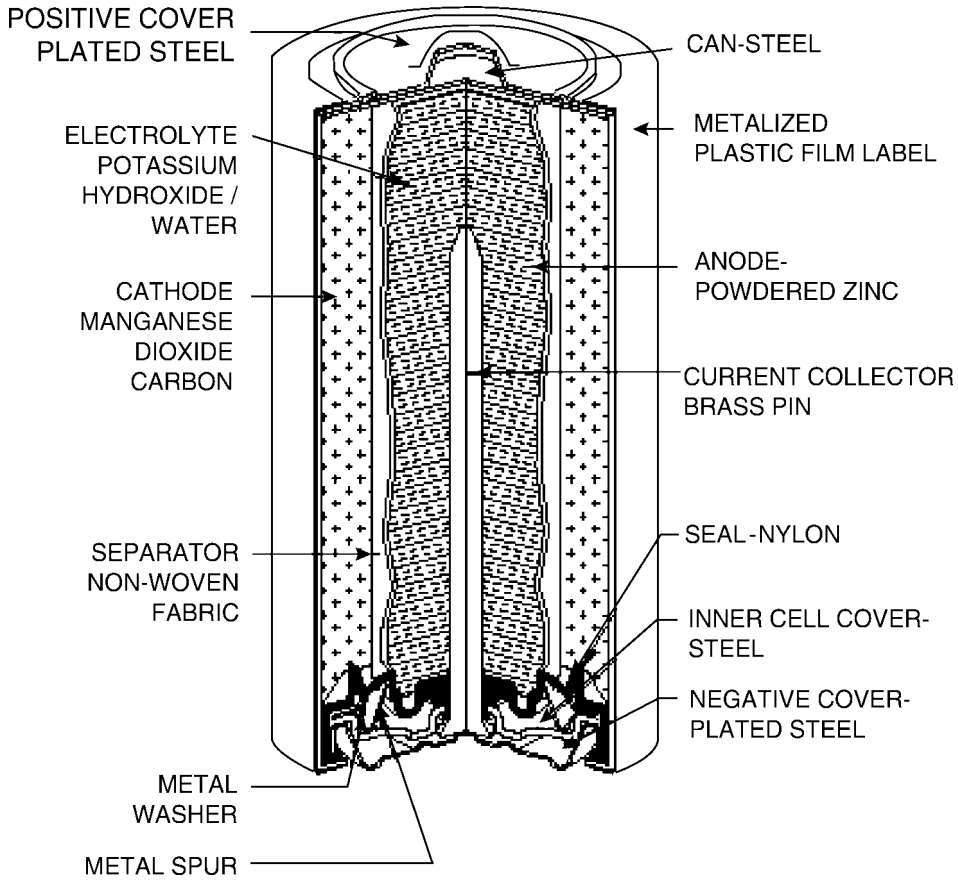

Fig. 2 Typical cell construction of the cylindrical alkaline cell. (From Ref.[14].)

hand, the anode current collector is usually made of brass strip or pins, and it is located in the center of the cylindrical can as shown in Fig. 2. The second major cell construction is the button cell, and its structure is schematically shown in Fig. 3. In this construction, there are two cups (anode cup at the top and cathode cup at the bottom, and both are made of stainless steel), a separator between them, and a thin plastic gasket to provide seal. The button cell structure is usually used for miniature cells that are widely being used as power sources of many low-drain devices such as memory back up, watches, calculators, and others. There are also alkaline Zn/MnO_2 batteries, typically, 9 V batteries, with a rectangular shape.

The alkaline Zn/MnO_2 cell is usually designed as ''anode-limited'' in terms of input capacity, which can prevent hydrogen gassing from the cathode, if the capacity of the cathode is consumed first otherwise.

CELL PERFORMANCE

General Performance Characteristics

The alkaline Zn/MnO_2 battery has a superior performance to the LeClanche battery. Table 1 summarizes a comparison of some characteristics between these two batteries.[15] Compared with Leclanche batteries, alkaline Zn/MnO_2 batteries have significantly higher energy density and power density because of its special chemical and structural characters, as discussed previously. The rate capability of alkaline Zn/MnO_2 batteries is especially superior to LaClanche. A comparison of discharge curves between these two systems is shown in Fig. 1.

Discharge Performance

Depending on applications, alkaline Zn/MnO_2 batteries can be discharged under different conditions, such as constant current, constant resistance, and constant power. In case of the constant current discharge, the capacity utilization can be affected by the applied current, and it decreases with increasing currents, as shown in Fig. 4 for Energizer's alkaline Zn/MnO_2 batteries. From Fig. 4, it is seen that the capacity utilization is relatively stable at low and medium currents, but it decreases rapidly when the current drain rate approaches 100 mA or higher. Besides, the discharge voltage decreases gradually with increasing current drain rates. On the other hand, the discharge capacity is also dependent on the cut-off voltage, with decreasing cut-off voltages, the capacity increases quite significantly, and this feature is also shown in Fig. 4.

Table 1 Typical performance characteristics of the alkaline and the LeClanche batteries

	Alkaline	LeClanche
Typical service capacity	30 mAh to 45 Ah	Several hundred mAh
Energy density, wh/liter	150–440	150
Specific energy, wh/kg	125–225	90
Operating temp. range	−18°C to 55°C	−5°C to 55°C
Storage temp. range	−40°C to 50°C	−40°C to 50°C
Low temp. performance	Good	Poor
Internal resistance	Very low	Moderate
Gassing	Low	Medium
% capacity loss per year at 0°C	1%	3%
% capacity loss per year at 20°C	3%	6%
% capacity loss per year at 40°C	8%	20%

Impact of Temperature on the Discharge

Normal operational temperature range of the alkaline Zn/MnO_2 battery is −18°C − +55°C (0°F–130°F).

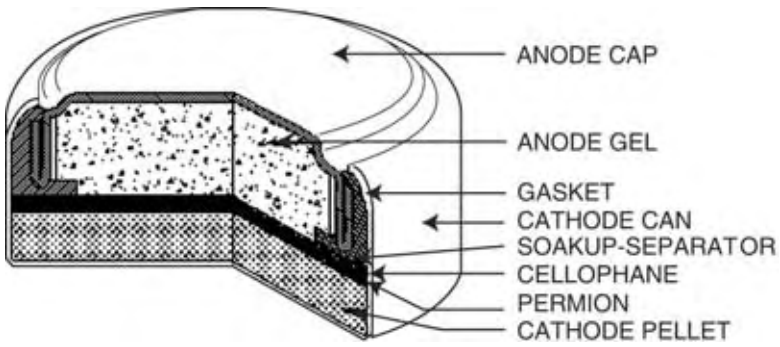

Fig. 3 Typical cell construction of the button alkaline cell. (From Ref.[14].)

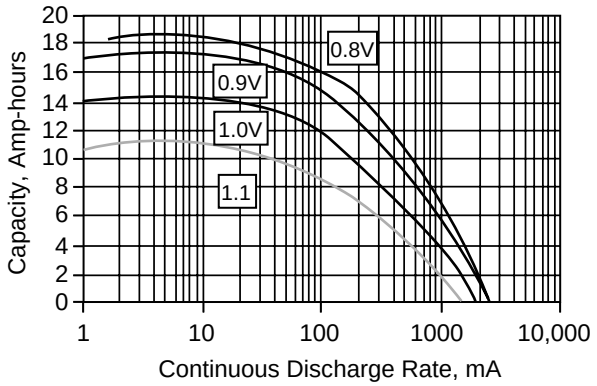

Fig. 4 Effect of drain rate and cut-off voltage on discharge capacity of alkaline cells. (From Ref.[14].) *(View this art in color at www.dekker.com.)*

In general, the capacity utilization decreases with decreasing operation temperatures, as shown in Fig. 5. The discharge voltage also decreases accordingly. Over-high operation temperature may adversely affect the battery sealing and, thus, the battery operational life. On the other hand, over-low operation temperature may lead to a significant increase in the battery internal resistance and, thus, affect discharge performance.

Impact of Temperature on the Self-Discharge and Storage Life

The self-discharge rate of the alkaline Zn/MnO_2 battery increases with increasing storage temperatures. Fig. 6 shows typical results of the impact of storage temperature on the cell capacity retention. The storage temperature of the alkaline Zn/MnO_2 battery is normally ranged in –40°C – +50°C, and it is preferable to store batteries at relatively lower temperatures, which provides a significantly longer storage time period compared with that at higher storage temperatures, while maintaining the same capacity retention, as shown in Fig. 7.

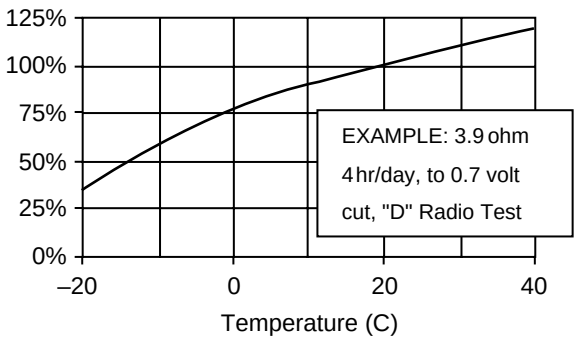

Fig. 5 Effect of temperature on capacity utilization of D size alkaline cells (3.9 ohm load). (From Ref.[14].)

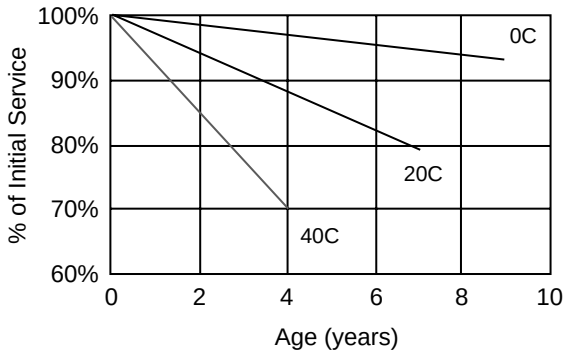

Fig. 6 Effect of storage temperature and time duration on relative service time of alkaline cells. (From Ref.[14].) *(View this art in color at www.dekker.com.)*

RECHARGEABLE ALKALINE Zn/MnO_2 BATTERY

The rechargeable (or reusable) alkaline Zn/MnO_2 battery has been mass-produced by Rayovac, since 1993. The technology was licensed from Kordesh's breakthrough work in late 1970s to 1980s, and even in the earlier work, which can be traced back to the development devoted by Union Carbide in 1970s. The rechargeable alkaline Zn/MnO_2 battery has the same cell reaction as that of the primary alkaline Zn/MnO_2 battery, described by Eq. (11) above, but the reaction must be restricted strictly to the one-electron transfer stage (the discharge cut-off voltage $\geq$0.9 V) to ensure rechargeability of the cathode MnO_2 material. The rechargeable alkaline Zn/MnO_2 battery has similar cell composition as that of the primary alkaline Zn/MnO_2 battery, namely, EMD cathode, zinc powder anode and concentrated KOH electrolyte, but it has a stronger two- or multi-layer separator to prevent internal short circuit caused by zinc dendrites, which may be formed during the charging process of the battery. The rechargeable alkaline Zn/MnO_2 battery has similar cell construction as that of the primary alkaline Zn/MnO_2 battery too, the most common cell construction is the cylindrical AA and AAA type.

The rechargeable alkaline Zn/MnO_2 battery has a normal cycle life of about 25 cycles at 100% DOD (depth of discharge), and the cycle life is much longer if shallow charge-discharge cycles (low DOD) are applied. The rate capability of the rechargeable Zn/MnO_2 battery is lower than its primary counterpart mainly because of its higher internal resistance. In general, this battery can be charged with constant current, constant voltage or pulse current modes, and the overcharge must be avoided. Compared with the rechargeable Ni–Cd batteries, the rechargeable alkaline Zn/MnO_2 battery has a number of advantages, such as lack of toxic and heavy metals, low cost,

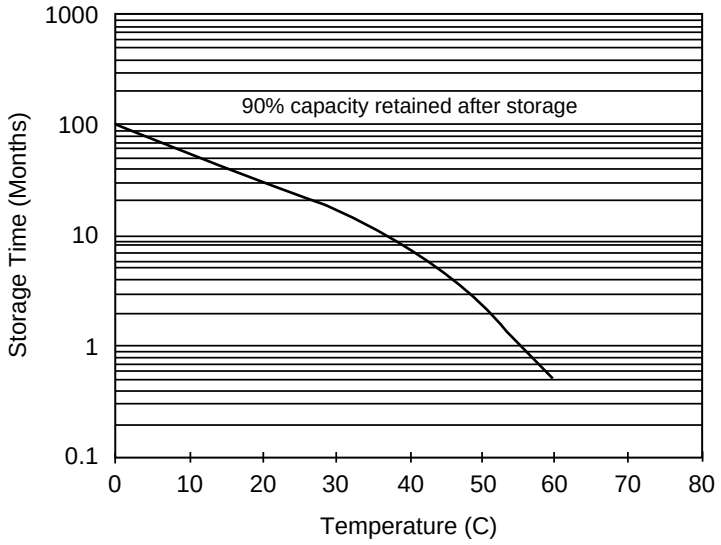

Fig. 7 Relationship between storage temperature and storage time period to keep 90% capacity retention for alkaline cells. (From Ref.[14].)

long shelf life, and lack of the memory effect. The main disadvantages of the rechargeable Zn/MnO_2 battery are its short cycle life and relatively low drain rate.

CONCLUSIONS

The alkaline Zn/MnO_2 battery is one of well-developed battery systems in the industrial and consumer markets, and is still undergoing continuous developments to improve its performance. The developments include: the improvement in active materials and its purity to enhance battery energy capacity; the improvement in the cell structure and cell composition to enhance battery power density; the improvement in sealing materials and the sealing structure to enhance the battery storage and operational life, and to further prevent leakage.

Alkylation Processes to Produce High-Quality Gasolines

A

Lyle F. Albright
School of Chemical Engineering, Purdue University, West Lafayette, Indiana, U.S.A.

James M. Ryan
Ryan Consulting, Inc., Fort Myers, Florida, U.S.A.

INTRODUCTION

Isobutane is alkylated with C_3–C_5 olefins to produce the highest-quality and cleanest-burning gasolines. More than 1.1 million barrels of alkylate/day are produced in the United States (P. Pyror, personal communication). The amounts of alkylate produced in the remainder of the world are considerably less, but they are increasing at a significant rate. In the United States, about 11–13% of the total gasoline pool is alkylate. This percentage depends on the location in the United States and on the season. Alkylate production will likely increase substantially in the future.

Alkylation was first practiced for gasoline production about 60 yr ago. At that time, most of the alkylate was used as fuel for the airplanes used in World War II. Four quite distinct reactors were developed in which isobutane and olefins were introduced as liquids to the reactor. In the reactor, the hydrocarbon liquids are contacted with either liquid sulfuric acid or liquid hydrofluoric acid (HF), which acts as a catalyst. Dispersions of these two relatively immiscible liquids are formed. The alkylate product formed is a mixture of mainly C_5–C_{16} isoparaffins. Alkylate products often have research octane numbers (RONs) varying from 93 to 98 (the motor octane numbers tend to be two to three units lower).

The alkylates and by-products produced using sulfuric acid and HF have compositions that differ in several respects, as discussed later. About 50 yr ago, considerably more alkylate was produced using sulfuric acid. For the next 30–35 yr, the relative importance of the two processes using HF as catalyst increased until essentially equal amounts of alkylate were produced with each acid. In the late 1980s, however, two events occurred that indicated safety concerns with HF needed to be re-examined. First tests were conducted in which 1000 gallons of liquid HF were ejected into the atmosphere.[1] An aerosol cloud formed that contained lethal levels of HF at ground level for 5–6 mi downwind. Alkylation units at the time sometimes had much larger liquid HF inventories. Second, a major release of gaseous HF occurred in an American refinery as the result of an accident. No human fatalities occurred probably because the release was gaseous HF and no aerosol cloud formed. Many residents living within several blocks of the refinery, however, required medical care. Liquid HF often results in serious skin burns and even damage to bones. Also in the late 1980s, two workers in an alkylation plant were killed because of an HF release. Since that time, no grassroot alkylation plants have been built in the United States, but several with sulfuric acid have been.

In current processes that use either sulfuric acid or HF, isobutane in large excess and olefins are introduced as liquids into the reactor. After completion of the reactions, the liquid–liquid dispersions are separated by decanting. The alkylate product is separated by distillation or stripping from the unreacted isobutane, which is recirculated to the reactor. This entry reviews the chemistry, physicochemical phenomena, current processes, and finally suggests methods to improve significantly the alkylation process.

CHEMISTRY OF ALKYLATION

Production of Alkylate: The basic chemistry that explains the wide range of qualities (or octane numbers), by-products and side reactions, and yields has been reported.[2–5] The following two reactions have often been used to represent the overall process:

$$\textit{tert}\text{-butyl cation } (t\text{-}C_4H_9^+) + \text{isobutylene (or a 2-butene)} \rightarrow \text{trimethylpentyl cation } (TMP^+) \quad (1)$$

There are four different TMP^+s.

$$TMP^+ + \text{isobutane} \rightarrow \text{trimethylpentane (TMP)} + t\text{-}C_4H_9^+ \quad (2)$$

The overall chemistry is much more complicated, however, and these two equations have been misinterpreted. For example, they suggest that isobutane and the olefins react by a chain sequence. Olefins and, especially, isobutylene and i-C_5 olefins, react instead prior to and more rapidly than isobutane.[6] Although

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120015543

isobutane contributes the hydride ion (H^-) that converts TMP^+ (and other isoalkyl cations) to TMP (and C_5–C_{16} isoparaffins), the transfer is not by the simple chemistry of Eq. (2).[7] Extensive experimental evidence indicates that the H^- from isobutane is predominately transferred first to conjunct polymers dissolved in sulfuric acid or HF; then the H^- is transferred to TMP^+ or other isoalkyl cations located at or at least near the interface between the acid and hydrocarbon liquid phases in the dispersion. Isobutane and olefins often react on essentially an equimolar basis, but as indicated later more moles of isobutane often react than those of olefins, especially when HF is the catalyst.[8] The above two equations fail to explain the C_8 isoparaffins produced with 1-butene. When 1-butene reacts with a t-$C_4H_9^+$, a dimethylhexyl cation (DMH^+) is produced that is then converted to a dimethylhexane (DMH) isomer. When HF is used as the catalyst, DMHs are indeed major products. With sulfuric acid, TMPs are, however, the major C_8 family produced. The above equations also provide no explanation for the production of lighter and heavier isoparaffins.

Four reaction sequences (mechanisms) actually occur to produce C_5–C_{16} isoparaffins, as discussed next.[2,7,8]

Mechanism 1: This mechanism is the only true alkylation sequence. Only C_7, C_8, or C_9 isoparaffins are produced when isobutane is alkylated with propylene, C_4 olefins (four isomers), or C_5 olefins (six isomers), respectively. Important intermediates formed include isoalkyl sulfates because sulfuric acid reacts with much of either propylene, n-C_4 olefins, or n-C_5 olefins. Hydrofluoric acid also reacts but to a much reduced extent with n-olefins producing isoalkyl fluorides. When n-C_4 olefins are used forming sec-butyl sulfates (or sec-butyl fluoride), the sulfates (or fluorides) react at preferred operating conditions with isobutane to form TMPs in high yields with the regeneration of sulfuric acid (or HF). The intermediate sec-butyl sulfates explain why both 2-butenes and 1-butene produce essentially identical high-quality alkylates when sulfuric acid is the catalyst. For alkylations using HF, considerably lower-quality alkylates containing more DMHs are produced when 1-butene is part of the olefin feed.

Much smaller fractions of isobutylene and i-C_5 olefins react via mechanism 1 as compared to n-olefins. *Iso*-olefins instead react in substantial amounts via mechanisms 2 and 3.

Mechanisms 2 and 3: These two mechanisms are related in that two or more olefins react initially with a single t-$C_4H_9^+$ forming i-C_{10}^+ to i-C_{20}^+s. For mechanism 3, a H^- (generally from conjunct polymers) transfers to the heavy cations to produce C_{10}–C_{20} (and more generally C_{10}–C_{16}) isoparaffins. With mechanism 2, which is always of greater importance than mechanism 3, the heavy cation fragments, because they are relatively unstable, form i-C_4 to i-C_{16} cations and olefins. These latter cations and olefins are converted to i-C_4 to i-C_{16} isoparaffins after suitable H^- transfer, as already discussed, plus H^+ transfer (from the acid). Three points need to be emphasized: first, light isoparaffins such as i-C_5 to i-C_7s are produced (this is frequently the only way such isoparaffins are produced when pure C_4 olefins are used); second, some isobutane is also produced, as has been indicated by tagged carbon research; third, production of DMH is relatively high, which explains the rather high concentrations produced when isobutylene is the olefin feed.[4]

Mechanism 4: This mechanism is always of major importance when HF is the catalyst, but is generally of little or no importance with sulfuric acid. The reaction sequence is complicated, but the overall reaction is often reported in an oversimplified manner as follows:[9]

$$\text{2-isobutane} + n\text{-olefin} \rightarrow n\text{-paraffin} + i\text{-}C_8H_{18} \quad (3)$$

Several points need to be emphasized. First, the i-C_8H_{18} (frequently indicated in the literature as TMP) is really a mixture of C_5–C_{16} isoparaffins, often with RON values in the 93–94 range. This mixture (or alkylate) is formed basically by mechanism 2 reactions. Second, when n-olefins (propylene, n-butenes, and n-pentenes) are used, the light n-paraffins formed are propane, n-butane, or n-pentane, respectively; none are suitable in the gasoline pool. Third, isobutane consumption per production of a given quantity of alkylate is often increased by 6–10% when HF is employed because of the importance of mechanism 4, as compared to little or most likely no importance for alkylations with sulfuric acid.[8] Fourth, C_5 olefins are not usually used in the feedstocks when HF is the catalyst because of the large amounts of isopentane and n-pentane produced; further, isobutane consumption increases.

With HF as catalyst, mechanism 4 can be promoted by higher temperatures and also higher isobutane/olefin ratios.[9] Plant operators using HF often deliberately promote mechanism 4 for alkylations using propylene or 1-butene to produce higher-quality alkylates and more TMPs. Operating costs, however, increase because of increased isobutane consumption and higher costs to recover and recycle the additional unreacted isobutane.

Conjunct Polymer Formation: The polymers (also called acid-soluble oils or red oil) dissolve in the acid phase (sulfuric acid and HF). They have a hydrogen/carbon atomic ratio (H/C) of about 1.75 and a molecular weight of 270–325.[10] They contain numerous –C=C– bonds, which react to a significant extent with sulfuric acid to produce conjunct acid sulfates or with HF, conjunct polymer fluorides. These sulfates (or fluorides)

serve as surfactants and some collect at the liquid–liquid interfaces. As they contain numerous tertiary C–H bonds, they are the main source of H^-s involved in the production of alkylate. Laboratory evidence indicates that these polymers are formed mainly from olefins; pseudoalkylates are also simultaneously produced.[11]

Pseudoalkylate: Using C_4 olefins as an example, *sec*-butyl acid sulfates are first formed; they dissolve in the sulfuric acid phase.[11] When the resulting acid mixture is allowed to warm to room temperature, almost identical amounts of conjunct polymers and pseudoalkylates are produced within several minutes. The following two simplified equations plus carbon and hydrogen balances support this finding:

$$n\text{-}C_4H_8(H/C = 2) + \text{sulfuric acid} \rightarrow \textit{sec}\text{-butyl acid sulfate} \quad (4)$$

$$\textit{sec}\text{-butyl acid sulfate} \rightarrow \text{conjunct polymers sulfate } (H/C = 1.75) + \text{pseudoalkylate (H/C ratio of 2.25)} \quad (5)$$

The RON values of the pseudoalkylate are in the low 80s. Both conjunct polymers and pseudoalkylate are also produced when light olefins are bubbled through sulfuric acid.

Hydrocarbon layers frequently form above used acids in storage tanks. This layer is with high probability partly, if not mainly, a pseudoalkylate produced when isoalkyl acid sulfates dissolved in the used acid decompose. In at least two storage tanks, serious explosions of hydrocarbon–air mixtures have occurred.[12,13]

Decomposition of TMPs and Other Isoparaffins: TMPs and other isoparaffins in alkylates contain tertiary C–H bonds, which permit degradation reactions. First, sulfuric acid acts as an oxidant to start a series of reactions that convert TMP into a mixture of C_4–C_{16} isoparaffins.[14] Second, because of their tertiary C–H bonds, TMPs react (are actually alkylated) with C_3–C_5 olefins; mechanism 2-type reactions are predominant. Both types of reactions lower the quality and the quantity of the alkylate.

Oxidation Reactions in Used Sulfuric Acid: Sulfuric acid reacts with conjunct polymer dissolved in the acid.[15] Sulfur dioxide and water are produced. Such oxidation has occurred on occasion with large releases of sulfur dioxide from storage tanks or railroad tank cars, especially in summer when the acid heats up.

PHYSICOCHEMICAL PHENOMENA RELATIVE TO ALKYLATION

The interfacial area between the acid/hydrocarbon dispersions is the location at which most, if not all, of the C_5–C_{16} isoparaffins are produced.[5,16,17] In industrial units, the preferred dispersions are acid-continuous as compared to hydrocarbon-continuous. Albright and am Ende found at least with sulfuric acid that acid-continuous dispersions tend to have significantly larger interfacial areas.[18] Some important experimental findings related to physicochemical phenomena are discussed next.

Increased levels of agitation that result in increased interfacial areas were found in alkylation experiments using 2-butenes and sulfuric acid to increase the RON value; in one comparison, the RON increased from 86.2 at 1000 rpm to 98.7 at 4000 rpm.[19] Increased agitation also increases the kinetics of alkylation. In one case, the optimum residence time of reactants in the reactor was decreased to about 5 min. In commercial reactors, residence times are often in the 20–30 min range. In commercial reactors using HF as the catalyst, the alkylation reactions are often completed in 10–15 sec or even less; two factors that promote these fast reactions are higher operating temperatures and especially much larger interfacial areas.[3]

In addition to agitation, the interfacial areas are significantly affected by the following: acid/hydrocarbon ratio, acid composition (and especially the amounts of dissolved conjunct polymers), and temperature.[3,18] Conjunct polymers are surfactants that collect in appreciable concentrations at the interface. Here, they act as a reservoir of H^-s in the transfer steps from isobutane or other isoparaffins to the i-C_5 to i-C_{16} cations. Conjunct polymers also have a major effect on the viscosity and other physical properties of the acid phase. In the alkylation reactor, the preferred sulfuric acid and HF phases contain appreciable amounts of conjunct polymers; optimum amounts result in higher RON values, higher yields, less by-products, etc.

At least with sulfuric acid, key intermediates transfer from and across the interfaces. For example, *sec*-butyl acid sulfate transfers into the acid phase, whereas di-*sec*-butyl sulfate transfers into and dissolves mainly in the hydrocarbon phase. No information is available on the fraction of isoalkyl fluorides in the two phases. This fraction likely depends on the amount of conjunct polymers in the HF phase.

In one reactor, the sulfuric acid/hydrocarbon ratio in the dispersion varied substantially with location.[20] Variations occurred depending on the distance from the agitation impeller and the height. Clearly, droplets were coalescing and fragmenting in the reactor; in addition, partial separation of the two phases plus later redistribution was occurring. Obviously, the average residence times of the acid and of the hydrocarbon phase in commercial reactors often differ significantly. In most, if not all, commercial reactions, the average residence time of the acid phase is greater.

Because the main alkylation reactions occur at the interface, both isobutane and olefins in the dispersed droplets are transferred to the interface, and the resulting C_5–C_{16} isoparaffins are transferred from the interface back into the droplet.[5,16,17] Experimental data indicate that such transfer steps are in part at least rate controlling steps. In any case, each droplet acts as a different reaction zone (basically a separate mini-reactor). As droplets of different compositions and sizes occur in all commercial reactors, the alkylation results differ in various droplets, i.e., different alkylates, RONs, yields, amounts of by-products, etc. Improved results would occur if alkylation reactors could be designed and operated so that all the alkylate was produced only at optimal conditions.

FEEDSTREAMS FOR ALKYLATION

Isobutane and light olefins are the desired hydrocarbon feeds. Unfortunately, impurities such as acetylenes, dienes, sulfur- and oxygen-containing hydrocarbons, cyclopentene, and water are also often present. Purification of the feeds is expensive, but is sometimes cost-effective as a means of reducing the buildup in the acids of conjunct polymers. Dry hydrocarbon feeds are preferred, especially with HF. The water transfers to the HF and is a concern relative to metal corrosion. Solid adsorbents are often used for drying of feedstocks.

The feed ratios of isobutane to olefins with sulfuric acid tend to be lower, such as 6 : 1 to 8 : 1. When HF is used, the ratios are often 10 : 1 to 15 : 1; higher ratios then promote both mechanisms 1 and 4. Higher ratios, however, increase operating costs substantially with regard to the recovery and recycling of the unreacted isobutane. Isopentane, which is also readily alkylated, is sometimes deliberately added to supplement isobutane. Much lower-quality alkylates are produced, especially when propylene is a feed olefin, in which case, dimethylhexanes are produced in large amounts.

The compositions (or concentrations) of both the feed acid and the acid present in the reactor are of major importance. The feed sulfuric acids are frequently in the 98.5–99.5% range. The more concentrated feed acid results in the production of more alkylate per unit weight of feed acid.[21] The preferred acid concentration in the reactor varies from about 90% to 95% depending especially on the composition of the olefin feeds. Stronger acids are preferred with propylene-rich olefins, whereas the lower concentrations are preferred with C_5-rich olefins. Less information is available with HF catalysts. Eastman et al. report the HF compositions in a Phillips reactor as 82–85.5% HF, 8–12% acid-soluble oils (or conjunct polymers), and 0.1% water.[22] The unaccounted material in this analysis is probably HF that has reacted to form conjunct polymer fluorides.

In commercial reactors, the acid phase is recirculated numerous times. A small amount of the used acid is removed and sent to the regeneration unit. A similar amount of feed acid is added to the recycle stream. At least with sulfuric acid, major reductions of acid consumption can be obtained when two and preferably more reactors are used in a refinery. Proper arrangements of the acid flows, method of adding different olefins, and adjusting operating conditions in the different reactors can often result in the reduction of acid composition from about 0.5–0.8 to 0.25–0.3 lb/gal.

REACTORS USING SULFURIC ACID

Two types of reactors have been used for over 50 yr. Modifications have occurred with time.

Stratco Reactors: These reactors designed by Stratco, Inc. produce about 34% of the alkylate produced worldwide (P. Pyror, personal communication). In 2003, Stratco was purchased by E.I. du Pont de Nemours, Inc. A reactor, often called a Contactor, is a horizontal cylindrical vessel, as shown in Fig. 1, with the following features.[21,23] An impeller at one end recirculates the acid/hydrocarbon dispersion many times (on average) over a U-tube bundle to regulate the temperature of the dispersion at about 5–10°C. A cylindrical circulation shell located in the reactor provides an annular space so that the dispersion flows from one end of the reactor to the other, where it makes a 180° turn and flows back over the tube bundle.

Injection devices are provided at or near the eye of the impeller for the hydrocarbon feed mixture of isobutane and olefins and for the acid feed (mostly recycled acid). A small fraction (mix to settler or decanter) of the dispersion flowing in the annular region is removed from the reactor through the outlet line positioned on top at the other end (relative to the impeller). The average time that the dispersion remains in the reactor is about 20 min, but obviously there is a wide range of times.

After the dispersion leaving the reactor is separated in the settler (decanter), the liquid hydrocarbon product stream is partially flashed, forming a vapor phase, mainly isobutane. The remaining liquid is hence cooled, and it is used as the coolant in the tube bundle of the reactor. As heat is transferred there, more hydrocarbons vaporize, forming a liquid–gas mixture. Obviously, temperature gradients occur on both sides of the tube bundle as a function of reactor length. Heat transfer (and temperature control) is an important design consideration in contactors.

In addition to temperature variations in the reactor, there are variations throughout the reactor in the composition and size of dispersed droplets, and also different acid/hydrocarbon ratios. Stratco has rather

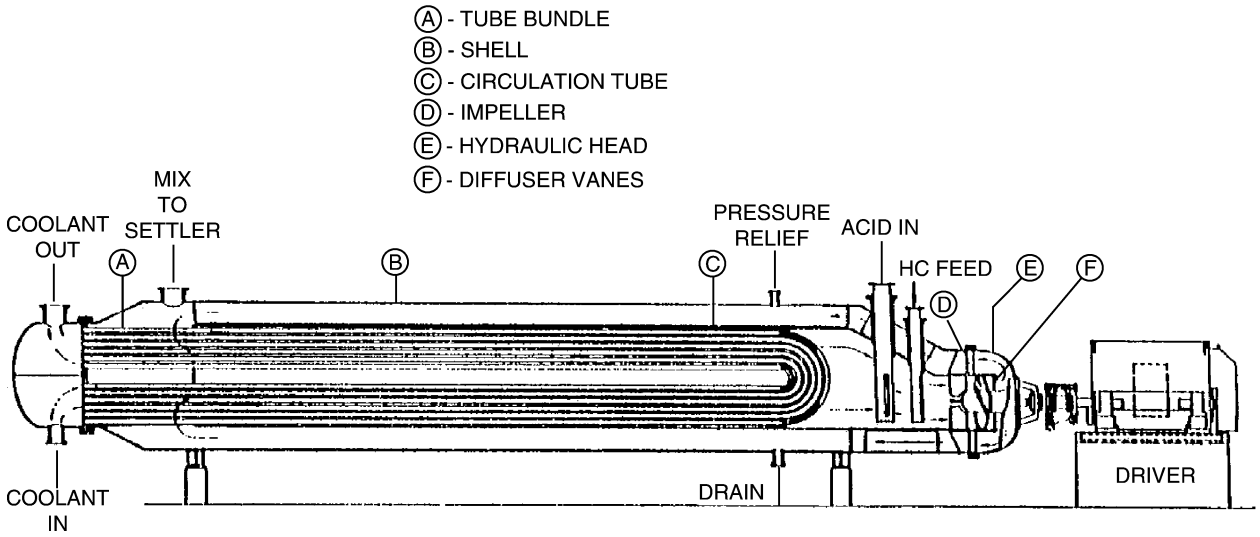

Fig. 1 Contactor designed by Stratco, Inc.: employs sulfuric acid as catalyst.

recently made several modifications including improved and bigger heat transfer systems, improved injectors and impellers, and lowering the impeller to below the axis of the reactor to obtain more uniform dispersions. More modern reactors can provide the following advantages (or some combination): lower operating temperatures, improved quality alkylates, lower acid consumption, larger production capacities, and/or lower compressor duty (or less refrigeration costs).

The emulsion leaving the reactor enters a settler. Residence times there often average up to 60 min to permit separation of the two liquid phases. Most of the acid phase is recycled to the reactor, being injected near the eye of the impeller. The hydrocarbon phase collects at the top of the decanter; it contains unreacted isobutane, alkylate mixture, often some light *n*-paraffins, plus small amounts of di-isoalkyl sulfates. The sulfates must be removed to prevent corrosion problems in the distillation columns. Caustic washes are often employed to separate the sulfates; they result in destruction of the sulfates. Acid washes have the advantage that most of the sulfates eventually react to reform sulfuric acid, which is reused, and to produce additional alkylate product.

Cascade Reactors: At least two types of these reactors and/or operating conditions are currently employed. Units designed by M.W. Kellogg were built until the mid-1960s, and some still produce about 8% of the total alkylate (P. Pyror, personal communication). Exxon-Mobil now designs units, as shown in Fig. 2, which account for about 6% of all alkylate produced worldwide. They refer to their units as ''stirred autorefrigerated alkylation reactors.'' At least one refinery claims their cascade reactors differ from the above two.

All cascade reactors are relatively long cylindrical vessels positioned horizontally. Reactors are partitioned into 4–10 reactor compartments; Fig. 2 shows 10 compartments. Each compartment contains an agitator, which produces and maintains the acid/hydrocarbon dispersion that is circulated repeatedly. Part of the dispersion in a compartment flows over the vertical plate, separating the compartments; this overflow enters the next compartment. The acid to the cascade reactor enters the first compartment, as does part of the isobutane feed (designated in Fig. 2 as recycle refrigerant). The feed isobutane, recycled isobutane from the distillation section, and all of the olefins are premixed, and essentially identical amounts are jetted into each compartment, probably into the eye of the impeller. Details of the design of the impeller, injection device, etc. have not been reported by Exxon-Mobil. The level of agitation is, however, thought to be less than that in Stratco units, based on agitation energy requirements.[24]

In each compartment, the pressure is regulated so that some of the dispersed hydrocarbons vaporize. Light hydrocarbons and especially isobutane vaporize; this vaporization removes most but not all of the following: heats of reaction plus energy provided by agitation. Ackerman et al. have reported that there is a temperature increase from the first to the last compartment; simultaneously, the quality of the alkylate decreases.[24] The vaporization, with high certainty, occurs mainly in those droplets positioned at or near the top surface of the dispersion, where the pressure is lowest. Hence, many of the droplets that pass over the vertical plate from one compartment to the next have experienced vaporization (and have reduced concentrations of isobutane).

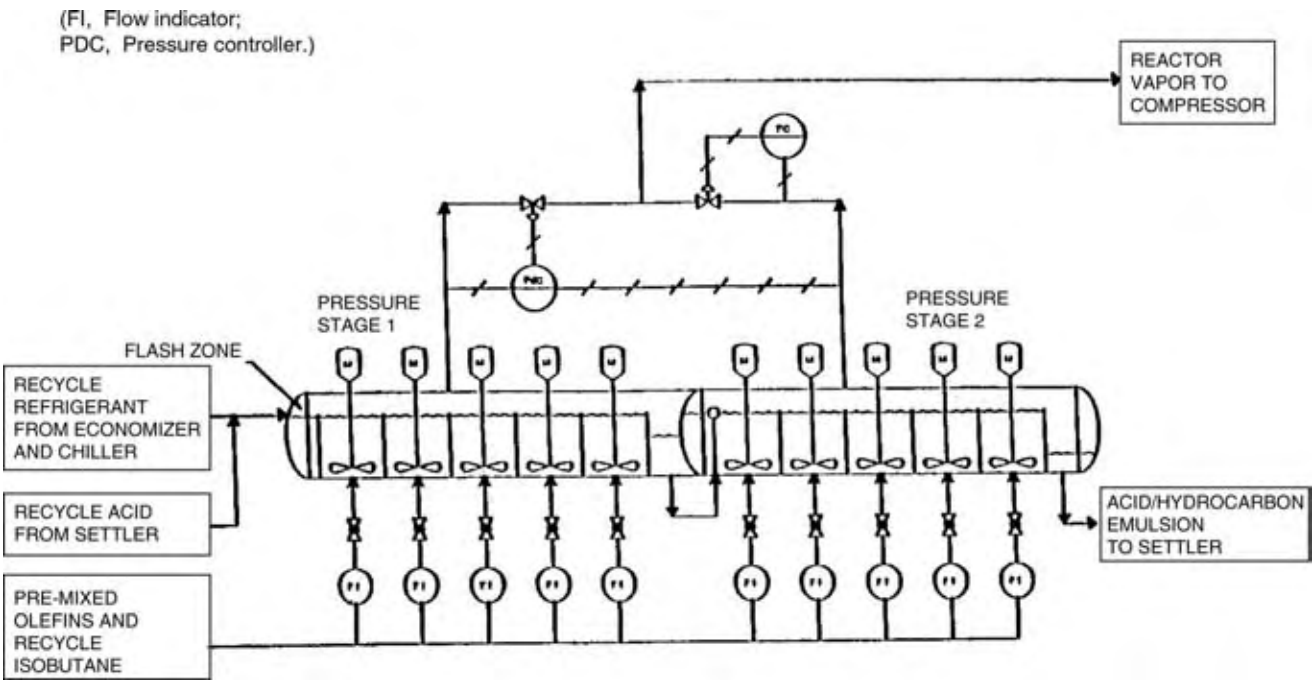

Fig. 2 Reactor designed by Exxon Research and Engineering Co.: employs sulfuric acid as catalyst.

The compositions and sizes of droplets obviously vary greatly in a given compartment. In the first reactor compartment, droplets containing all of the following occur: relatively pure isobutane, feed mixture of isobutane and olefins, hydrocarbon mixture of unreacted isobutane and alkylate, hydrocarbon mixture of alkylate plus the remaining isobutane after vaporization, and combinations of the above. Coalescing and fragmentation of droplets obviously occur as the dispersion flows toward and into the eye of the impeller and as the dispersion flows away from the impeller.[20] There are also significant differences in the droplets from the first to the last compartment. Since residence times in cascade reactors are often as high as 30 min, a small but significant amount of TMPs degrade in cascade reactors, probably a higher fraction than in Stratco reactors.[21]

The gases (mainly isobutane) leaving the top of cascade reactors are compressed, condensed, and then cooled by partial vaporization; the resulting liquid isobutane (refrigerant) is recycled to the reactor. The dispersion leaving the reactor is separated by decanting. Most of the acid is then recycled to the reactor.

A comparison of Stratco and Cascade reactors indicates the following differences:

1. More isobutane needs to be flashed in Stratco reactors to provide sufficient temperature differences for adequate heat transfer. Compressor costs in Stratco units tend to be higher. Less isobutane, however, generally needs to be separated by distillation in Stratco processes; hence, the energy costs for distillation tend to be lower.
2. Stratco reactors are generally smaller, often producing 3500–4500 barrels of alkylate/day. Cascade reactors tend to be larger, often producing 10,000 barrels/day or even greater. Plant operators often think large reactors reduce operating costs per unit amount of alkylate produced. But as already discussed earlier, combinations of two or more small reactors often result in much reduced acid consumption plus improved quality alkylates.[25,26] Such arrangements can result in significant economic benefits.

REACTORS USING HF

The reactors designed by Phillips Petroleum (now Conoco–Phillips) and UOP produce about 32% and 20%, respectively, of all alkylate produced worldwide (P. Pyror, personal communication). The HF/hydrocarbon dispersions in these reactors have much larger interfacial areas (probably by a factor of about 10) as compared to areas in sulfuric acid/hydrocarbon dispersions.[3] This is a major reason why the kinetics of alkylation is much higher with HF.

Conoco–Phillips Reactor: This reactor is basically a vertical tube in which the HF/hydrocarbon dispersion

flows upward, as shown in Fig. 3. Most of the reactions occur in the bottom section of the reactor, within several seconds, as indicated by temperature increases there of several degrees Celsius.

When the feed mixture of isobutane and olefins is introduced in the liquid HF, it provides sufficient energy so that the resulting liquid–liquid dispersion flows upward in the reactor riser and exits into a settler (decanter). The hydrocarbon product stream collects in the top portion of the decanter. The HF phase collects in the bottom of the settler and then flows downward because of gravity through the reactor standpipe to heat exchangers. Here, the HF is cooled using cooling water as the coolant. An advantage of this process is no pump is needed to recirculate the liquid HF. The reactor temperatures probably vary from 30°C to 40°C depending to some extent on the temperature of the available cooling water. The higher temperatures likely occur during summer or in the hotter regions of the country.

UOP Reactors: These reactors are vertical cylindrical vessels with cooling coils inside. The HF flows upward and mixtures of isobutane and olefins are injected at several different heights to form HF-continuous dispersions. Once again the reactions occur within several seconds and at about 30°C to 40°C. A pump is needed in this process to maintain the flow of liquid HF. Such a pump has resulted in HF leaks and must be handled with care.

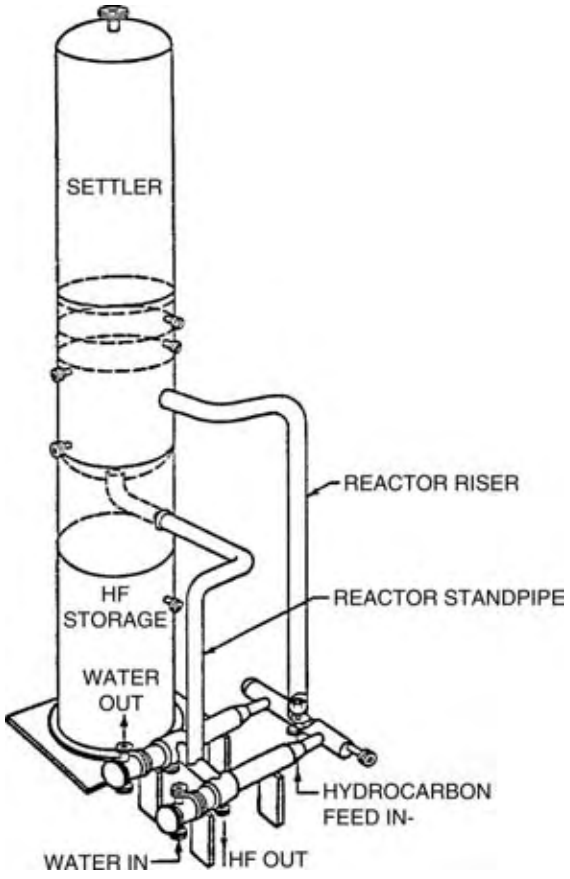

Fig. 3 Reactor designed by Phillips Petroleum Co.; employs HF as catalyst.

Both Phillips and UOP have employed additives dissolved in the liquid HF. The objective is to reduce the tendency to form, as a result of an accident, highly toxic aerosol clouds. Claims have been made that the additives reduce the amount of the HF that enters such a cloud by 65–90%. Although such a reduction is obviously important, no information is available on the hazards that still exist or how far toxic levels of HF might still be transferred. The additives eventually need to be separated, recovered, and recycled. The concentrations of the additives in the HF have apparently not been reported in any detail. Additives increase operating costs significantly. Somewhat high-quality alkylates are, however, produced in at least some cases when additives are used. Conoco–Phillips use sulfolane as their additive while UOP has tested both pyridine and picolene. These additives likely form hydrogen bonds with HF, and also affect the interfacial areas of the dispersions.

Water sprays have also been proposed to reduce HF releases in case of an accident. How to direct the spray at the location of the leak, designing the spray to remain operative after an accident, and providing sufficient water are all concerns. Numerous refineries have also installed ''protected'' storage facilities for feed HF and used HF to minimize potential leaks in or near the refinery.

SEPARATION AND RECOVERY OF ALKYLATE

Two to four distillation columns are usually required to separate the liquid hydrocarbon product stream that contains unreacted isobutane, alkylate mixture, *n*-butane, and propane. The major column is designated as the deisobutanizer (DIB) column. Often this column separates the isobutane as the overhead stream, the alkylate as the bottom stream, and a *n*-butane rich sidestream. In many plants, the feed isobutane is also fed to the DIB to remove most of the *n*-butane. A second column is generally needed to remove propane from the isobutane. Sometimes a third column is provided to purify further the *n*-butane sidestream and to recover more isobutane. In an alternate arrangement, the bottom stream of the DIB column is a mixture of alkylate and *n*-butane. This mixture is then separated in another column.

Alkylation processes using HF require in general larger columns, which also have significantly higher operating costs. First, they operate in general with

substantially higher ratios of isobutane to olefins. Hence, more isobutane is vaporized and separated, which necessitates higher energy costs. Second, some HF is dissolved in the hydrocarbon phase (or is present as isoalkyl fluorides). During distillation, HF is freed and is recovered as an immiscible liquid. The presence of HF necessitated safety provisions to prevent HF releases. Third, as propane and *n*-butane are produced as by-products of mechanism 4, more of both needs to be separated.

In HF-type processes, used HF (containing dissolved conjunct polymers) is separated by distillation to obtain relatively pure liquid HF and conjunct polymers. This column is relatively small and with much lower energy requirements as compared to the DIB column. Safety provisions are important since relatively pure HF is produced.

COMPARISON OF ALKYLATION PROCESSES WITH DIFFERENT CATALYSTS

Up to 10–15 yr ago before HF safety concerns had been determined in detail, it was often thought that HF-type processes had lower operating costs, primarily because of the following two features. First, cooling water is used as a coolant; such cooling is considerably cheaper than using isobutane as a refrigerant. Relatively large compressors are then needed to obtain operating temperatures in the reactor of about 5–15°C. Second, regeneration of used HF is much cheaper than that of used sulfuric acid. Several years ago, sulfuric acid costs accounted for perhaps 25–30% of the total operating costs.

Sulfuric acid-type processes have the following advantages. First, separation (or distillation) costs are substantially cheaper. Second, costs of feedstocks (and especially isobutane) are smaller by several percentages.[8] Third, higher-quality alkylates can be produced from 1-butene. Fourth, it is often feasible to use C_5 olefins as feeds.

Recently, significant improvements have been made for processes using sulfuric acid. First, acid consumption has been reduced by as much as 50% in at least select refineries. Second, simultaneously the quality of alkylates has increased. Even further improvements of these processes seem likely, especially if improved reactors are built.

Although sulfuric acid is potentially hazardous, it seems to be significantly less hazardous even when additives or water sprays are employed in units employing HF. Schechler and Schmidt reported in 1997 that sulfuric acid type processes are the benchmark alkylation processes, which they likely will continue to be in the foreseeable future.[27]

Animal Cell Culture

Shang-Tian Yang
Shubhayu Basu
Department of Chemical and Biomolecular Engineering, The Ohio State University, Columbus, Ohio, U.S.A.

INTRODUCTION

Animal cell culture or the ability to continuously grow animal cells in vitro after removing them from animal tissue opens up a plethora of windows in the field of biology and medicine. They provide a platform to investigate the normal physiology and biochemistry of cells, test the effects of drugs and other compounds in vitro, produce artificial tissue for implantation, synthesize valuable products from large-scale cultures, and can even be used as models in studying diseases. Animal cells in culture have been used as end products to provide artificial skin grafts, islet cells, hepatocytes, and bone marrow implants and to produce recombinant and natural proteins like human growth hormone, nerve growth factor, epidermal growth factor (EGF), monoclonal antibodies (MAb), vaccines, interferons, and blood clotting factors. Animal cells are often more advantageous than yeast or bacterial cells for the production of recombinant proteins on a large scale. Proteins that need to be heavily glycosylated for function, or need a proper folding environment because they have a large number of disulfide bonds, are often made in animal cells. Bacterial cells cannot perform glycosylation or phosphorylation, and yeast cells cannot carry out complex glycosylation reactions. Often the glycosylation carried out by yeast cells is not authentic. Animal cells not only secrete the products efficiently but also provide excellent glycosylation and phosphorylation.

Animal cells have very different morphology and characteristics from microbial cells. They secrete an extracellular matrix (ECM), which provides a medium for the cells to interact and migrate. Animal cell lines can be anchorage dependent or independent, and require a suitable medium, temperature, pH, and dissolved oxygen concentration to grow. This entry discusses the structure of the animal cell, the basic procedures associated with animal cell culture, and the important process parameters governing it. The growth environment is highly important for animal cells as changes in the environmental factors can induce growth arrest or apoptosis or even stimulate proliferation or differentiation. Animal cell culture kinetics follows a similar trend as microbial cultures, but, in general, the cell cycle duration for animal cells is much longer than for prokaryotic cells. General animal cell culture kinetics and the cell cycle are reviewed. The intricacies of the animal cell and its shear sensitivity and anchorage dependence make it difficult to scale up bioprocesses involving animal cells. This entry discusses these problems and a variety of bioreactors designed to meet these requirements for large-scale animal cell culture processes.

ANIMAL CELL

Cell Structure

A variety of cell types, including epithelial cells, fibroblasts, muscle cells, nerve cells, cardiac cells, mesenchymal cells, endocrine cells, and embryonic stem cells, have been successfully cultured and maintained in vitro. These animal cells can vary widely in shape, size, and function depending on their sources. Fig. 1 shows a typical animal cell with its internal structure and organelles. In general, animal cells are much larger than microbial cells with a diameter between 10 and 30 μm. Though they lack chloroplasts (and therefore are not photosynthetic), they have many specialized cell organelles, such as Golgi bodies, endoplasmic reticulum, and mitochondria, each surrounded by its own plasma membrane. The nucleus is the most prominent organelle in the animal cell and houses chromosomes and other nuclear proteins. Also present in the nucleus are one or more nucleoli, which are involved in ribosome synthesis. The compartmentalization of different organelles facilitates the separation of specific metabolic functions that are incompatible otherwise. Other membrane bound organelles include lysozomes and peroxisomes, which mainly contain digestive enzymes for specific metabolic processes. It is important to note that, apart from chloroplasts, animal cells also lack vacuoles and a rigid cell wall that are present in plant cells. The lack of a cell wall makes the animal cell highly sensitive to shear forces.

Nonmembranous organelles within the cell include microtubules, microfilaments, and centrioles. The microtubules and microfilaments form a framework

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120017564

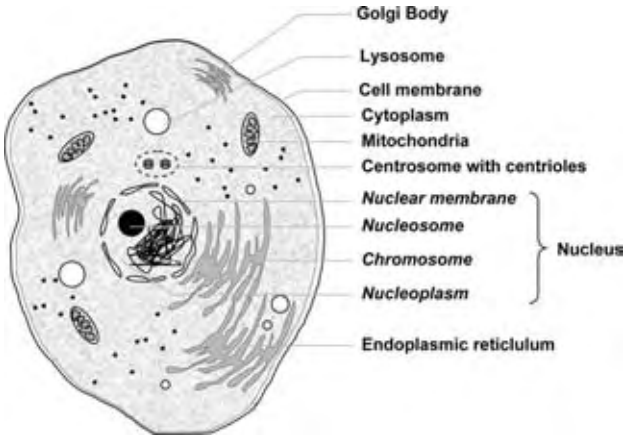

Fig. 1 The structure of a typical animal cell. *(View this art in color at www.dekker.com.)*

called the cytoskeleton that helps the animal cell to maintain its form and keep the organelles in place. The cytoskeleton is also involved in the process of cell division and migration. The larger the cell, the more intricate and elaborate its internal cytoskeletal structure.

Extracellular Matrix

In contrast to prokaryotes, which are unicellular and therefore can live as single entities, animal cells need to socialize—an observation that can be attributed to their origin from higher multicellular organisms. Cells in tissues are usually in contact with a complex network of secreted extracellular proteins referred to as the ECM. This matrix holds the cells together and provides a medium for the cells to interact and migrate.[1] The ECM is secreted mainly by the cells within it and comprises primarily two classes of macromolecules: 1) the glycosaminoglycans, which are linked to proteins in the form of proteoglycans, and 2) the fibrous proteins. Some fibrous proteins are structural proteins such as collagen and elastin, which provide rigidity and elasticity to tissue, respectively, and some are mainly adhesive proteins such as fibronectins and laminins. Fibronectin is a large glycoprotein with binding domains for other ECM proteins and is of primary importance. Mice with their fibronectin gene ''knocked out'' either die in the embryonic stage or grow up to have multiple morphological defects. Of equal importance are the integrins—transmembrane proteins that interact with the cellular cytoskeleton and thereby anchor the cells to the ECM. They are heterodimers, which mediate bidirectional interaction between the cytoskeleton and the ECM. The fibronectins and the integrins together function to attach the cells to their surroundings. It is because of this interdependence of the integrins and the fibronectins that some animal cells can be cultured only when they have a substratum to grow on. This anchorage dependence of some animal cells helps each cell to attach to the substrate and spread along it to interact with other neighboring cells and thus mimics the functions of a tissue in vitro. Fig. 2 illustrates how the ECM molecules help cells attach and spread on the surface of the substratum. Also, cells may have different shapes when attached on the two-dimensional surface or in a three-dimensional space with cell–cell interactions.

Transformed and tumorigenic cells are different from normal cell lines in that they are not usually anchorage dependent. They exhibit a spherical shape, increased life span and lateral diffusivity of membrane proteins, decreased cell receptors and membrane proteins, and a different cytoskeletal structure.[2] The decrease in the concentration of the cell adhesion molecules in the cell membrane of these cells causes the anchorage independence. Transformed cell lines also do not assemble a normal ECM. It is important to note that some cell lines (e.g., lymphocytes) that are normally anchorage dependent can be induced and then adapted to become anchorage independent. This is of tremendous importance to recombinant protein production as discussed later, because the scale-up of suspension cultures is easier than that of anchorage-dependent cell lines.

Cell Lines

The first stage of tissue culture is the primary cell culture. After isolating a desired piece of tissue, it is disaggregated either mechanically or enzymatically. The resulting tissue fragments are then used to inoculate the culture vessel that contains medium. Most normal cells are anchorage dependent. Hence, some of these fragments attach to the vessel wall and migrate out along the surface. Such a culture, before it is first passaged or subcultured, is called a primary culture. As the cells proliferate, they keep spreading out on the culture dish surface until the dish is covered by a single layer of cells. The cells are then said to have reached confluence. Once the cells form this continuous sheet, they stop proliferating because of contact inhibition. Transferring them at low densities (a process termed subculturing or passaging) to new culture vessels that contain fresh medium induces them to resume proliferation. Such a cell population that can continue to grow through many subcultures is called a normal, untransformed cell line.

After about 50 divisions, however, proliferation slows down and the cells show senescence and begin to die. Some of the cells in the culture may undergo some genetic modifications or transformation, which allows them to escape senescence. As long as they are

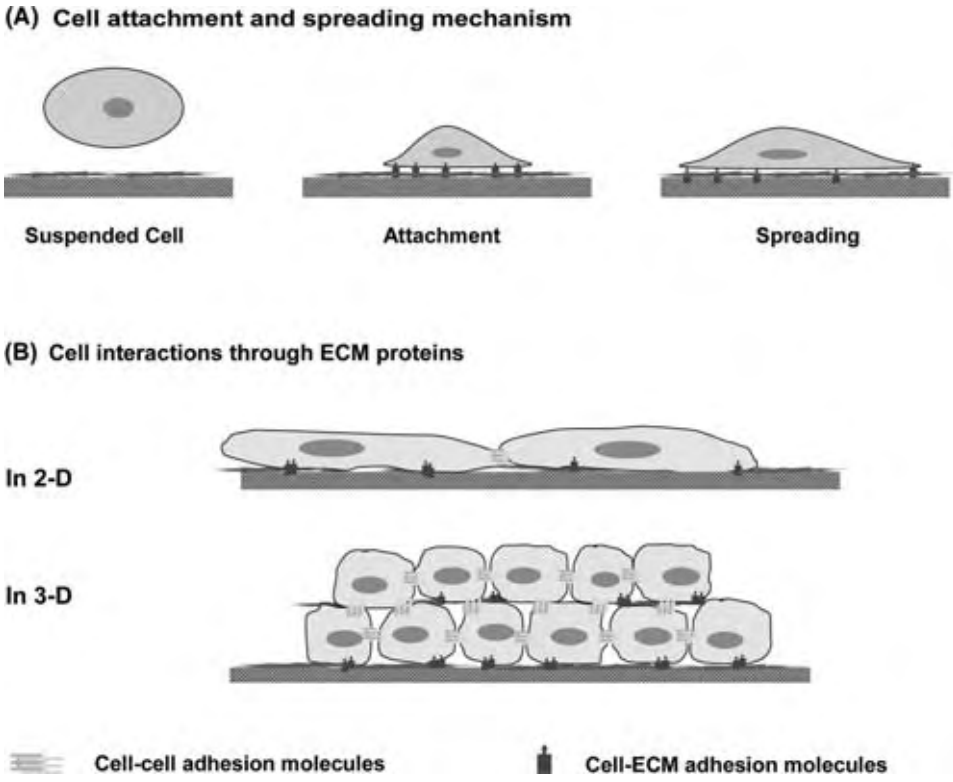

Fig. 2 Cell attachment on surface through cell–ECM interactions. (A) Cell attachment and spreading mechanism. (B) Cell–cell and cell–substratum interactions in two-dimensional and three-dimensional environments. *(View this art in color at www.dekker.com.)*

subcultured periodically, they can grow indefinitely. Such cells with an infinite life span are said to have undergone ''immortalization'' and the cell line is called a transformed cell line. Transformed cells have an enhanced growth rate and may lose anchorage dependence. Tumorigenicity is analogous to transformation but not all transformed cells are tumorigenic or malignant. However, all tumorigenic cells have an infinite life span and enhanced growth rate akin to transformed cells and are mostly anchorage independent.

Table 1 shows some animal cell lines that are commonly used in various applications. Creating a stable, permanent cell line is the first critical step in producing recombinant proteins for therapeutic and diagnostic applications. Hybridoma, commonly used in the production of MAb, are generated by fusing antibody-producing spleen cells, which have a limited life

Table 1 Common cell lines and their application

Cell line	Origin	Cell type	Application
BHK	Baby hamster kidney	Fibroblast	Vaccine production
COS	African green monkey kidney	Fibroblast	Transient expression of recombinant genes
Vero	African green monkey kidney	Fibroblast	Human vaccine production
3T3	Mouse connective tissue	Fibroblast	Development of cell culture technique
CHO	Chinese hamster ovary	Epithelial	Recombinant glycoprotein production
HeLa	Human cervical carcinoma	Epithelial	Animal cell model

ES-D3	Mouse embryo	Pluripotent embryonic stem cell	Insulin production

(Adapted from Ref.[3].)

span, with cells derived from an immortal tumor of lymphocytes (myeloma). The resulting hybrid is capable of unlimited growth and producing the antibody. Industrial cell lines used for recombinant protein production usually have been genetically engineered to improve the cell in its growth and ability to produce the protein product at a high expression level.

CULTURING CONDITIONS FOR ANIMAL CELLS

Animal cells can be anchorage dependent or independent but all cell lines need nutrients, a suitable temperature, pH, and dissolved oxygen level to grow. The growth environment for animal cells is highly important because environmental stimuli can trigger different responses from the cell. Changes in growth conditions can induce growth arrest or even apoptosis, or may also stimulate proliferation or differentiation. It is therefore crucial to maintain and closely monitor the growth environment so that the cells grow to high cell densities, have stable genotypic and phenotypic expression, and are able to efficiently express recombinant genes if desired. Some important parameters in animal cell culture are discussed here.

Substrate for Cell Attachment

In earlier days, reusable borosilicate glass bottles were used for animal cell cultures. The hydrophilic glass surface was suitable for cell attachment and growth. With the advent of the plastic age, presterilized polystyrene culture apparatus are readily available for cell growth. The polystyrene surface is usually sulfonated to make it hydrophilic and is sterilized by γ-irradiation. They are meant for a ''one-time'' use and reduce the risk of contamination. Popular forms of culture flasks are T-flasks, Petri dishes, and multiwell plates. Cells grown on the flat or two-dimensional surface such as in a T-flask usually stretch and show a somewhat flattened morphology (Fig. 3A). Stretching allows cells to migrate on the surface and promotes proliferation.

Microcarriers have also provided a good way to increase the available surface area per unit volume in large-scale bioreactors. Various types of microcarriers have routinely been used for the growth of anchorage-dependent cells.[4] Cylindrical cellulose-based microcarriers (DE-53) were among the first used.[5] Since then, different materials like collagen coated-glass beads, gelatin, DEAE dextran, glass-coated plastic, collagen-coated polystyrene, and polyacrylamide have been used.[6] These beads range from 90 to 330 μm in diameter and can be optimized for different cell lines. Calcium alginate gel beads and new surface modified polystyrene have also been used.[7] Cells

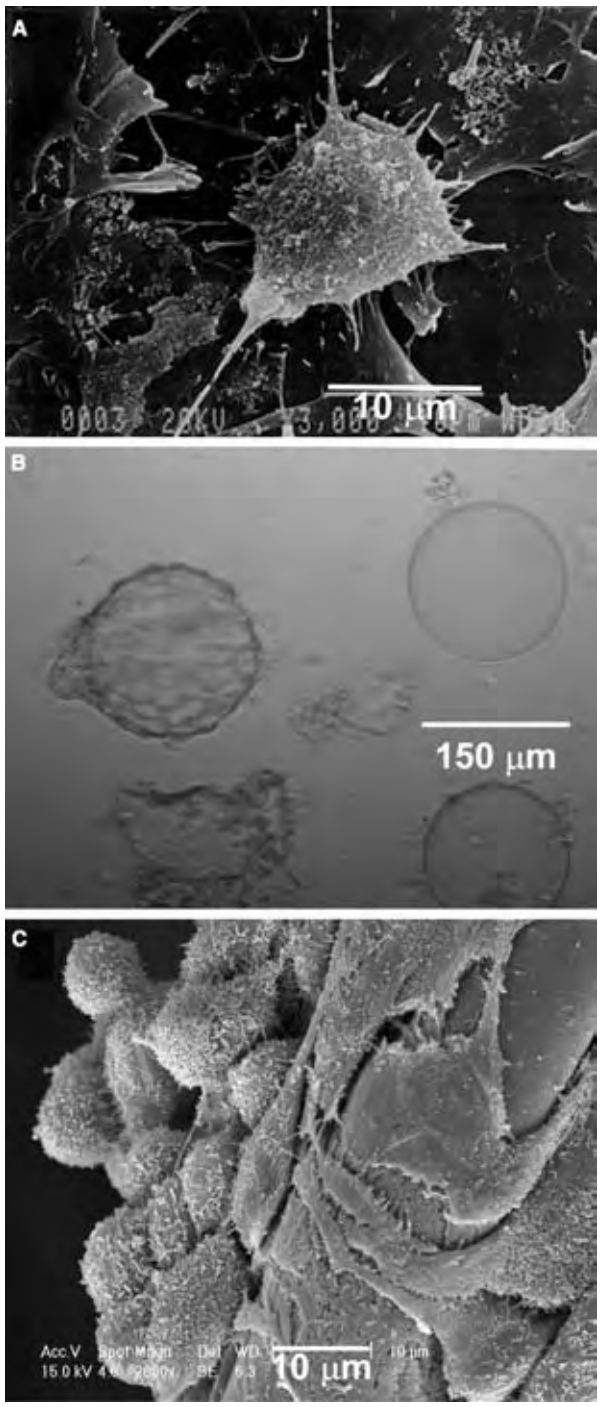

Fig. 3 Different cell morphologies observed for growth on different substrata: (A) cow luteal cells grown on the surface of a T-flask; (B) osteosarcoma cells grown on microcarriers; and (C) osteosarcoma cells grown on a fiber in nonwoven polyester fabrics. *(View this art in color at www.dekker.com.)*

attached and grown on microcarriers usually form a monolayer and reach confluence during the culture (Fig. 3B).

So far, discussions have focused on animal cell growth in monolayers or two dimensions. However,

for tissue engineering applications, cell masses need to aggregate into a three-dimensional tissue construct. To aid this process, tissue scaffolds are used as a matrix to guide animal cell growth in three dimensions. In general, a variety of scaffold types have been used. A broad classification would be foam-like scaffolds (e.g., alginate sponge, chitosan, collagen foam, and PLA foam) and fibrous scaffolds like collagen fibers, nonwoven polyethylene terephthalate, and polypropylene mesh. Cells cultivated in the three-dimensional support environment can not only attach to the surface of the substratum but also grow into the three-dimensional space to form aggregates (Fig. 3C).

Culture Medium

Various types of media have been used to cultivate different cell lines. The choice is mostly empirical, but formulations can be optimized for different cell lines and purposes. Most media, however, have the following essential components: balanced salt solutions (BSS), essential amino acids, glucose, vitamins, buffers, and antibiotics. The BSS provides a concoction of inorganic salts required by the cells and usually has an osmolality between 260 and 320 mOsm/kg, which is similar in range to that experienced by cells in vivo.[8,9] Balanced salt solution often contains sodium bicarbonate and phosphates, which apart from nutrient value, also act in a buffering capacity.

Glucose is the major carbon and energy source in medium formulation, but its concentration varies in different media. Eagle's minimum essential medium contains 1 g/L of D-glucose, whereas Dulbecco's modification incorporates a higher glucose concentration of 4.5 g/L. Amino acids are important nutrients for cell growth and are additional sources for carbon and energy.[10] Essential amino acids are those that cannot be synthesized by the cell metabolic machinery and, therefore, need to be supplemented through the media. Most cell culture media contain 2–4 mM of L-glutamine.

Buffers are inherent constituents of all media formulations and can maintain the medium pH within an acceptable range.[9] The most commonly used buffer is sodium bicarbonate and CO_2, which is usually provided in air at 5%. Dissolved CO_2 reacts with water to form carbonic acid, which dissociates into the bicarbonate ion [Eq. (1)]:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^- \quad (1)$$

So, increased amounts of dissolved CO_2 increase the acidity of the medium. This action is countered by the presence of sodium bicarbonate [Eq. (2)]:

$$NaHCO_3 \leftrightarrow Na^+ + HCO_3^- \quad (2)$$

The dissociation of sodium bicarbonate to bicarbonate ions in solution shifts the equilibrium of the reaction in Eq. (1) back, thereby effectively maintaining the pH at 7.4. Good et al. came up with a range of zwitterionic buffers.[11] Such buffers, like *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid, have a pK_a of 7.31, which is optimal for cell culture, do not penetrate the cell membrane, and equilibrate with air.[9]

The pH indicator phenol red (phenol sulfonphthalein) is often added to commercially available media. It is pale yellow at pH 6.5, orange at pH 7.0, and red at pH 7.4. It becomes purplish above pH 7.4. Growth media are also often supplemented with antibiotics to promote the growth and propagation of antibiotic resistant strains and also to prevent contamination by micro-organisms. But the presence of antibiotics in the medium does not obviate the use of good aseptic techniques. Nowadays, however, most commercially available media are presterilized as are the polystyrene culture dishes.

Serum

Different types of serum have been used to supplement media with various necessary growth factors and hormones that cells need for their growth. Serum also contains various adhesion factors and antitrypsin activity, which promotes cell attachment. Serum components can act as buffers and as chelators for labile or water insoluble nutrients, bind and neutralize toxins, and provide protease inhibitors. Serum can also reduce oxidative injury to cells caused by ferrous ions.[12] Reduced serum conditions have also been reported to increase the susceptibility of cells to apoptosis.[13]

Various types of serum are fetal bovine serum—the most widely used type, newborn calf serum—which is derived from animals less than 10 days of age, donor calf serum—which is obtained from processed whole blood of calves up to 8 mo old, and horse serum. Human serum and chicken serum have specialized uses for those cells that require a serum derived from similar species, e.g., chicken serum has been repeatedly used for growing various types of avian cells.[9] Serum can be stored safely for over 12 mo at −20°C and longer storage is possible at −70°C. Serum can also be heat inactivated (incubation at 56°C for 30 min) to remove toxic compounds or other agents that can interfere with tissue typing assays.

However, as serum contains a wide range of components whose exact concentration is not known, there is a lot of variability from batch to batch. The presence of serum in culture medium is undesirable in cases where a protein or product has to be purified for commercial use. The cost of serum and the possibility of viral contamination also inhibit its use.

Serum-Free Medium

Many attempts have been made to replace serum and add defined amounts of the essential components of serum to form what is known as serum-free medium (SFM). Serum-free medium, generally, consists of a basal medium and additional supplements. The basal medium provides the essential and nonessential amino acids, vitamins, nucleic acids, lipids, inorganic salts, and a carbon source. The additional supplements are: growth promoters such as insulin, insulin-like growth factors, EGF, platelet-derived growth factor, estradiol, and dexamethasone; attachment factors like collagen, fibronectin, and laminin; and transport proteins and detoxifying agents like albumin and transferrin.[14] Ito et al. reported that insulin immobilized on microcarriers promoted growth of anchorage-dependent cells in a protein-free cell culture system.[15] Some serum-free systems have even used the structural heterogeneity of high-density lipoproteins to influence cell proliferation.[16] Serum-free systems are also very useful in reducing downstream processing steps for recombinant protein production using animal cell culture. Unfortunately, the transition to SFM has not been easy. Different cell lines require several growth factors and the specific growth rates of cells are usually slower in SFM. Moreover, SFM can also be expensive.

Temperature and pH

In contrast to micro-organisms, mammalian cells do not show great adaptation to varying temperature or pH ranges. Most cell lines prefer a pH of 7.4. Eagle reported that normal fibroblasts grow within a pH range of 7.4–7.7, while transformed cells prefer a pH between 7.0 and 7.4.[17] Most cell lines grow best at a temperature of 37°C. Cells can tolerate considerably large drops in temperature in that they can be stored cryogenically in liquid nitrogen at −196°C for several months. At temperatures slightly lower than 37°C, the growth rate decreases, but the cellular metabolic activity does not cease totally. Reduction of temperature to 33.5°C resulted in a lowering of the specific growth rate of Chinese hamster ovary (CHO) cells while having no effect on the cell proliferation.[18] This could be attributed in part to the physical state of the lipid bilayer that makes up the plasma membrane. However, cells in general die at temperatures higher than 42–48°C, where the lipid bilayer exhibits a liquid crystal (fluid) behavior.[19] Temperature can also be used as a tool to control recombinant protein production by engineered cell lines. Hendrick et al. (2001) increased the productivity of tissue plasminogen activator under the control of the SV40 promoter in CHO cell, by a shift in temperature from 37°C to 32°C.[20]

Dissolved Oxygen

Oxygen is required for respiration and is thus a key nutrient for animal cell cultures even though requirements vary between cell lines.[21] Because of the low solubility of oxygen in water, oxygen must be provided continuously, usually by aerating the culture medium. Several authors have reported the importance and effects of oxygen in animal cell cultures. It is difficult to conclude a general trend for oxygen dependence vs. cell metabolism. In the case of antibody production using the AB2-143.2 hybridoma cell line, a pO_2 of 50% air saturation was optimum, while the highest immunoglobulin yield from human lymphoblastoid cells (RPMI #7430) was obtained at a low pO_2.[22,23] The trend is opposite for cell biomass production. While more hybridoma cells were obtained at a low pO_2 of 0.5% air saturation, more lymphoblastoid cells were produced at the highest atmospheric pO_2.[22,23] So, each cell line can be studied and grown at its own optimal pO_2 depending on the desired end product. Ma et al. also reported that a low (2%) oxygen tension promoted proliferation while a high (20%) oxygen tension induced differentiation in human trophoblast cells.[24]

CELL CULTURE KINETICS

The aim of animal cell culture can be either to use the cells as end products or to develop enough biomass (cells) to express a certain target protein of interest in economically viable amounts.

Growth Kinetics

Most animal cell cultures exhibit similar trends in their growth kinetics. While the specific growth rate of each cell line varies, all cell lines do exhibit a characteristic growth curve similar to the one shown in Fig. 4. Cells go through an initial phase of adjustment, the lag phase, after being either subcultured or dissociated from tissue. After this preliminary lag phase, the cells start growing exponentially and this phase is called the logarithmic phase. Following this phase of active growth, the cell growth rate reduces because of nutrient limitation and product accumulation. The total cell number then ceases to increase, a phenomenon triggered off not only by contact inhibition between cells but also because the cell culture reaches a dynamic equilibrium between the rate of cell growth and cell death. The last phase is the death phase, where cell number is reduced because of death caused by either apoptosis or necrosis.

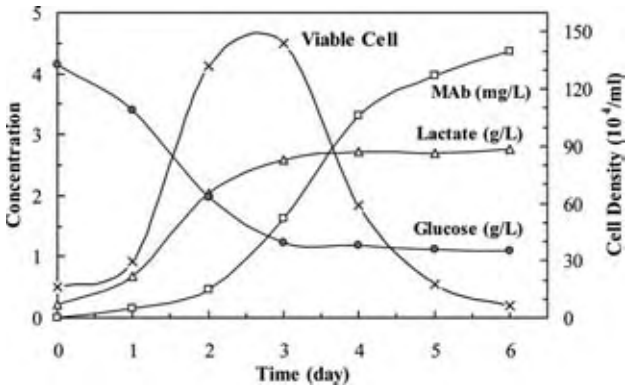

Fig. 4 Typical batch kinetics of a hybridoma culture showing characteristic growth curve and growth-associated production of lactate and nongrowth-associated production of antibodies.

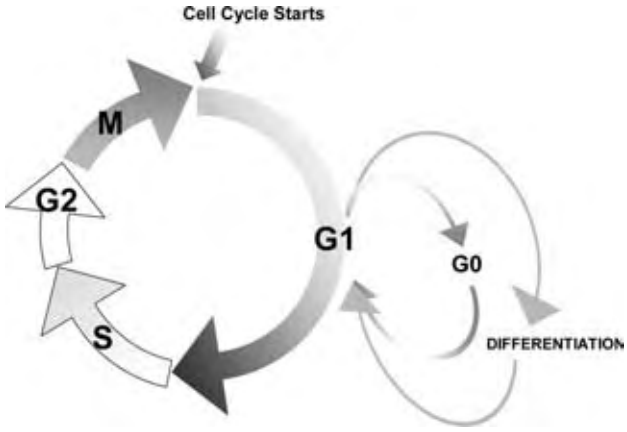

Fig. 5 The cell cycle. A proliferating cell goes through four phases: an initial growth phase (G1), a DNA synthesis phase (S), a second growth phase (G2), and, finally, a mitotic phase (M). During G1 the cell may also choose to differentiate into a new cell type or go into a quiescent state or G0 phase. *(View this art in color at www.dekker.com.)*

Cell Metabolism

Lactic acid is often a product of glucose metabolism via the glycolytic pathway, while ammonia is produced from the catabolism of glutamine and other amino acids. Cell growth can be inhibited by the accumulation of lactate and ammonia in the culture medium. Production of lactic acid can also lower the medium pH below the physiological range. Reducing or selectively removing toxic metabolites in the culture medium is critical to the efficient production of recombinant proteins by animal cells. The production of primary metabolites such as lactate is usually growth associated, whereas protein expression can be either growth associated or nongrowth associated. Fig. 4 shows a typical batch hybridoma culture with the production of MAb mainly in the stationary phase.

Cell Cycle

For a cell to grow and reproduce, it must go through the cell cycle shown in Fig. 5. The two major events in the cell cycle are DNA replication followed by cell division into two new daughter cells. A cell entering the cell cycle first goes through a gap phase (G1). During this phase, it undergoes protein synthesis, which primes the cells for the next phase, the synthesis (S) phase. A second copy of the cellular genome is made during the S phase, thus ensuring that fidelity is maintained when the cell divides. The third phase (G2) is another phase of protein synthesis and it prepares the cell for division, and mitosis finally occurs in the M phase. Essentially, the duration of the cell cycle is an important factor in determining the fraction of dividing cells in a given population. The cell cycle not only controls the rate of cell proliferation and growth, but also may affect protein expression as production of some recombinant proteins by animal cells is cell-cycle dependent.

Cell lines vary in their cell cycle duration, but all of them follow a basic pattern and are tightly regulated at certain checkpoints. If anything goes wrong, the regulatory machinery promptly causes a cell cycle arrest and eventual cell death. Deprivation of growth factors can cause a cell to exit from a proliferating mode to a quiescent mode (G0). During this phase, the whole cell metabolic machinery is suppressed. Addition of growth factors can again stimulate a cell to re-enter the G1 phase. The cell can also exit the cell cycle to differentiate into a new lineage or head toward programmed cell death or apoptosis.

Apoptosis

Apoptosis or programmed cell death contributes to cell death in in vitro cultures under suboptimal conditions. Nutrient deprivation like glucose, glutamine, serum or oxygen limitation, or mild hydrodynamic stress can induce apoptosis. High levels of apoptosis have been reported following deprivation of glucose and essential amino acids.[25] A number of studies have demonstrated that the suppression of this death pathway, by means of overexpression of survival genes such as *bcl*-2, results in improved cellular robustness and antibody productivity during batch culture.[26]

It is important to know the cell cycle and the points where it can be regulated. This is because cancer basically results when the cell cycle control machinery fails and the cell undergoes rapid proliferation and metastasis. On the other hand, apoptosis is also not desirable

in cells growing in bioreactors as it would lower the specific productivity of cells.

There is a plethora of proteins responsible for controlling and regulating the cell cycle and thereby deciding which course the cells should take. They can be broadly divided into the cyclins and cyclin-dependent kinases (Cdks), which interact with each other during regulation. In general, cyclin Ds are associated with the G1 phase, cyclin Es with the transition from G1 to S, cyclin As with the S phase, and both cyclin As and Bs with the transition from G2 to M. The Cdk–cyclin complexes can be inhibited by the Cdk inhibitors, which add an extra level of regulation.

ANIMAL CELL BIOREACTORS

A variety of bioreactors have been developed and used for animal cell cultures, from simple static T-flasks and roller bottles to more complicated multitray and rotating disk reactors. Because most animal cell lines are anchorage dependent, scale-up for animal cell cultures is usually based on providing the maximum surface area for cell attachment. For this reason, microcarriers have been developed for use in culturing animal cells in conventional stirred-tank and airlift reactors. A recent industrial trend is to adapt animal cells to grow in suspension without needing microcarriers for surface attachment. Immobilized cultures in hollow-fiber, packed-bed, and fluidized-bed reactors also have been used to greatly increase cell density and reactor productivity. Improvements in bioreactor design have focused on increasing oxygen transfer, reducing shear and bubble damages, and increasing cell density by cell recycle or immobilization in perfusion cultures. Fig. 6 shows different types of animal cell bioreactors.

Bioreactors for Suspension Cultures

Bioreactors for suspension cultures are similar to the common microbial fermenters. However, the increased shear sensitivity of animal cells necessitates a few changes. The fermenters for this purpose usually lack baffles and other sharp projections that can cause turbulence.[27] The interior of these fermenters is usually lined with glass or finished to a high grade of smoothness to minimize mechanical damage and to enhance cleanliness. The impeller designs are different too.[28,29] Modified marine and pitched-blade impellers usually cause much less cell damage than conventional disk turbine blades. Nevertheless, cell damage and death caused by mechanical agitation and gas sparging is still a major concern in reactor design and scale-up. For cell lines like hybridoma, which are extremely sensitive to shear stress, novel methods have been developed. The Vibro fermenter (Chemap) uses a plate that vibrates (0.1–3 mm) in the vertical plane to achieve mixing. Airlift bioreactors do away with mechanical agitation and achieve mixing by the process of aeration itself. Airlift bioreactors in general consist of two concentric tubes. The inner tube carries a sintered steel ring or other oxygenation apparatus through which air containing 5% CO_2 is bubbled. Air escapes at the top and the liquid comes down the outer tube. Hybridoma cells have been successfully grown in airlift bioreactors.[30] In general, cell densities in suspension cultures are lower than 10^6–$10^7\,ml^{-1}$ because of limited oxygenation at low agitation and aeration rates used to avoid severe cell damages.

Apart from ingenious modifications to the typical bioreactor, rotating wall culture vessels have also been in use (1). But a recent resurgence in their use has been triggered off by the discovery that gravity, or rather the lack of it, plays an important role in the morphology and physiology of tissue constructs.[1,31] The reactor cultures cells in a slowly rotating horizontal cylinder, which produces low shear stress and the continuous rotation keeps the cells always in a state of free fall to simulate microgravity conditions.

Perfusion Cultures

To achieve high cell densities, perfusion cultures have also been used. Perfusion implies the continuous or semicontinuous addition of fresh medium and withdrawal of used medium. This, however, dictates the need for cell separation. This has been achieved by using spin filters, hollow-fiber filters, gravitational settling, or centrifugal separation. Spin filters are usually attached to the stirrer shaft. As they spin, they create a boundary layer effect around them that reduces cell attachment and clogging. Centrifugal methods employ a recycle stream that passes through the centrifuge. Hollow-fiber filters operated under tangential flow allow continuous removal of medium filtrate without significant membrane fouling. Gravitational settlers using inclined tubes allow cells in the outflowing stream to return to the reactor. Bierau et al. used ultrasound to aggregate cells for their fast separation from liquid medium in the settler.[32]

Microcarrier Cultures

As microcarriers provide a good surface area for attachment per unit volume, various types have been routinely used to grow anchorage-dependent cell lines in bioreactors primarily used for suspension cultures. Airlift reactors can also be operated using microcarriers. Wang et al. reported the use of a fluidized-bed

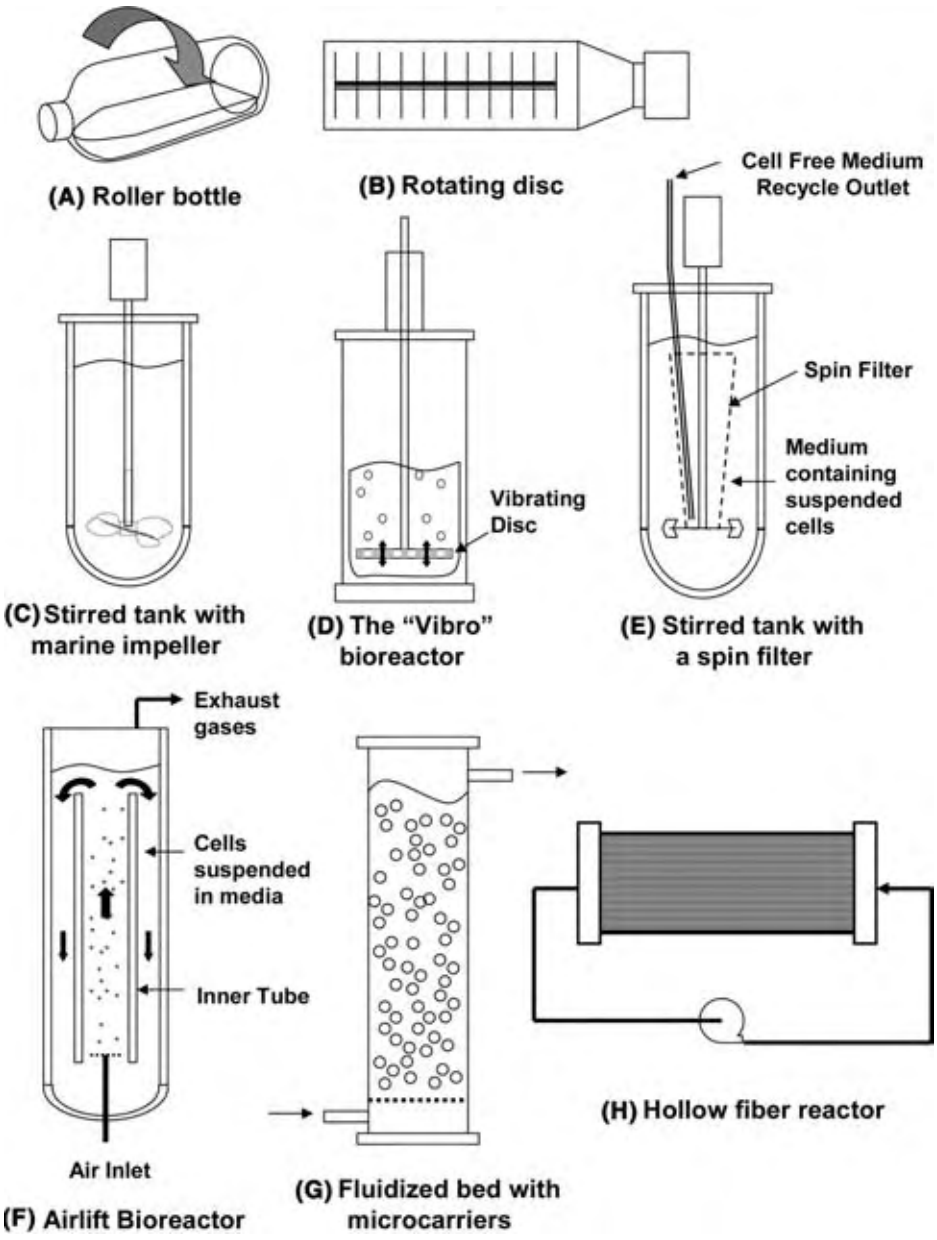

Fig. 6 Various types of animal cell bioreactors: (A) roller bottle; (B) rotating disk; (C) stirred tank with a marine impeller; (D) tank with a pulsating agitator; (E) stirred tank with a spin filter; (F) airlift; (G) fluidized bed; and (H) hollow fiber. *(View this art in color at www.dekker.com.)*

bioreactor in which cells were attached to Cytoline-1 macroporous microcarriers.[33] The upward flow of the medium fluidized the beads or carriers and provided a unique perfused system that gave higher erythropoietin (EPO) production than a conventional stirred-tank bioreactor. Fluidized-bed bioreactors have also been used for suspension cultures of hybridoma.[34] Chong et al. used microcarriers to form a packed-bed reactor to grow CHO cells and report cell density as high as 2×10^7 cells/ml.[35]

However, cells grown on solid microcarriers are often subjected to fluid mechanical damages caused by small turbulent eddies as well as by collision between microcarriers and against the impellers and other bioreactor parts.[36] The development of macroporous microcarriers has largely solved this problem of shear damage to cells. As the name suggests, macroporous microcarriers have a network of pores within them, which not only present a larger surface area for cell attachment but also protect the cells from shear damage. Macroporous microcarriers are mostly made of gelatin, collagen, cellulose, polystyrene, and polyethylene, and the cell distribution in them can be studied by confocal laser scanning microscopy.[37,38]

Hollow-Fiber Reactors

Hollow-fiber reactors are widely used in the production of MAb and can reach cell densities higher than

2×10^8 cells/ml of the fiber volume.[39,40] With continuous perfusion and intermittent harvesting, hollow-fiber reactors can give high reactor productivity and produce antibodies at a high concentration comparable to or even higher than that in mouse ascites.[41] The gradients of metabolites and nutrients created along the axis of the hollow-fiber reactor are undesirable. This problem can be overcome with the radial flow hollow-fiber reactor, which consists of a central flow distributor tube surrounded by an annular bed of hollow fibers.[42] The central flow distributor ensures an axially uniform radial convective flow of nutrients across the fiber bed. In this reactor, the cells grow on the outer side of the fibers. However, in conventional hollow-fiber reactors, the cells could be on either side depending on the inoculation method used and the way the process is carried out. Hollow-fiber reactors have also been used for perfusion cultures. A practical problem with these systems is that the cell density cannot be directly monitored. Hollow-fiber reactors are also expensive, and their uses are limited to small-to-medium scale production of antibodies.

Fibrous-Bed Bioreactors

A promising new technology has been the immobilization of animal cells to fibrous beds rather than microcarriers. The CelliGen Plus® bioreactor uses polyester fabric disks packed in a basket inside a stirred tank for immobilizing animal cells. The reactor productivity was reported to be as high as 12-fold of that in static and stirred suspension culture systems for antibody production.[43] Chen et. al. also developed a fibrous-bed bioreactor to successfully grow osteosarcoma cells to cell density as high as $3 \times 10^8\,ml^{-1}$ with 90% cell viability for as long as 4 mo.[44] The three-dimensional structure provided by the fibrous matrix has been shown to have profound effects on cell growth and protein production.[25,45] This three-dimensional culturing method provides a new technique for the scale-up of animal cell culture.

INDUSTRIAL APPLICATIONS

Animal cell cultures are increasingly being used for the production of recombinant glycoproteins, viral vaccines, and MAb in the biotechnology industry. They are far superior to yeast and bacterial cells in carrying out the complex post-translational modifications that major recombinant protein products require. Not only can animal cells provide better glycosylation and phosphorylation of complex proteins, but they can also carry out authentic proteolytic cleavage, subunit association, and chemical derivatization. However, large-scale animal cell cultures are more difficult to commercialize than microbial cultures because the growth rate of animal cell cultures is much slower, the nutrient requirements are more complex, and the growth conditions more stringent. In addition, there are several parameters that need to be considered. Not only is the required inoculum size large ($\sim 10^5\,ml^{-1}$ or $1–5 \times 10^4\,cm^{-2}$), but the cell proliferation rate is also much slower. The productivity of the target protein is also in the milligram per liter range as compared to the higher production (often in g/L) in microbial cells. The medium is usually more expensive and the cells are highly sensitive to toxic metabolites and shear. In the case of suspension cultures, the scale-up is relatively easy as a range of fermentation equipment developed for microbial cultures can be modified to adapt to animal cell cultures. However, anchorage-dependent cells require a large surface area per unit volume and are therefore more difficult to scale up.

In spite of these hurdles, the last two decades have seen an immense leap in animal cell culture technology both at the laboratory scale as well as the industrial scale. A variety of bioreactors and instrumentation have been ingeniously been devised for the scale up and process control of animal cell cultures. Serum-free media development has considerably reduced the downstream processing costs in the recombinant protein production and purification process. The capability to induce some cell lines to lose anchorage dependence has also been an important breakthrough.

Table 2 lists various types of biopharmaceutical products from animal cell cultures. Viral vaccines are usually produced by first culturing the host cells (e.g., MRC-5 and WI-38) to form a cell layer on the surface of substratum. Seed virus is then added and incubated for about 3 weeks for replication in the host cells without killing them. After washing to remove the medium components, the cells are lysed to release the virions for harvesting and purification. The inactivated viral vaccine is produced by inactivation with formaldehyde and adsorption onto aluminum hydroxide adjuvant.

Roller bottle reactors have been widely used in the past and can generate cell densities upto 5.4×10^6 cells/ml.[46] However, roller bottles are difficult to scale up and cannot meet the growing demand for therapeutic recombinant proteins. Their popularity is on the decline and are largely replaced by microcarriers, and stirred-tank or airlift bioreactors in process scale-up. Initially, industrial production of EPO by CHO cells is carried out in hundreds of roller bottles in incubation rooms equipped with robots for medium changes and product harvesting. The newer production plant for second-generation EPO employs state-of-the-art bioreactors and has three times the production capacity of the old EPO plant.

Table 2 Some important biopharmaceutical products from animal cell cultures

Type	Examples
Vaccines	Polio, hepatitis A, measles, mumps, rubella, yellow fever, rabies, and influenza
Glycoproteins	Interferons
	Blood clotting factors (factors VIII, IX)
	Glycoprotein hormones, EPO
	Plasminogen activators, t-PA
MAb	Diagnostics
	Therapeutics—prevention of respiratory syncytial virus (RSV) infection, treatments of inflammation, breast cancer, non-Hodgkin's lymphoma, and treatment or prevention of transplant rejection
Hormones	Human growth hormone, insulin, calcitonin, and parathyroid hormone
Growth factors	Nerve growth factor and EGF
Proteases	Urokinase

Monoclonal antibodies have been widely used in biomedical research and in diagnostics. Because MAb bind to specific cell surface receptors, they can be used for treatments of transplant rejection, cancer, autoimmune and inflammatory diseases, and infectious diseases. Currently, MAb products comprise about 25% of all biotech drugs in clinical development. Commercial MAb production uses two methods: 1) in vivo cultivation in mouse or rabbit ascites and 2) in vitro cell culture in tissue flasks or bioreactors. For mass production of therapeutic antibodies, the latter method is used. For example, recombinant paliviumab is produced by culturing murine myeloma cells (NS0) in a stirred-tank fed-batch bioreactor. The manufacturing process starts with a vial containing about 10 million frozen cells, which are cultured in T-flask and then in spinner flask to expand the number of cells. These cells are subsequently used in the larger-scale bioreactor process with the culture volume increased incrementally to the final volume of 10,000 L. After inoculation of the production bioreactor, the fermentation takes about 20 days to reach the final titer of the MAb product, which is about 1 g of MAb per liter of the culture medium. The high titer of MAb production in this system was accomplished through extensive research and development works on cell line improvement, medium optimization, and process optimization and control.

CONCLUSIONS

Animal cells in culture have been widely used to study the physiology, metabolism, and biochemistry of cells; test the effect of compounds on different cell types; in tissue engineering applications; and for the production of recombinant glycoproteins, viral vaccines, and MAb. Though several challenges remain to be overcome, the future of developing more products using animal cell cultures is very bright.

Antioxidants

S. Al-Malaika
H. H. Sheena
Polymer Processing and Performance Research Unit, School of Engineering and Applied Science, Aston University, Birmingham, U.K.

INTRODUCTION

Antioxidants are ubiquitous and essential ingredients to life and living matter, as well as natural and synthetic organic materials. This entry deals with the fundamental and applied aspects of hydrocarbon oxidation and antioxidants with particular emphasis on polymers. Some aspects of polymer oxidation are introduced first before discussing antioxidants and their mechanisms of action in polymer stabilization. Examples of major antioxidant classes are given together with critical evaluation of performance in selected polymers. Recent progress in the areas of biological, reactive, and macromolecular antioxidants are also presented.

OXIDATION AND ANTIOXIDANTS

Hydrocarbon Oxidation

Molecular oxygen is the major cause of irreversible deterioration of hydrocarbon substrates, leading to the loss of useful properties and to the ultimate failure of the substrate. The oxidation process of hydrocarbons is autocatalytic: oxidation starts slowly, sometimes with a short induction period, followed by a gradual increase in the rate, concomitant with the build up of hydroperoxides, which eventually subside, giving rise to a sigmoidal oxidation curve.[1–6] When initiators such as peroxides are present, the length of the induction period is absent, or very short, but it can be prolonged by antioxidants, as shown in Fig. 1. The basic autoxidation theory of hydrocarbons involves a complex set of elementary reaction steps in a free radical-initiated chain reaction mechanism; the basic tenets of this theory apply equally to polymer oxidation.

Polymer Oxidation

The basic autoxidation theory of hydrocarbons, which involves a complex set of elementary reaction steps: initiation, propagation, and termination, is similarly valid for polymer oxidation. Other factors such as heat, mechanical stress, light, and transition metal impurities, contribute to the initiation step, which leads to the formation of the first macro-alkyl radicals (see Scheme 1, Reaction 1).

Propagation reactions involve the very fast reaction of oxygen biradical ($O^{\bullet}$–$O^{\bullet}$) with polymer alkyl radicals leading to the formation of macro-alkyl peroxyl radicals (Scheme 1, Reaction 2). This is followed by abstraction of hydrogen from another macromolecule resulting in hydroperoxide formation, the first molecular product of the chain oxidation process (Scheme 1, Reaction 3). This reaction involves the breaking of a C–H bond and, therefore, requires higher activation energy than Reaction 2. The rate of Reaction 3, which in most polymers at normal oxygen pressures determines the overall oxidation rate, is a function of both the C–H bond dissociation energy (allyl < benzyl < tertiary < secondary < primary) and the stability of the resulting macro-alkyl radical.[5] The macro-hydroperoxides formed can undergo homolysis under the effect of heat, light, or metal ions giving rise to alkoxyl- and hydroxyl-macroradicals (Scheme 1, Reaction 4). Both these radicals can abstract hydrogen from another polymer molecule, leading to new macro-alkyl radicals (Reactions 5 and 6a), which continue the chain reaction. Alkoxyl radicals can undergo further reactions, e.g., β-scission (see Reaction 6b), that would lead to cleavage of the macromolecular backbone and the generation of further radicals.

The oxidative process is terminated through radical combination and disproportionation reactions; the exact nature of the terminating step is determined by the polymer structure and the oxygen concentration. Since Reaction 3 (Scheme 1) is rate determining, alkylperoxyl radicals are the predominant reactive species under normal oxygen pressure (oxygen saturation), i.e., $[ROO^{\bullet}] > [R^{\bullet}]$, and termination occurs primarily through Reaction 7, giving rise to diperoxides, carbonyl compounds, and alcohols.[7] By contrast, under oxygen-deficient conditions, alkyl radicals predominate, i.e., $[R^{\bullet}] > [ROO^{\bullet}]$, and bimolecular termination steps 8–10 dominate, leading to cross-linking (and increased molar mass, Reaction 9) and/or disproportionation (with no

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007666

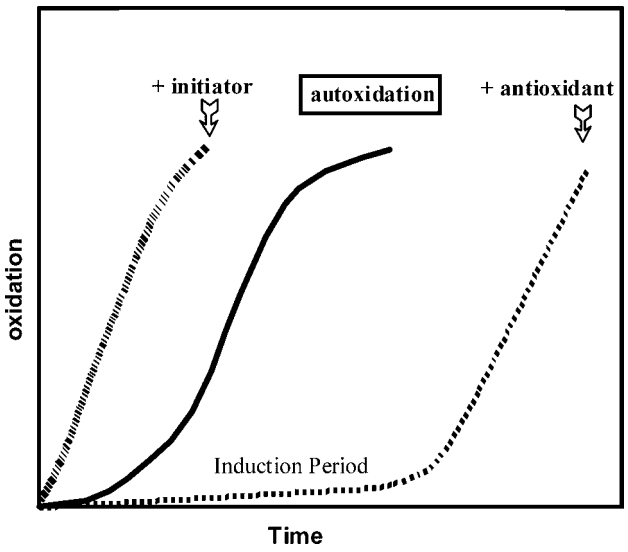

Fig. 1 Generalized shape of autoxidation curve and changes caused by the addition of an initiator and an antioxidant.

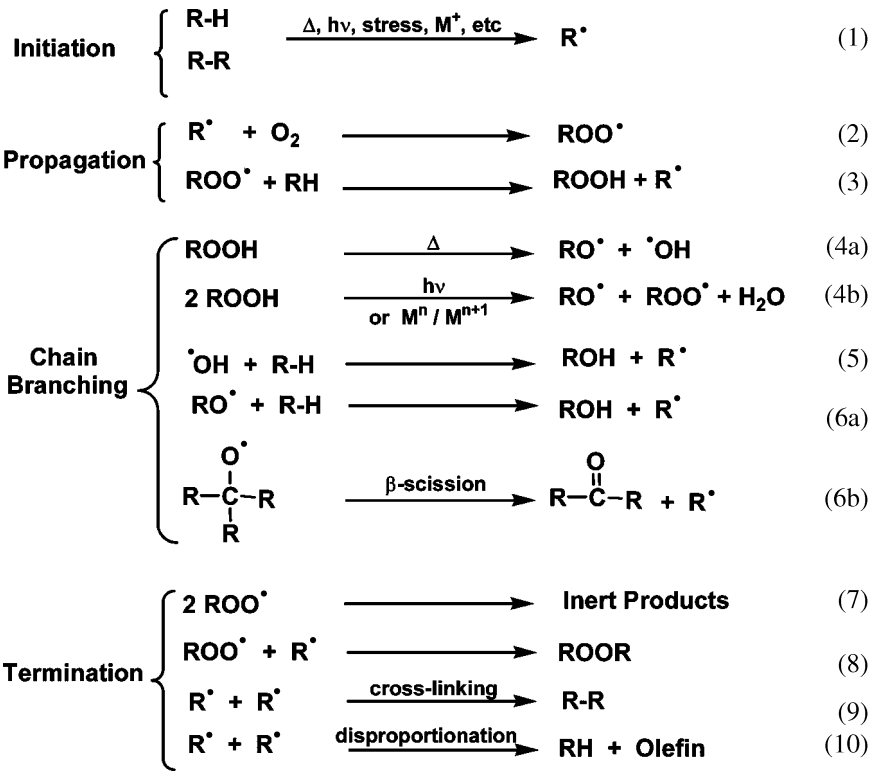
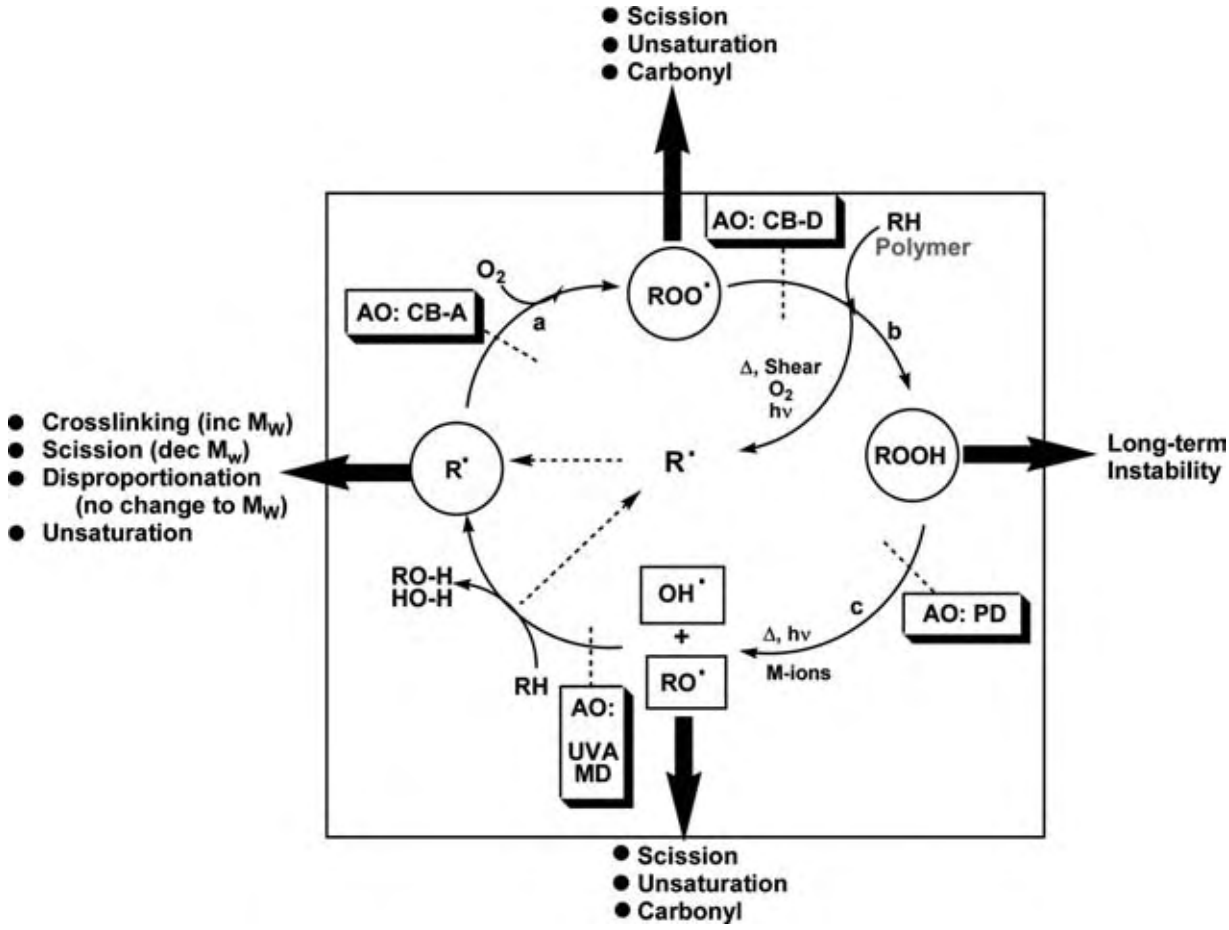
change in molar mass Reaction 10) polymer reactions (see Scheme 1). Both "limiting conditions'' are encountered throughout the polymer lifecycle: oxygen-rich environment during end-product use, and oxygen-deficient conditions during polymer processing (e.g., extrusion), as well as in thick cross-sections, when the rate of oxidation is controlled by the oxygen diffusion rate. Other radical-polymer reactions, including fragmentation and addition to double bonds to give rise to further free radicals, can also take place depending on the reaction conditions.[8–10] These macromolecular changes lead ultimately to the loss of mechanical properties (e.g., impact strength, tensile strength, elongation), changes in surface appearance (e.g., yellowing, crack formation, loss of gloss, "chalking''), and premature failure. The deleterious effect of molecular oxygen is accelerated by many other factors: sunlight, heat, ozone, atmospheric pollutants, water, mechanical stress, adventitious metal, and metal ion contaminants. Further, the prior thermal-oxidative history of polymers determines, to a large extent, their photoxidative behavior in service during outdoor weathering.[11] The cyclical oxidation pathways and the nature and effects of oxidation products arising from the different propagating species are highlighted in Scheme 2.

In the presence of oxygen, mechanical, thermal, photochemical, and environmental factors are extremely detrimental to polymer properties: during processing, storage, and first and subsequent lives as end-use products. Inhibition of the oxidative degradative process in polymers can be achieved by the incorporation of low levels (0.03–2%, but for plastics usually at 0.03–0.3%) of antioxidants and stabilizers during the fabrication process. Antioxidants and stabilizers, therefore, occupy a key position in the market of compounding ingredients for polymers, in particular the high volume commodity polymers, e.g., polypropylene, polyethylene, and polyvinyl chloride.



Scheme 1 Basic autoxidation reactions.



Scheme 2 Schematic presentation of the cyclical oxidation process and some of the main reactions/products formed from the propagating radicals. The antioxidant mechanisms interrupting the oxidative cycles are also shown.

Antioxidants and Mechanisms of Action

Antioxidants are chemical compounds or species that interfere with the degradative oxidative cycles in polymers, through chemical processes involving inhibition or retardation mechanisms. The two major antioxidant mechanisms, chain breaking and the preventive, are outlined in Scheme 2.[12,13] Examples of commercial antioxidants are shown in Table 1, under their primary mode of action, albeit most antioxidants operate by more than one mechanism.

Chain breaking (CB) antioxidants (sometimes referred to as primary antioxidants) act by removing the propagating radicals (the alkyl peroxyl $ROO^{\bullet}$ and the alkyl $R^{\bullet}$) formed during the primary oxidation cycle.[12,14,15] Chain breaking donor (CB-D) antioxidants operate by reducing the radical $ROO^{\bullet}$ to ROOH (Reaction 1a). Therefore, good CB-D antioxidants (e.g., hindered phenols, AH) must be able to compete effectively with the chain propagating Reaction 1b. The antioxidant radical ($A^{\bullet}$) produced from reaction 1a should also lead to stable molecular products. Hindered phenols and aromatic amines (see Table 1, AOs 1–12) are important examples of commercial CB-D antioxidants. Chain breaking acceptor antioxidants (CB-A) operate by oxidizing $R^{\bullet}$ in a stoichiometric reaction (Reaction 2a) and are effective only under oxygen deficient conditions (i.e., must be able to compete effectively with the chain propagating Reaction 2b). Quinones and stable free radicals, which can act as alkyl radical trapping agents are representative examples of CB-A antioxidants. Hindered amine derivatives (alias hindered amine light stabilizers, HALS, e.g., AOs 25–27, Table 1) operate also by a chain breaking mechanism and, through their transformation products, are able to trap both $R^{\bullet}$ and $ROO^{\bullet}$ through a cyclical regenerative mechanism,[16–22] see Scheme 3.

$$O_2 + P^{\bullet} \longrightarrow POO^{\bullet} \quad (2b)$$

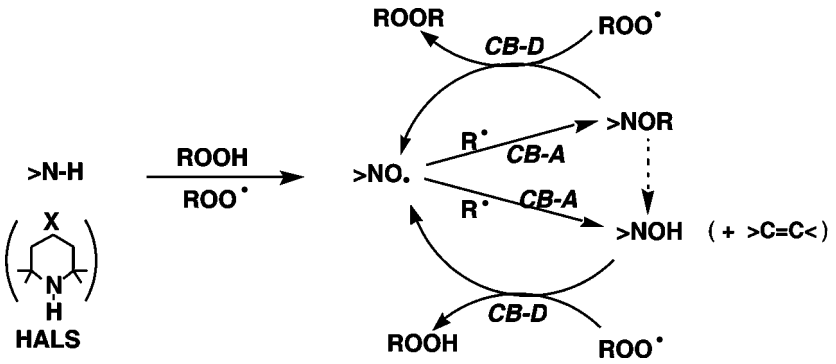
(Propagation Reaction)

where AH is a CB-D antioxidant, $A^{\bullet}$ is the antioxidant radical and LA is a CB-A antioxidant, PH is a polymer.

Preventive antioxidants (sometimes referred to as secondary antioxidants) act by interrupting the secondary oxidation cycle to prevent or inhibit the generation of free radicals.[13] The most important preventive mechanism is the nonradical hydroperoxide decomposition, PD. Phosphite esters and sulfur-containing compounds, e.g., AOs 15–24, Table 1, are the most important groups of peroxide decomposers. Phosphite esters are known as stoichiometric peroxide decomposers (PD-S): they reduce hydroperoxides to alcohols and are themselves oxidized to the corresponding phosphates in 1 : 1 stoichiometric reactions (see Reaction 3). Additionally, some phosphite esters can act as catalytic peroxidolytic agents (PD-C), whereas others (e.g., hindered aryl phosphites, AOs 11 and 12, Table 1) can act by a chain breaking (CB) mechanism; the relative contribution of each of these modes of action to the overall mechanism depends on the structure of the phosphite, the oxidizability of the substrate and the reaction conditions.[23,24]

$$P(OR)_3 + ROOH \xrightarrow{PD\text{-}S} O{=}P(OR)_3 + ROH \quad (3)$$

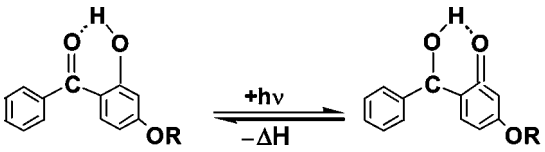
Sulfur compounds are known as catalytic hydroperoxide decomposers (PD-C): one antioxidant molecule destroys several hydroperoxide molecules by the action of intermediate sulfur acid moieties.[25–28] Thioethers and esters of thiodipropionic acid and metal dithiolates are examples of commercial significance (see Table 1, AOs 19–24).



Scheme 3 Reaction mechanism of HALS.

Metal deactivators (MD) act, primarily, by retarding metal-catalyzed oxidation of polymers and are added to polymers used in contact with metals, e.g., wires and power cables. Metal deactivators are normally polyfunctional metal chelating compounds (e.g., Table 1, AOs 33 and 34) that can chelate with metals and decrease their catalytic activity.[29–31]

UV absorbers (UVA) act by absorbing UV light to retard the photolysis of hydroperoxides. Typical examples are based on 2-hydroxybenzophenones (AO 28) and 2-hydroxybenzotriazoles (e.g., Table 1, AOs 29–32); both are photo-stable with high molar absorptions over the region 300–360 nm. Their activity is based essentially on absorption of the harmful UV-radiation and its harmless dissipation as heat. For example, in 2-hydroxybenzophenones, UV-light induces intramolecular hydrogen transfer to yield an enol, which reverts back to the original ketone in a radiationless process,[32] Reaction 4.



(4)

ANTIOXIDANT PERMANENCE: EFFECTS OF CHEMICAL AND PHYSICAL FACTORS

There are many limitations to the use of antioxidants in applications involving the human environment, e.g., food packaging, medical applications, etc. Apart from the risks associated with premature failure of a product, the physical loss of antioxidants into the contact media can also have adverse toxicological effects. Although all antioxidants, which are licensed for use in polymers for food contact and medical applications, have to undergo strict toxicity testing regimes, their approval, however, does not necessarily mean that their oxidation products (derived from the parent antioxidant during processing or as a result of its antioxidant action in the substrate) are also nontoxic.

Low molar mass antioxidants are known to suffer from physical loss and research in recent years has, therefore, focused on finding substantive alternatives. For example, reactive antioxidants, which can be chemically anchored on the polymer backbones to prevent physical loss during processing or in-service, have been explored as nonmigratory antioxidants.[33–39] Clearly, there are many factors that need to be considered before choosing antioxidants in end-use applications. The success of an antioxidant package is critically dependent on the underlying chemical and physical factors that influence antioxidant performance in different substrates and environments.

Chemical Factors

The intrinsic chemical activity of an antioxidant is a function of its molecular structure. This can be determined accurately in a model substrate where the antioxidant is fully soluble and in a test where no physical loss is possible. However, using the chemical activity alone as an indicator, can lead to unreliable predictions of the efficiency of antioxidants in polymers under practical conditions because of the dominating influence of physical factors under certain environments. For example, the hindered phenol BHT (AO 1, Table 1) is amongst the most efficient antioxidants known for liquid hydrocarbons (based on its intrinsic chemical activity determined by oxygen absorption), but is ineffective in protecting thermoplastic polymers (during accelerated air oven ageing) because of physical loss through volatilization.[11] Higher molecular mass antioxidants, based on the same hindered phenol function, e.g., Irganox 1010, Irganox 1330 (Table 1, AOs 5 and 2) outperforms BHT under these conditions.[40–42]

Physical Factors

The physical behavior of an antioxidant is a major factor affecting its permanency, efficiency, and acceptability, especially when the polymer (e.g., fibers, films) artifact is placed directly in contact with aggressive environments, e.g., organic solvents including dry cleaning solvents, hot water and detergents, hot oils, acids, fatty food, hot air, and intense solar radiation. Physical factors, which control the permanence and efficacy of an antioxidant include distribution, solubility, diffusivity, volatility, and leachability.

Distribution of antioxidants and polymer morphology

In order to inhibit the oxidation of polymers, the antioxidant has to be present in sufficient concentration at the various oxidation sites. In this respect, both the distribution of antioxidants and the morphology of the host polymer assume greater significance. Examination of the distribution of photo-antioxidants in typical commercial semi-crystalline polymers, such as polyolefins, has shown[43,44] that they are rejected into the amorphous region on the boundaries of spherulites. Such nonuniform distribution of antioxidants leads to an increase in their concentration in the amorphous region,[43] which is most susceptible to oxidation (the crystalline phase is normally impermeable to oxygen). However, in the case of polymer blends, a nonuniform distribution of antioxidants can undermine the overall stability of the blend, especially when the more oxidizable component of the polymer blend is left unprotected.

Compatibility of antioxidants with polymers

Antioxidants are generally less soluble in polymers than in lower molar mass liquid models. Although antioxidants are usually highly soluble at the elevated processing temperatures (and form with the polymer a homogenous solution), they come out of solution on cooling at room temperature with the solidified polymer supersaturated with the antioxidant. In turn, the antioxidant may precipitate as a separate phase, and exudes to the polymer surface (this is called ''blooming''),[43] leading to a build up of a concentration gradient near the surface and greater tendency of migration of the antioxidant from the bulk. Consequently, an antioxidant with low solubility and high diffusion rate is susceptible to blooming and loss to the surrounding medium by evaporation (air stream as contact media) or through leaching (extraction by a liquid contact media), leaving behind an unprotected polymer surface.

Generally, the compatibility of antioxidants in polymers is improved when the antioxidant and the host polymer have similar characteristics. Compatibility of antioxidants in nonpolar hydrocarbon polymers, therefore, decreases with increasing antioxidant polarity and increases with the number, length, and branching of the inert alkyl substituents attached to the antioxidant function.[45,46] Many commercial antioxidants with higher molecular masses (e.g., Table 1, compare AO 5 with AO 1) have been developed and many have inert long (8 to 18 C-atoms) alkyl chains (e.g., Table 1, AO 4).

Antioxidant diffusion, volatility, and leachability

The permanency of antioxidants is affected by diffusion characteristics of the antioxidant, the nature (gas, liquid, and solid) of the surrounding medium, and the temperature.[43,45,47] Generally, the diffusion coefficient of antioxidants decreases with increasing polar interactions with the polymer, increasing molar mass of antioxidants and branching in their alkyl side chain.

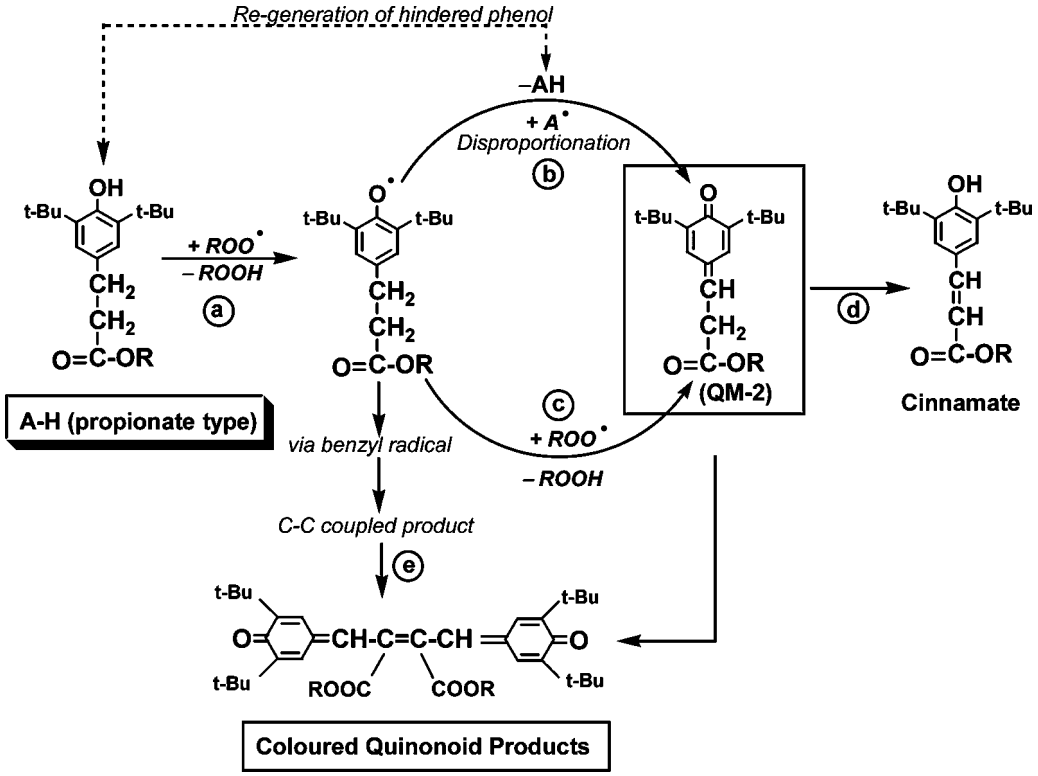
In the presence of a stream of hot air or high temperature and low pressure (e.g., during polymer melt processing) volatility becomes very important: it is governed by the rate of diffusion of antioxidants, which, in turn, determines the rate at which the surface is replenished.[43] The influence of polymer sample shape and the structure and molar mass of antioxidants on volatility has received much attention. The rate of evaporation of antioxidants from rubber and polyethylene, for example, was found[45] to be inversely proportional to the thickness of the sample and directly proportional to its surface area. Furthermore, an increase in molar mass results in an increase in intermolecular dispersion forces, which brings about a decrease in volatility of the antioxidants from the polymers.

In liquid contact media (e.g., foodstuffs, oils, solvents), the rate of loss of antioxidants from the polymer surface depends both on their diffusion coefficient and their partition coefficient between the liquid and the polymer. This is complicated by the varying ability of different solvents (liquid media) to swell polymers, giving rise to an increase in the diffusion coefficient of the antioxidant, which leads to higher loss rates.[47] As in the case of volatilization, the rate of leachability of antioxidants from the surface of polymers into liquid contact media increases with temperature and surface area-to-volume ratio, e.g., in thin polymer samples.

ANTIOXIDANTS: THERMAL STABILIZATION

Stabilization of polymers against the effect of temperature, shear, and other oxidizing agents is required, both to prevent mechano-thermal oxidation at the processing stage (processing antioxidants) and to afford protection during in-service (long-term thermal stabilizers). In addition, the thermal stability of reprocessed polymers (recycled) must be preserved and reinforced by additional stabilization (recycling stabilizers) for further reprocessing and end-use. Different classes of antioxidants are used, and their stabilizing action in polymer melts is outlined below.

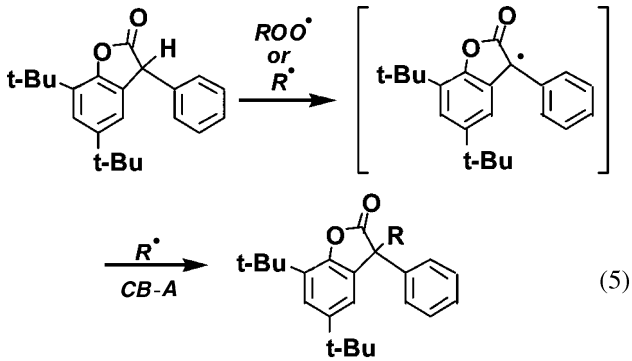
Aromatic amine antioxidants based on *p*-phenylenediamine, e.g., AOs 11 and 12, Table 1, are highly effective peroxyl radical scavengers (more effective than hindered phenols). Their use, however, is limited to elastomers because of their extreme staining power. Sterically hindered phenols (also efficient CB-D antioxidants), on the other hand, have been used extensively as melt processing stabilizers in plastics, as they do not suffer as much from the problem of polymer discoloration during melt processing, but yellowing can still occur because of the formation of colored conjugated quinonoid-type transformation products with visible absorption wavelengths, extending to more than 400 nm.[48] Hindered phenols containing propionate esters, e.g., AOs 4 and 5 are good stabilizers for polyolefins and styrenics, the propionamide AO 6 is used in aliphatic polyamides, and the ester AO 7 is suitable for polyesters. Scheme 4 shows some key reactions of propionate-based hindered phenols used for polymer stabilization, in order to illustrate their antioxidant action and the formation of discoloring products. The primary step in their stabilizing action involves the scavenging of alkylperoxyl ($ROO^{\bullet}$) radicals; a step, which also leads to the

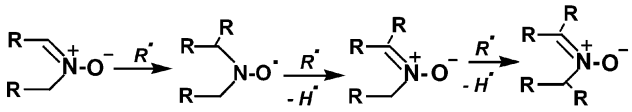


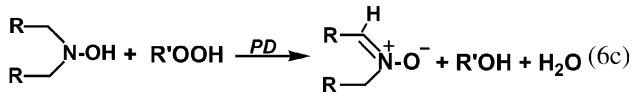
Scheme 4 Key reactions that take place during the antioxidant action of 4-propionate-hindered phenols.

production of harmful hydroperoxides, see Scheme 4a. In practice, therefore, hindered phenols are generally used in combination with peroxide decomposers, typically a hydrolysis-resistant phosphite.[34,41,49] It is clear from Scheme 4 that the major transformations of phenolic antioxidants during melt processing consist of quinone-type products, C–C and C–O coupling product. Transformation products of antioxidants can further influence their overall stabilization effect by exerting either anti- or pro- oxidant effects, thereby synergizing or antagonizing the action of the parent antioxidant.

Antioxidants that act by CB-A mechanism are particularly suitable for melt stabilization. The bifunctional hindered phenol semi-acrylate antioxidant, AO 8 in Table 1, which acts primarily by deactivating alkyl radicals, is an effective processing stabilizer for styrene-butadiene-styrene copolymers.[50] Lactone stabilizers, see AO 13, Table 1, which are used commercially in phenol-free blends (e.g., with phosphites) or in blends containing combinations of hindered phenols and phosphites, have been shown[51,52] to be highly efficient in oxygen deficient-environment particularly during melt processing. They act by trapping macroalkyl radicals, as well as peroxyl radicals, through the intermediacy of the resonance stabilized lactone (benzfuranyl) radical, Reaction 5. Similarly, the hydroxylamines, see AO 14, Table 1, which can also scavenge the macroalkyl radicals via the intermediacy of nitrones, as well as reducing hydroperoxides to alcohols, have been shown[53] to be highly efficient processing stabilizers, Reaction 6.







Alkyl and aryl phosphite esters are also effective melt stabilizers. They are often used in combination with hindered phenols to give highly efficient melt stabilizing systems and to reduce discoloration of the polymer because of the oxidation products of the phenols present. Phosphites (particularly those derived from aliphatic alcohols and unhindered phenols) are, however, generally susceptible to hydrolysis. Consequently, moisture-sensitive phosphites affect adversely the handling characteristics (i.e., flow properties) of the additive package and are a source of other problems: corrosion of metal surfaces, formation of dark colored spots, and gel formation. In practice, hydrolysis-resistant phosphites based on sterically hindered phenols are used, e.g., AOs 17 and 18, Table 1.

Sulfur-containing compounds are highly effective PD antioxidants, but they are more complex in their behavior than the phosphites. They react with hydroperoxides in a catalytic process, which leads to the formation of sulfur acids that are responsible for the catalytic nonradical destruction of hydroperoxides. The ''simple'' dialkyl sulfides, e.g., thiodipropionate esters, such as Irganox PS800 and PS 802 (AOs 19 and 20, Table 1), function as weak melt stabilizers as they give rise to a pro-oxidant effect in the polymer because of the generation of free radicals by an initial redox reaction with hydroperoxides, see Scheme 5.[54] In view of the pro-degradant effects of thiodipropionate esters, these sulfide antioxidants are always used in combination with CB-D antioxidants, such as Irganox 1010 (AO 5) in order to deactivate the free radicals formed.

Metal carboxylates (e.g., lead carbonate, calcium, barium, and zinc soaps) and tetravalent derivatives of tin (e.g., dibutyl tin maleate, DBTM, AO 35, Table 1) are frequently used as antioxidants for PVC stabilization. Melt stabilization of PVC is normally aimed at reducing the formation of HCl and hydroperoxides in the polymer, and at removing the developing unsaturation, which is both the source of color and further instability. In general, plasticized PVC is processed at lower temperatures than rigid PVC, and lesser damage is expected during melt processing of the former. The elimination of labile chlorine atoms from the polymer backbone is the most important stabilization mechanism for PVC. Dialkyl tin maleates (e.g., DBTM) and thioglycollates (e.g., DOTG, AO 36, Table 1) function by eliminating HCl, see Reaction 7. In addition, the maleates also act by removing the unsaturation and limiting color development, whereas the thioglycollates have an additional peroxidolytic function.[34]

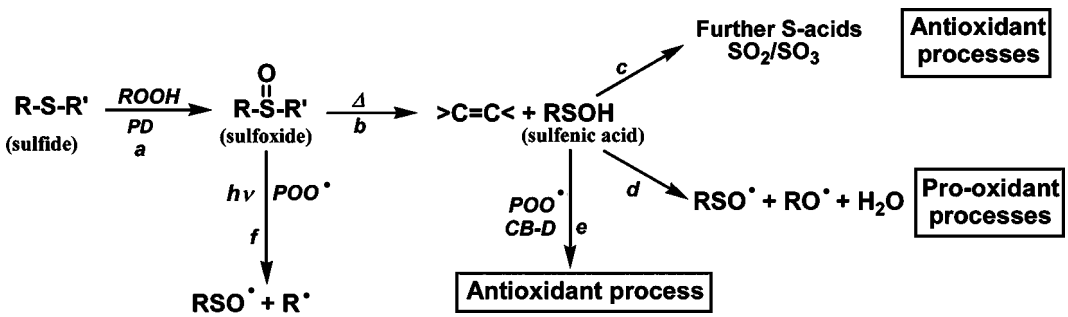
XR = SCH_2CO_2R and R′ = Oct

ANTIOXIDANTS: PHOTOSTABILIZATION

As with thermal stabilizers, photostabilizers must satisfy basic chemical and physical requirements (see the section titled ''*Antioxidant permanence: effects of chemical and physical factors*''). In addition, they must be photo-stable, i.e., stable to UV-light, to withstand continuous periods of UV-exposure, without being prematurely destroyed or effectively transformed into sensitizing products. There are essentially three classes of compounds that are categorized as photostabilizers/photoantioxidants: UV-absorbers and pigments, peroxide decomposers including nickel complexes, and sterically hindered amine light stabilizers.

Most of the UV-absorbers (UVA) used commercially fall into two main classes of compounds, the 2-hydroxybenzophenones, e.g., AO 28, Table 1, and the 2-hydroxybenzotriazoles, e.g., AOs 29–32, Table 1, with the 2-hydroxy group being essential for their activity.[55] These UVAs operate by additional mechanisms too, for example, by removing initiating radicals (e.g., alkoxyl radicals) in a weak chain breaking-donor (CB-D) mechanism.[56] UV absorbers, such as AO 28, also synergize effectively with peroxide decomposers, e.g., metal dithiolates, see Table 4.



Scheme 5 Peroxidolytic and chain breaking activity of phosphorus antioxidants.

Metal complexes of dithioic acids, e.g., dithiocarbamates, dithiophosphates, xanthates (MDRC, MDRP, MRX, respectively) see AOs 21–24, Table 1, which are highly effective catalytic peroxide decomposers (PD-C) and excellent melt stabilizers, are generally effective photo-antioxidants.[13,25,26] Their effectiveness is attributed mainly to the much higher UV stability of dithiolates compared to simple sulfides. Both the nature of the metal ion in the dithiolate complexes and their concentration play a crucial part in their overall effectiveness as UV stabilizers. Transition metal complexes containing Ni, Co, and Cu are more photostable than Zn- and Fe-containing complexes, hence are more effective, see Table 2. Furthermore, the photo-antioxidant activity of nickel dithiolates is greatly affected by their solubility in the polymer.[46] These peroxide decomposers also synergize effectively when used in combination with UV-absorbers, Table 2.

Hindered piperidines (known as HALS, hindered amine stabilizers), see AOs 25 and 26, Table 1, have been used extensively as photo-stabilizers in commercial polymers. HALS is a unique class of photostabilizers that do not function as UV screens singlet oxygen, triplet carbonyl quenchers, or as peroxide decomposers. Their effectiveness is attributed to their primary transformation product, the corresponding nitroxyl radicals (>NO$^{\bullet}$), which is capable of scavenging alkyl radicals in competition with oxygen, i.e., an effective CB-A antioxidant. Its photostabilizing mechanism also involves the regeneration of the nitroxyl radical from both the corresponding hydroxylamine (>NOH an effective CB-D) and alkylhydroxylamine,[22,40,57,58] see Scheme 3. Overall, the photoantioxidant activity of HALS can be ascribed to a regenerative donor-acceptor (CB-A/CB-D) antioxidant mechanism involving >NO$^{\bullet}$ and >NOH.

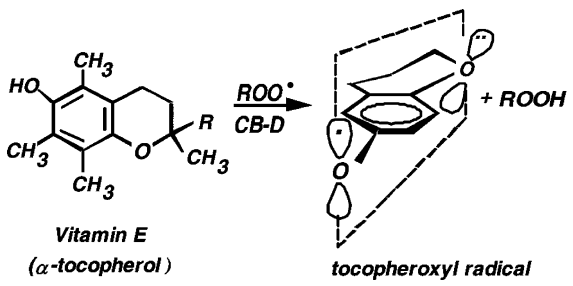
ANTIOXIDANTS: METAL DEACTIVATOR

The main function of metal deactivators (MD) is to retard efficiently metal-catalyzed oxidation of polymers. Polymer contact with metals occur widely, for example, when certain fillers, reinforcements, and pigments are added to polymers, and, more importantly when polymers, such as polyolefins and PVC, are used as insulation materials for copper wires and power cables (copper is a pro-oxidant since it accelerates the decomposition of hydroperoxides to free radicals, which initiate polymer oxidation). The deactivators are normally polyfunctional chelating compounds with ligands containing atoms like N, O, S, and P (e.g., see Table 1, AOs 33 and 34) that can chelate with metals and decrease their catalytic activity. Depending on their chemical structures, many metal deactivators also function by other antioxidant mechanisms, e.g., AO 33 contains the hindered phenol moiety and would also function as CB-D antioxidants.

ANTIOXIDANTS: BIOLOGICAL

The use of antioxidants in human-contact applications, e.g., food-contact, medical, and pharmaceutical, present a challenge in terms of their safety and level of migration into the contact media, e.g., food and body fluids. The biological antioxidant vitamin E, which is a suitable candidate for such areas of application, is a fat-soluble, and sterically hindered phenol antioxidant with the most bioactive form of the vitamin being the α-tocopherol (Table 1, AO 10).

In-vitro rate studies on the antioxidant activity of α-tocopherol has shown that it is one of the most efficient alkylperoxyl radical traps, far better than the commercial hindered phenols, e.g., BHT (2,6-di-*tert*-butyl-4-methylphenol, AO 1).[59] Its efficiency was attributed to stereo electronic effects: the electronic synergy between a fully methylated aromatic ring and the chroman moiety results in a highly stabilized tocopheroxyl radical, formed during the rate limiting step, Reaction 8, because of the interaction between the p-orbitals on the two oxygen atoms.[59]



(8)

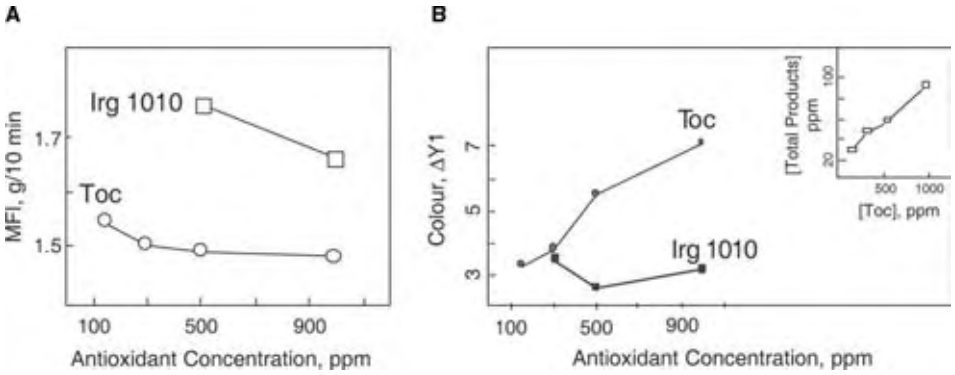


Fig. 2 Melt and color stability of PP processed in the presence of antioxidants. *(View this art in color at www.dekker.com.)*

α-tocopherol has been shown to be a very effective melt processing antioxidant for PP, especially at low concentration.[49,60,61] A comparison of the antioxidant efficiency of α-tocopherol with that of Irganox 1010 (AO 5) during melt extrusion of PP at 260°C shows (see Fig. 2A) clearly the superior performance of the former at all concentrations and, in particular, at very low concentrations. Tocopherol can, therefore, be used cost-effectively at only one-quarter of the concentration typically required for the stabilization of PP by synthetic hindered phenols, such as Irganox 1010. The activity of the former is attributed to the rapid rate of deactivation of radicals responsible for PP chain scission. A further important contribution to its antioxidant activity stems from its oxidation products, which are formed during polymer melt processing; these products were shown to be very effective antioxidants.[61] Tocopherol products formed during PP and PE melt processing consist mainly of direct coupling products, leading to the formation of dihydroxydimer, DHD and quinonoid-type products, trimers, TRI, spirodimers, SPD, quinone methides, QM, together with some aldehydes, ALD,[62] see Fig. 3 for structures of these products. All the oxidation products were shown to be more highly colored than tocopherol itself, with the aldehydes being the most colored, and the trimers the least colored.

In general, sterically hindered phenols contribute to some discoloration (yellowing) of polyolefins during processing. Yellowing of polyolefins containing hindered phenols has been attributed to a number of factors including the formation of colored oxidation products, e.g., quinonoid structures, and interactions between the phenols and transition metal ion catalyst residues from the polymerization stage.[60,63] The extent of discoloration depends on the chemical structure of the parent antioxidant, the oxidation products, and the type and amount of catalyst residues in the polymer. It was shown[49] that at low concentration, both tocopherol and Irganox 1010 cause comparable

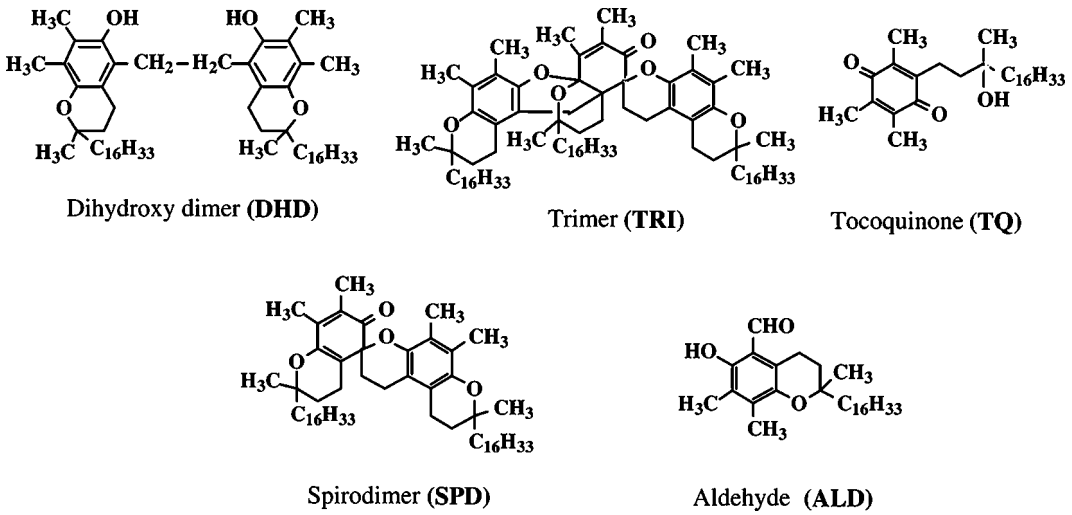

Fig. 3 Structures of the main transformation products of α-tocopherol formed during melt processing of polyolefins.

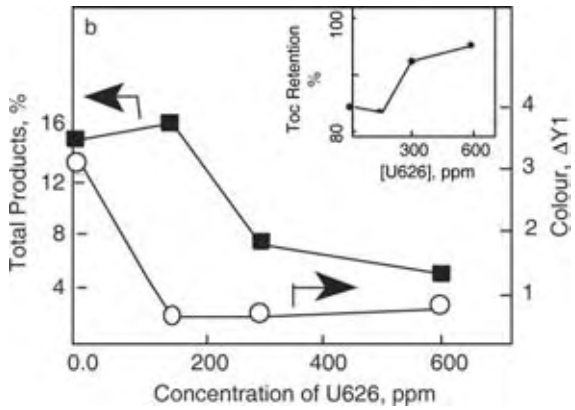

Fig. 4 Color stability of PP processed in presence of 300 ppm tocopherol in combination with the phosphate U-622. Total amount of products formed from tocopherol is also shown.

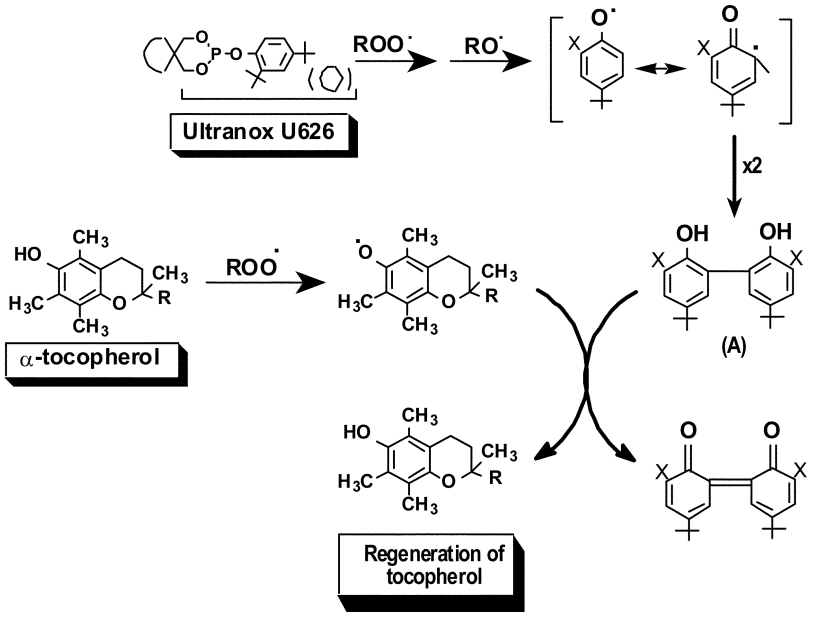
levels of discoloration during melt processing of PP. At increasingly higher concentrations, however, the extent of discoloration affected by tocopherol is higher (Fig. 2B). In order to reduce the extent of discoloration, very small concentrations, e.g., 300 ppm, of a phosphate antioxidant can give rise to a pronounced color suppression, together with higher levels of retention of the tocopherol in the polymer (Fig. 4). The higher retention of the tocopherol antioxidant observed when a small amount of the phosphite U-626 was used has been attributed to[61] first, a reduction in the amount of the more intensely colored transformation products, and second to the regeneration of tocopherol in the presence of the phosphite, via a redox-type reaction, through the formation of a phosphite-phenol C–C coupled product (Scheme 6).

ANTIOXIDANTS: REACTIVE

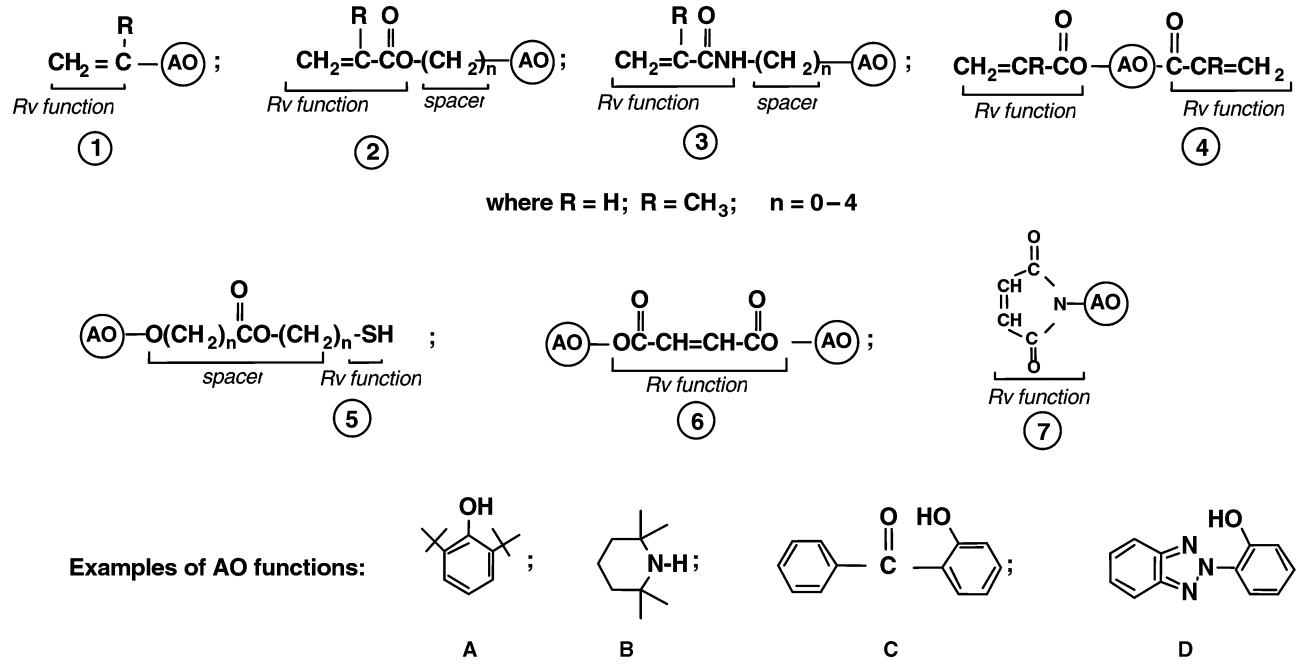
A strategy that is based on the use of reactive antioxidants can also be explored to achieve stabilization of polymers suitable for human-contact applications. Reactive antioxidants that become an integral part of the macromolecular chain can result in nonmigratory stabilizer systems that would be unaffected by extractive hostile contact media.

In general, reactive antioxidants are compounds that contain one or more antioxidant functions (the antioxidant, AO component) and one or more chemical functions that are capable of reacting either with monomers (same or different) or with polymers (the reactive, Rv, component). The AO function is based on any antioxidant moiety (see examples A–D in Scheme 7), whereas the reactive moiety can either be a polymerizable (e.g., Rv functions 1–4) or nonpolymerizable (e.g., Rv functions 5–7) groups, and may or may not contain a spacer (an inert flexible and short chemical link connecting the antioxidant moiety to the reactive function).

Reactive antioxidants may either be copolymerized with monomers during polymer synthesis or grafted on preformed polymers; they are therefore linked to the polymer. Although the copolymerization route has been successfully exploited,[35,64,65] it has not received greater attention because of cost incurred in the synthesis and production of tailor-made "speciality" materials for low-volume specific applications. On the



Scheme 6 Redox reactions resulting in the regeneration of tocopherol.



Scheme 7

other hand, grafting of antioxidants on preformed polymer melts can offer a more flexible and versatile approach where standard compounding and processing machines are used to conduct chemical grafting reactions. Both routes, however, offer tremendous advantages in terms of the physical persistence of antioxidants in the polymer. In both cases, the process of chemical attachment (target reaction) of antioxidants onto the polymer backbone proceeds in competition with other undesirable processes. The main prerequisite here, therefore, is to achieve the target reaction without detriment to the overall polymer properties and the fabrication process.

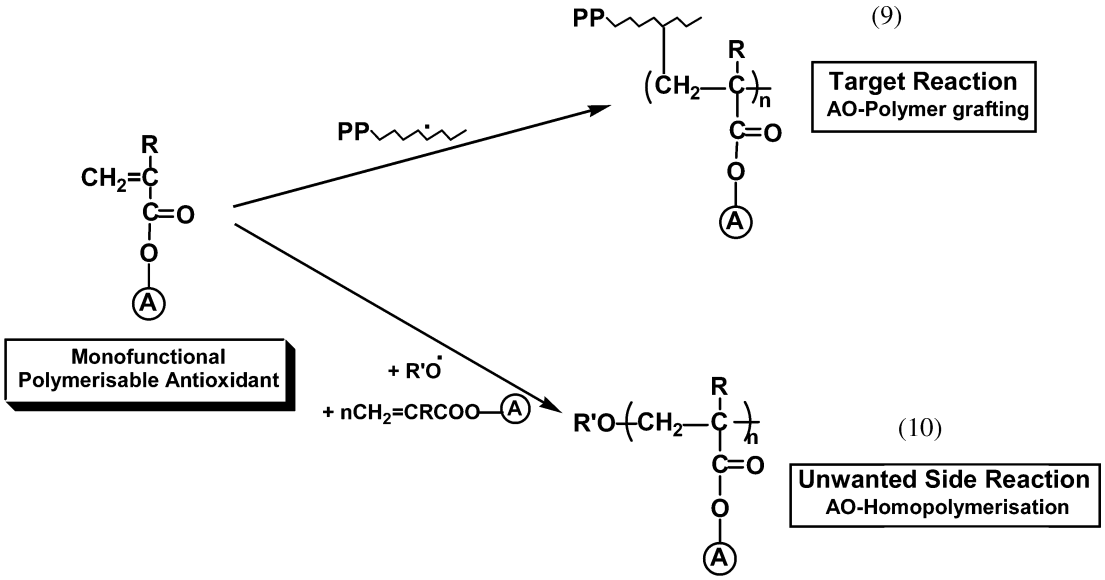
Both thermal- and photo-antioxidant functions have been grafted on polyolefins during melt processing in the presence of a free radical initiators.[66–68] The practical success of in situ melt grafting of antioxidants on polyolefins, however, depends on the correct choice of chemical systems and processing variables that would reduce the interference of side reactions, without altering significantly the polymer characteristics, e.g., molar mass, morphology, and physical properties.

The three different types of reactive antioxidant systems typically used for grafting reactions on polyolefins are briefly as described in the following.

Monofunctional Polymerizable Antioxidants

The use of polymerizable monofunctional antioxidants with one reactive group per antioxidant molecule is considered here. Production of these antioxidants is generally straightforward. Therefore, it can offer, a broad, versatile, and economic route for the production of a range of polymer-grafted antioxidants and antioxidant concentrates. Different monofunctional antioxidants have been reactively grafted on polyolefins, e.g., PP, LDPE, HDPE, poly (4-methyl-1-ene), in the presence of free radical initiators using single- or twin screw extruders, or internal mixers.

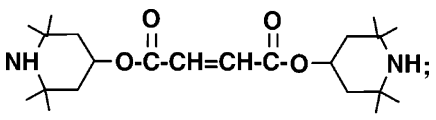
It has been demonstrated, however, that the efficiency of chemical attachment of such monofunctional polymerizable antioxidants on polyolefins (Reaction 9) is always low.[66,69] This is mainly because of the highly competitive homopolymerization reaction of the reactive antioxidant (Reaction 10). For example, studies on the effect of processing variables on the extent of melt grafting on PP of different mono-acryloyl-containing hindered phenol (DBBA) and hindered amine (AOTP) antioxidant functions have shown that grafting efficiency is less than 50%.[69,70] The remaining ungrafted antioxidants were recovered, almost completely, as homopolymers of the parent antioxidants, which were incompatible with the host polymer and were readily removed by extractive solvents. Furthermore, the performance of these homopolymers, when incorporated in the polymer matrix as conventional antioxidants, is very poor. The problems of homopolymer formation and low efficiency of grafting of mono-functional polymerizable antioxidants in polyolefins were subsequently



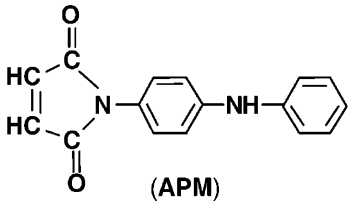
addressed by alternative approaches (see Reactions 9 and 10, above).

Monofunctional Nonpolymerizable Antioxidants

Non-polymerizable monofunctional antioxidants were subsequently used to avoid the problem of homopolymerization of the antioxidant. For example, melt grafting of the two maleated antioxidants, BPM and APM (see below), on PP was shown to lead to high grafting efficiencies (up to 75% in the former and >90% in the latter), which were attributed to the nonpolymerizable nature of the maleate (maleimide) functions.[71] The performance of these antioxidants, especially under extractive organic solvent conditions, was also shown to far exceed that of conventional antioxidants with similar antioxidant function.



(BPM)



(APM)

Bifunctional Polymerizable Antioxidants

The use of reactive antioxidants containing two polymerizable polymer-reactive functions in the same antioxidant molecule is outlined here. Careful choice of the processing parameters, the type, and the amount of free radical initiator can lead to very high levels of antioxidant grafting.[71] For example, melt grafting of concentrates (e.g., 5–20 wt.%) of the di-acrylate hindered piperidine, AATP, on PP in the presence of a peroxide initiator has led to almost 100% grafting. This exceptional grafting efficiency of AATP is in marked contrast with the much lower grafting levels achieved with the mono-functional HALS analogues, e.g., MyATP and AmyTP.[70] Examination of the mechanisms involved in the grafting process of such bifunctional antioxidants has shown that the grafting reaction occurs through the intermediacy of a cross-linked structure, involving the polymer and the reactive antioxidant, lead finally to an antioxidant grafted polymer product, which remains comparable in its general characteristics, e.g., solubility, crystallinity, molar mass, to a conventionally stabilized sample.[70,71]

Monofunctional Polymerizable Antioxidants in the Presence of a Comonomer

The use of a reactive di- or poly-functional comonomer (nonantioxidant), which can co-graft with a monofunctional polymerizable antioxidant on polymers, can improve the grafting efficiency from as low as 10–40% to an excess of 80–90%. This strategy, however,

presents immense challenges because of the presence of more than one polymerizable group in the comonomer, which could lead to additional undesirable (competing) side reactions, complicated by the possibility of comonomer-induced crosslinking reactions of the polymer. The success of this ''one-pot'' synthetic approach lies in the ability to achieve a delicate balance between the composition of the chemical system (antioxidant, comonomer, free radical initiator) and reaction conditions (e.g., temperature, residence time) with the aim of promoting the target grafting reaction at the expense of all competing side reactions.[69,70]

In practice, the success of this method has been clearly illustrated.[69,70] The novelty of this approach lies in the fact that co-grafting of polymerizable polyfunctional agents (traditionally used as crosslinkers, e.g., the trimethylol propane triacrylate, Tris) with mono-vinyl antioxidants (and other additives) in extruders or mixers leads to the production of highly grafted antioxidants in a noncrosslinked polymer. This co-grafting method can be applied to a wide range of antioxidant functions (e.g., HAS, UVA, hindered phenols, aromatic amines) to achieve outstanding levels of antioxidant grafting. Table 3 shows an example, which illustrates the excellent performance, especially under extractive conditions, of a highly bound synergistic antioxidant system (hindered phenols + UV absorber) produced by this method in PP compared to a conventional (unbound) commercial antioxidant system.

ANTIOXIDANT MIXTURES: SYNERGISM AND ANTAGONISM

The interaction between two or more antioxidants (or antioxidant functions) in plastics formulations can lead to enhanced performance by more than the sum of their individual effects; i.e., synergistic effects. Synergism can result from the combined action of two chemically similar antioxidants (homosynergism), e.g., two hindered phenols, or from two different antioxidant functions present in the same stabilizer molecule (autosynergism), e.g., Irganox 1081 (AO 9, Table 1), or when separate stabilizer molecules that carry different antioxidant functions are physically blended in a stabilizer formulation (heterosynergism). Conversely, antioxidant combinations resulting in reduced performance, relative to the sum of their individual contribution, are called antagonistic.

Highly effective UV stabilizing systems can be achieved by the use of synergistic mixtures of compounds acting by different mechanisms. Table 4 illustrates the synergism obtained from combinations of different metal dithiolates with the UV absorber Chimassorb 81 (AO 28, Table 1) in LDPE. Hindered phenol antioxidants combined with sulfur-containing compounds exhibit synergism during thermal stabilization of polyolefins. In contrast, similar combinations of Irganox 1076 (AO 4, Table 1) with different metal dithiolates lead to antagonism during photostabilization, see Table 4.[26,72] This antagonistic behavior has been attributed to sensitization leading to photolytic destruction of the dithiolates by oxidation products of phenols, particularly stilbenequinones. Stabilizers that contain two different antioxidant functions (e.g., PD and CB activities) in the same molecule, such as phenolic sulfides, show much higher molar intrinsic activity as thermal antioxidants (because of autosynergism) than conventional hindered phenols with only CB activity.[11]

HALS exhibit a complex behavior when present in combination with other antioxidants and stabilizers. Effective synergism in both melt and thermal stabilization has been achieved when secondary and tertiary HALS were used in combination with both aromatic and aliphatic phosphites; the synergistic optimum depends on the structure of the phosphite.[73] HALS also synergize the action of UV-absorbers, e.g., benzotriazoles, in different polymers such as polypropylene, polystyrene, and ABS.[74]

Table 3 Comparison of the antioxidant performance (accelerated UV aging) of synergistic mixture (melt grafted in presence of Tris) with a conventional antioxidant mixture based on the same antioxidant functions (at 1 : 1 w/w ratio)

Antioxidant (0.4% in PP films)	UV embrittlement time (hr)	
	Unextracted	Extracted
None	75	70
DBBA[a]	205	80
HAEB[b]	330	70
PP-g(DBBA-HAEB)$_{Tris}$	1160	1130

UV531 is a commercial UV absorber, 2-hydroxy-4octyloxy benzophenone Tris is a triacrylate comonomer.
[a]Unbound, processed alone (no Tris) as a conventional antioxidant.
[b]See Table 2 for structures.

CONCLUSIONS

Antioxidants and stabilizers are generally used in the chemical processing industry for the protection and preservation of properties of materials, including food, with the aim of prolonging and extending their shelf life. They are essential ingredients for the long-term durability of many polymers, such as

Table 4 Synertistic and antagonistic effects on photostability of LDPE processed at 150°C

Stabilizer system	Concentration ($\times 10^{-4}$ M 100 g^{-1})	Photo-embrittlement time (hr)		References
		Observed	Calculated effect[a,b]	
Control PP (no antioxidant)	—	1000	—	[26]
ZnDEC	3	1400	—	[26]
NiDEC	3	1800	—	[26]
Tinuvin 770	3	2400	—	[26]
Irganox 1076	3	1750	—	[26]

Antagonistic systems				
NiDEC + Irganox 1076	3 + 3	1580	3550	[26]
ZnDEC + Irganox 1076	3 + 3	1250	3150	[26]
NiDEC + Tinuvin 770	3 + 3	1850	4200	[26]
NiDBP + Irganox 1076	2.5 + 5	—	—	[72]

[a]Concentration of HOBP in this case was 5×10^{-4}M 100 g^{-1}.
[b]% Synergism = $\{[(E_s - E_c) - (E_1 - E_c) + (E_2 - E_c)]/(E_1 - E_c + E_2 - E_c)\} \times 100$, where E_s is the embrittlement time of synergist, E_c the embrittlement time of control, E_1 the embrittlement time of antioxidant 1, and E_2 the embrittlement time of antioxidant 2.

polyolefin, and are crucial to the upgrading of their performance, and for achieving the benefits of sustainable development in polymers recycling programs.

Antioxidants and stabilizers are chosen for target applications on the basis of chemical, physical, toxicological, and economic factors. The final selection of an antioxidant package must take into consideration the performance requirements of the end-use polymer article including toxicity, compatibility, appearance, and color. Issues of efficacy and safety have been the driving force behind much of the recent progress made in the areas of biological, reactive, and macromolecular antioxidants.

More stringent regulations and legislations for certain applications of stabilized polymers, such as in food, toys, medicine, and other health-related areas, would promote further interest in the use of biological and naturally occurring antioxidants and reactive antioxidants for chemical processing, and for producing safe and ''permanently'' stabilized polymer compositions. Current emphasis on sustainable development and green chemistry approaches should lead to further exploration of the benefits of renewable resources and environmentally benign synthetic routes in the development and procurement of new antioxidants, or for replacing existing ones.

Compared to conventional antioxidants, reactive antioxidants that are capable of becoming covalently bound to the polymer backbone are not readily lost from polymers during fabrication and in-service. There is a lot of evidence that demonstrates the performance (in terms of polymer protection) of ''immobilized'' antioxidants in practice, especially when polymer products are subjected to harsh environment, e.g., exposure to high temperatures, UV-light and leaching solvents. It is clear from this that high mobility of low molar mass antioxidants is not a necessary prerequisite to achieving stabilization and attachment of antioxidants to polymers can be industrially beneficial.

Reactive antioxidants grafted on polymer melts behave in a similar way to low molar mass conventional antioxidants, but offer many additional advantages. The polymer-linked antioxidants do not suffer from the problem of compatibility, volatility, and migration, i.e., they do not suffer physical loss even under highly aggressive and extractive environments. Such antioxidant systems would be much more risk-free and environmentally friendly. The ability to produce highly grafted antioxidant concentrates (master batches), which can be used in conventional (the same or different) polymers, as ''normal'' additives would extend the use of reactive antioxidants to new areas of application.

Biocatalysis

Tyler Johannes
Michael R. Simurdiak
Huimin Zhao
Department of Chemical and Biomolecular Engineering, University of Illinois, Urbana, Illinois, U.S.A.

INTRODUCTION

Biocatalysis may be broadly defined as the use of enzymes or whole cells as biocatalysts for industrial synthetic chemistry. They have been used for hundreds of years in the production of alcohol via fermentation, and cheese via enzymatic breakdown of milk proteins. Over the past few decades, major advances in our understanding of the protein structure–function relationship have increased the range of available biocatalytic applications. In particular, new developments in protein design tools such as rational design and directed evolution have enabled scientists to rapidly tailor the properties of biocatalysts for particular chemical processes. Rational design involves rational alterations of selected residues in a protein to cause predicted changes in function, whereas directed evolution, sometimes called irrational design, mimics the natural evolution process in the laboratory and involves repeated cycles of generating a library of different protein variants and selecting the variants with the desired functions (see the entry ''Protein Design''). Enzyme properties such as stability, activity, selectivity, and substrate specificity can now be routinely engineered in the laboratory. Presently, approximately 100 different biocatalytic processes are implemented in pharmaceutical, chemical, agricultural, and food industries.[1] The products range from research chemicals to commodity chemicals and the number of applications continue to grow very rapidly. In spite of these successes, however, the vast potential of biocatalysis has yet to be fully realized.

In this entry, we briefly outline the scope of biocatalysis and discuss its advantages and disadvantages as compared to chemical catalysis. We then review such topics as enzyme and whole-cell based biocatalysis, biocatalysts used in nonaqueous media, biocatalyst immobilization, discovery and engineering of novel enzymes, and hybrid approaches combining chemical and biological synthesis. An overview of the six general classifications of enzymes along with their relative use in industry is discussed. Selected industrial applications of whole-cell based biocatalysis including the production of lactic acid and 1,3-propanediol are also studied.

THE SCOPE OF BIOCATALYSIS

Advantages and Disadvantages of Biocatalysis vs. Chemical Catalysis

Similar to other catalysts, biocatalysts increase the speed in which a reaction takes place but do not affect the thermodynamics of the reaction. However, they offer some unique characteristics over conventional catalysts (Table 1). The most important advantage of a biocatalyst is its high selectivity. This selectivity is often chiral (i.e., stereo-selectivity), positional (i.e., regio-selectivity), and functional group specific (i.e., chemo-selectivity). Such high selectivity is very desirable in chemical synthesis as it may offer several benefits such as reduced or no use of protecting groups, minimized side reactions, easier separation, and fewer environmental problems. Other advantages, like high catalytic efficiency and mild operational conditions, are also very attractive in commercial applications.

The characteristics of limited operating regions, substrate or product inhibition, and reactions in aqueous solutions have often been considered as the most serious drawbacks of biocatalysts. Many of these drawbacks, however, turn out to be misconceptions and prejudices.[2,3] For example, many commercially used enzymes show excellent stability with half-lives of months or even years under process conditions. In addition, there is an enzyme-catalyzed reaction equivalent to almost every type of known organic reaction. Many enzymes can accept non-natural substrates and convert them into desired products. More importantly, almost all of the biocatalyst characteristics can be tailored with protein engineering and metabolic engineering methods (refer to the section Biocatalyst Engineering and see also the entry ''Protein Design'') to meet the desired process conditions.

Biocatalytic processes are similar to conventional chemical processes in many ways. However, when considering a biocatalytic process one must account for enzyme reaction kinetics and enzyme stability for single-step reactions, or metabolic pathways for multiple-step reactions.[4] Fig. 1 shows the key steps

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120017565

Table 1 Advantages and disadvantages of biocatalysis in comparison with chemical catalysis

Advantages	Disadvantages
Generally more efficient (lower concentration of enzyme needed)	Susceptible to substrate or product inhibition
Can be modified to increase selectivity, stability, and activity	Solvent usually water (high boiling point and heat of vaporization)
More selective (types of selectivity: chemo-selectivity, regio-selectivity, diastereo-selectivity, and enantio-selectivity)	Enzymes found in nature in only one enantiomeric form
Milder reaction conditions (typically in a pH range of 5–8 and temperature range of 20–40°C)	Limiting operating region (enzymes typically denatured at high temperature and pH)
Environment friendly (completely degraded in the environment)	Enzymes can cause allergic reactions

(From Ref.[2].)

in the development of a biocatalytic process. It usually starts with the identification of a target reaction, followed by biocatalyst discovery, characterization, engineering, and process modeling. In many cases, biocatalyst engineering is the most time-consuming step, often involving two major approaches: rational design and directed evolution. In addition to biocatalyst development, product isolation is an important step. The overall process economics depends on all these factors, which needs to be demonstrated in a pilot-scale plant before scale-up. Biocatalysts can constitute a significant portion of the operating budget; however, their cost can be reduced by reusing them when immobilized (refer to the section Biocatalyst Immobilization).

Enzyme Based Biocatalysis vs. Whole-Cell Biocatalysis

Both isolated enzymes and whole cells can be used as biocatalysts. Compared to whole cells, isolated enzymes offer several benefits, including simpler reaction apparatus, higher productivity owing to higher catalyst concentration, and simpler product purification.[2] Until recently, only enzymes that were abundantly produced by cells could be used in industrial applications. Now it is possible to produce large amounts of an enzyme through the use of recombinant DNA technology. In brief, the DNA sequence encoding a given enzyme is cloned into an expression vector and transferred into a production host such as

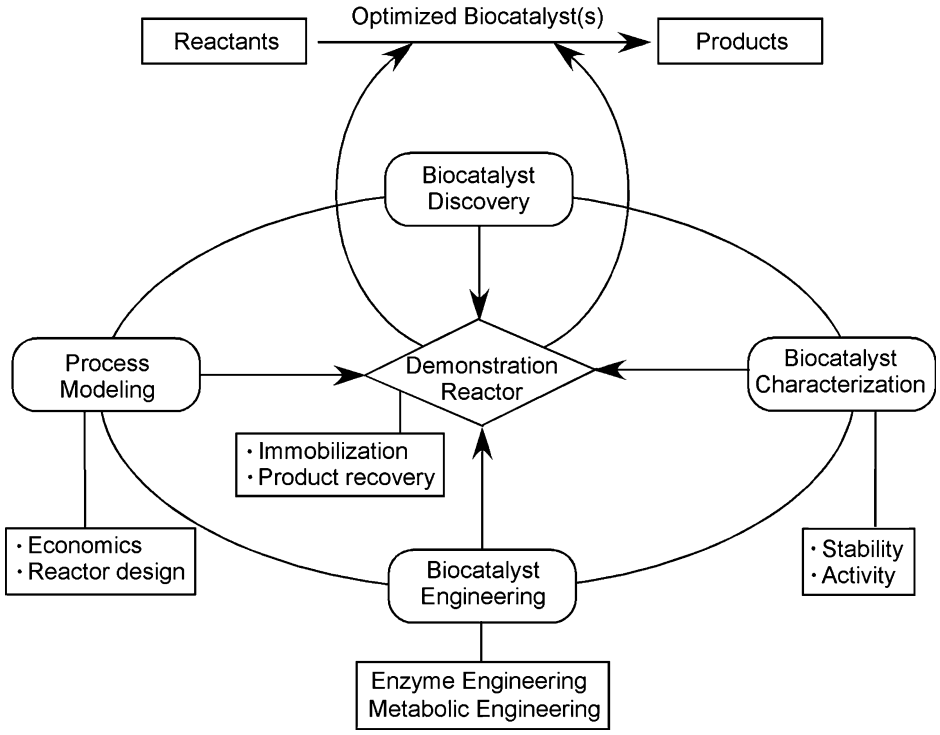

Fig. 1 Flowchart of the development of a biocatalytic process.

Escherichia coli or *Saccharomyces cerevisiae* for gene expression. The overexpressed enzymes are purified from the cell extracts based on their chemical and physical properties. The most commonly used enzyme purification techniques include electrophoresis, centrifugation, and chromatography. Centrifugation separates enzymes based on their differences in mass or shape, whereas electrophoresis separates enzymes based on their differences in charge. Liquid chromatography separates enzymes based on their differences in charge (ion-exchange chromatography), in mass (gel filtration chromatography), or in ligand-binding property (affinity chromatography).

The whole-cell biocatalysis approach is typically used when a specific biotransformation requires multiple enzymes or when it is difficult to isolate the enzyme. A whole-cell system has an advantage over isolated enzymes in that it is not necessary to recycle the cofactors (nonprotein components involved in enzyme catalysis). In addition, it can carry out selective synthesis using cheap and abundant raw materials such as cornstarches. However, whole-cell systems require expensive equipment and tedious work-up because of large volumes, and have low productivity. More importantly, uncontrolled metabolic processes may result in undesirable side reactions during cell growth. The accumulation of these undesirable products as well as desirable products may be toxic to the cell, and these products can be difficult to separate from the rest of the cell culture. Another drawback to whole-cell systems is that the cell membrane may act as a mass transport barrier between the substrates and the enzymes.

Nonaqueous Biocatalysis

Historically, enzymes have been used extensively in aqueous media. Enzymes are well suited to their natural aqueous environment; however, biotransformations in industrial synthesis often involve organic molecules insoluble in water. More importantly, because of its high boiling point and high heat of vaporization, water is usually the least desired solvent of choice for most organic reactions. Thus, shifting enzymatic reactions from an aqueous to an organic medium is highly desired.

Over the past 15 yr, studies have shown that enzymes can work in organic solvents.[5] However, the enzymatic activity is quite low in an organic solvent compared to that in water. Recent advances in protein engineering and directed evolution have aided in the development of enzymes that show improved activity in organic solvents. Progress has also been made in developing simple, scalable, and low-cost techniques to produce highly active biocatalyst preparations for use in organic solvents.[6] One such method improves enzyme activity in organic solvents by lyophilizing (freeze-drying) an aqueous biocatalyst solution in the presence of organic and inorganic molecules called excipients. These excipients include nonbuffer salts, crown ethers, cyclodextrins, and solid-state buffers.[7] Some remarkable results have also been achieved by using ionic liquids as solvents in biocatalytic reactions.[8]

Biocatalyst Immobilization

Immobilization is the process of adhering biocatalysts (isolated enzymes or whole cells) to a solid support. The solid support can be an organic or inorganic material, such as derivatized cellulose or glass, ceramics, metallic oxides, and a membrane. Immobilized biocatalysts offer several potential advantages over soluble biocatalysts, such as easier separation of the biocatalysts from the products, higher stability of the biocatalyst, and more flexible reactor configurations. In addition, there is no need for continuous replacement of the biocatalysts. As a result, immobilized biocatalysts are now employed in many biocatalytic processes.

More than one hundred techniques for immobilizing enzymes have been developed which can be divided into five major groups summarized in Table 2.[9] Adsorption of the enzyme onto a surface is the easiest and the oldest method of immobilization. Entrapment and cross-linking tend to be more laborious enzyme fixation methods, but they do not require altering the enzyme as much as other techniques. The formation of the covalent linkage often requires harsh conditions, which can result in a loss of activity because of conformational changes of the enzyme. It is important to note that most of these techniques can also be used to immobilize whole cells. In addition, although these types of immobilization are considered to be relatively old and well established, the emerging field of nanotube biotechnology has created another possible means of immobilizing biocatalysts.[10]

Biocatalyst Discovery: Sources and Techniques

Traditionally, potentially commercial enzymes are identified by screening micro-organisms, which are frequently isolated from extreme environments, for biocatalytic activity. Commercial enzymes are selected by probing libraries of related enzymes for a range of properties, including activity, substrate specificity, stability over a temperature range, enantio-selectivity, or compatibility under various physical and chemical conditions. Unfortunately, most of the commercially viable enzymes have been isolated in only a few microbial species such as *Bacillus* and *Pseudomonas* because

Table 2 Methods of enzyme immobilization

A. Covalent attachment
Isolated enzymes usually attached through amino or carboxyl groups to a solid support
Variety of supports such as porous glass, cellulose, ceramics, metallic oxides
B. Adsorption
Ion-exchangers frequently used in industry because of simplicity
Industrial applications include anion-exchangers diethylaminoethyl cellulose (DEAE-cellulose) and the cation-exchanger carboxymethyl cellulose (CM-cellulose)
C. Entrapment in polymeric gels
Enzyme becomes trapped in gel volume by changing temperature or adding gel-inducing chemical
Enzymes may be covalently bound to gel (for instance, polyacrylamide cross-linked with *N,N′*-methylenebisacrylamide) or noncovalently linked (calcium alginate)
D. Intermolecular cross-linking
Enzyme cross-linked with bifunctional reagents
Popular cross-linkers are glutaraldehyde, dimethyl adipimidate, dimethyl suberimidate, and aliphatic diamines
E. Encapsulation
Enzymes enveloped in semipermeable membrane, which allows low molecular weight substrates and products to pass through the membrane
Enclosed in a variety of devices: hollow fibers, cloth fibers, microcapsules, film

(From Ref.[9].)

of the limitations in micro-organism cultivation techniques.[11] It has been widely acknowledged that the majority of microbial species (up to 99%) have never been cultivated and thus have never been investigated. To access this vast untapped microbial diversity, several companies such as Diversa Corporation (San Diego, California, U.S.A.) and TerraGen Discovery (Vancouver, British Columbia, Canada) have successfully developed modern bioprospecting techniques such as multiple metagenome cloning to isolate novel industrial enzymes.[12]

New methods for exploring natural biodiversity have been greatly facilitated by high-throughput screening technologies and robust expression in recombinant organisms. Recombinant DNA technology makes it possible to produce enzymes at levels 100-fold greater than native expression and allows expression of genes from organisms that cannot be cultured. Although some problems may be resolved by screening larger libraries of DNA, this may not be the most efficient or expedient method of obtaining a viable biocatalyst. A more efficient means of obtaining a good biocatalyst may involve engineering the catalyst itself using various protein engineering and metabolic engineering techniques (refer to the section Biocatalyst Engineering and see also the entry ''Protein Design'').

Biocatalyst Engineering

Nature has supplied us with a vast array of biocatalysts capable of catalyzing numerous biological reactions. Unfortunately, naturally occurring biocatalysts are often not optimal for many specific industrial applications, such as low stability and activity. Moreover, naturally occurring biocatalysts may not catalyze the reaction with the desired non-natural substrates or produce the desired products. To address these limitations, molecular techniques have been developed to create improved or novel biocatalysts with altered industrial operating parameters. It should be noted that, for enzyme based biocatalysts, many molecular techniques have been developed for engineering enzymes with novel or improved characteristics. Readers are referred to the entry ''Protein Design.'' In this section, we mainly discuss the molecular techniques used for whole-cell based biocatalyst engineering, or metabolic engineering.

Metabolic engineering is a rapidly growing area with great potential to impact biocatalysis.[13] It has been broadly defined as ''the directed improvement of product formation or cellular properties through modifications of specific biochemical reaction(s) or the introduction of new one(s) with the use of recombinant DNA technology.''[14] In an industrial context, the ultimate goal of metabolic engineering is the development of optimal biocatalysts. In the past two decades, metabolic engineering has been successfully used to engineer micro-organisms to produce a wide variety of products, including polymers, aromatics, carbohydrates, organic solvents, proteins, antibiotics, amino acids, and organic acids. According to the approach taken or the aim, these applications can be classified into seven groups: 1) expression of heterologous genes for protein production; 2) extension of the range of substrate for cell growth and product formation; 3) design and construction of pathways for the production of new products; 4) design and

construction of pathways for degradation of xenobiotics; 5) engineering of cellular physiology for process improvement; 6) elimination or reduction of by-product formation; and 7) improvement of yield or productivity.[15] Several of these applications have been implemented at industrial-production scale (refer to the section Industrial Applications of Whole-Cell Based Biocatalysis) and the number of applications should continue to grow. In particular, with the recent advances in genomics, proteomics, and bioinformatics, many new genes and pathways will be discovered and the regulation of metabolic network will also be better understood, all of which will accelerate the development of more commercially viable bioprocesses through metabolic engineering.

Hybrid Approaches Combining Chemical Synthesis and Biocatalysis

Biocatalysts exhibit exquisite catalytic efficiency that is often unmatched by conventional catalysis. Nonetheless, conventional organic synthesis will likely remain the staple of the chemical and pharmaceutical industries. In the future, the integration of these two approaches will probably offer the optimal route for industrial synthesis. An illustration of this principle can be found in the selective deprotection of reactive functional groups. Enzymes are unique deprotecting tools for combinatorial synthesis because of their remarkable selectivity and ability to operate under mild reaction conditions. A recent example is the synthesis of long multiply lipidated peptides containing various side-chain functional groups.[16] In this study, penicillin acylase was used for selective N-deprotection of a highly labile S-palmitoylated oligopeptide. After removal of the protecting group, the S-palmitoylated oligopeptide was used as a building block in further synthetic steps.

INDUSTRIAL APPLICATIONS OF ENZYME BASED BIOCATALYSIS

With the rapid technical developments in gene discovery, optimization, and characterization, enzymes have been increasingly used as biocatalysts. According to the International Union of Biochemistry and Molecular Biology (IUBMB) nomenclature system, all enzymes are classified into six classes on the basis of the general type of reactions that they catalyze (Table 3). Within each class are subclasses and the enzymes themselves. The result is an ordered system of enzymes and the reaction(s) that each catalyzes. It is important to note that, in biological processes, every class of enzyme is utilized in the cell to a large extent. However, this is not the same in industrial processes, where certain classes of enzymes are used more often than others. As shown in Fig. 2, most of the enzymes that have been used as biocatalysts in industry are hydrolases (~65%), even though oxidoreductases are typically much more useful than hydrolases as catalysts. The utility of an enzyme class depends on the relative commercial importance of the products that each enzyme produces, the accessibility of the enzymes, and the specific characteristics of the enzymes (e.g., stability, activity, and selectivity).

Oxidoreductases

Oxidoreductases catalyze oxidation and reduction reactions that occur within the cell. They are very appealing for industrial uses because of the reactions that they are able to catalyze. However, they often need expensive cofactors such as nicotinamide adenine dinucleotides (e.g., NAD^+/NADH) and flavines (e.g., $FAD/FADH_2$) in the reactions. In fact, nicotinamide adenine dinucleotides are required by about 80% of oxidoreductases. Fortunately, several NAD(H)

Table 3 Classification of enzymes

Enzymes	Type of reactions	Representative subclasses
Oxidoreductases	Catalyze the transfer of hydrogen or oxygen atoms or electrons from one substrate to another	Oxidases, oxygenases, peroxidase, dehydrogenases
Transferases	Catalyze the group transfer reactions	Glycosyltransferases, transketolases, methyltransferases, transaldolases, acyltransferases, transaminases
Hydrolases	Catalyze hydrolytic reactions	Esterases, lipases, proteases, glycosidases, phosphatases
Lyases	Catalyze the nonhydrolytic removal of groups	Decarboxylases, aldolases, ketolases, hydratases, dehydratases
Isomerases	Catalyze isomerization reactions	Racemases, epimerases, isomerases
Ligases	Catalyze the synthesis of various types of bonds with the aid of energy-containing molecules	Synthetases, carboxylases

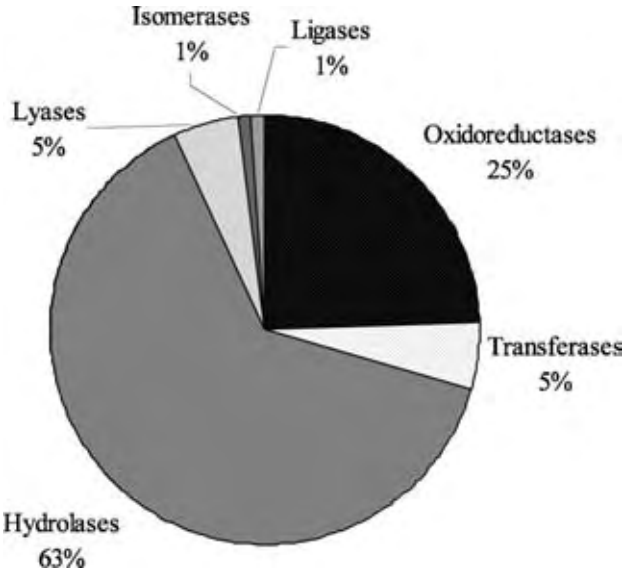

Fig. 2 The relative use of enzyme classes in industry. (From Ref.[2].)

regeneration systems have been developed, the most widely used being the formate/formate dehydrogenase (FDH) system.[17]

An example of a pharmaceutical synthesis reaction involving an oxidoreductase is the synthesis of 3,4-dihydroxylphenyl alanine (DOPA).[2] 3,4-Dihydroxylphenyl alanine is a chemical used in the treatment of Parkinson's disease. The industrial process that synthesizes DOPA utilizes the oxidoreductase polyphenol oxidase. As shown in Fig. 3, the monohydroxy compound is oxidized by the regio-specific addition of a hydroxyl group. It is worth mentioning that epinephrine (adrenaline) can also be synthesized by a similar reaction path using the same enzyme.[2]

Another example is the use of leucine dehydrogenase coupled with FDH for the reductive amination of trimethylpyruvate to L-*tert*-leucine (Fig. 4). The whole

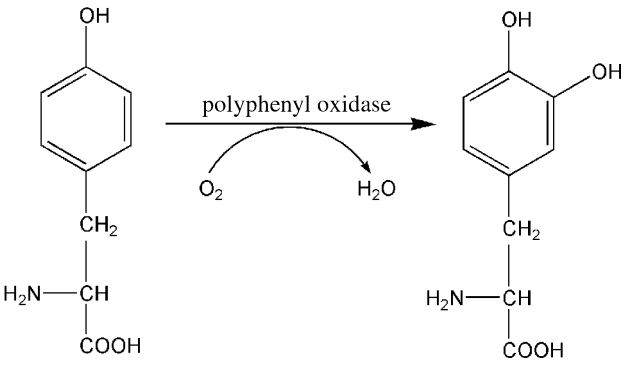

Fig. 3 Enzymatic synthesis of 3,4-dihydroxylphenyl alanine (DOPA).

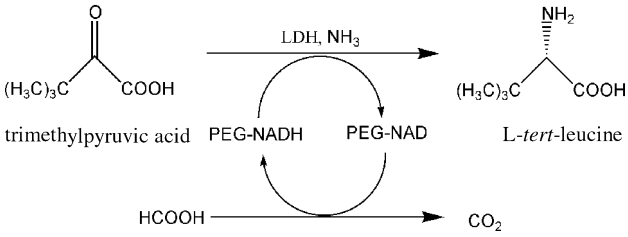

Fig. 4 Enzymatic synthesis of L-*tert*-leucine.

process is carried out in a membrane reactor in which the cofactor NAD^+ is regenerated by FDH. This process has now reached ton-scale production at Degussa (Germany).[18]

Transferases

Transferases catalyze the transfer of functional groups such as methyl, hydroxymethyl, formal, glycosyl, acyl, alkyl, phosphate, and sulfate groups by means of a nucleophilic substitution reaction. They are not widely used in industrial processes; however, there are a few examples of industrial processes that utilize transferases.

A classical example of industrial application of transferases is the use of various glycosyltransferases for the synthesis of oligosaccharides. Oligosaccharides and polysaccharides are important classes of naturally occurring compounds, which play vital roles in cellular recognition and communication processes.[19] Because of the required use of many protection and deprotection groups, chemical synthesis of complex oligosaccharides represents a daunting challenge in synthetic organic chemistry. By contrast, enzymatic synthesis of oligosaccharides by glycosyltransferases requires very few protection and deprotection steps because of the high regio- and stereoselectivity of glycosyltransferases, thus offering an attractive alternative.[2] Another example is the use of a glucokinase (a transferase) in combination with an acetate kinase for the production of glucose-6-phosphate (Fig. 5). This process is carried out in multikilogram scale by the Japanese company Unitika.[1]

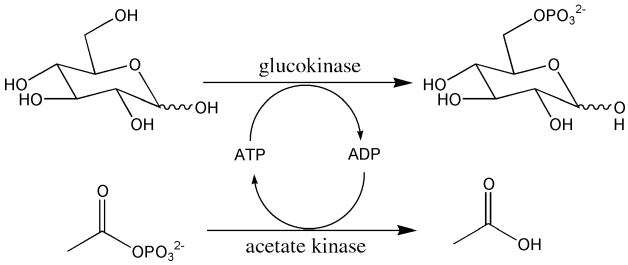

Fig. 5 Enzymatic synthesis of glucose-6-phosphate.

Hydrolases

Hydrolases catalyze the addition of water to a substrate by means of a nucleophilic substitution reaction. Hydrolases (hydrolytic enzymes) are the biocatalysts most commonly used in organic synthesis. They have been used to produce intermediates for pharmaceuticals and pesticides, and chiral synthons for asymmetric synthesis. Of particular interest among hydrolases are amidases, proteases, esterases, and lipases. These enzymes catalyze the hydrolysis and formation of ester and amide bonds.

Lipases can hydrolyze triglycerides into fatty acids and glycerol. They have been used extensively to produce optically active alcohols, acids, esters, and lactones by kinetic resolution. Lipases are unique, in that they are usually used in two-phase systems. A classic example is the use of a lipase for the production of (*S,R*)-2,3-*p*-methoxyphenylglycyclic acid, an intermediate for diltiazem. In this process, methyl-*p*-methoxyphenylglycidate is stereospecifically hydrolyzed by a lipase immobilized in a hollow fiber membrane reactor. The enzyme is located at the interfacial layer between an organic and an aqueous phase.[1]

Proteases such as α-chymotrypsin, papain, and subtilisin are also useful biocatalysts for regio-selective or stereoselective hydrolytic biotransformations. For example, dibenzyl esters of aspartic and glutamic acid can be selectively deprotected at the 1-position by subtilisin-catalyzed hydrolysis (Fig. 6).[2] In addition, α-chymotrypsin is used in the kinetic resolution of α-nitro-α-methyl carboxylates, which results in L-configured enantiomers of the unhydrolyzed esters with high optical purity (>95% e.e.).[2]

Lyases

Lyases are the enzymes responsible for catalyzing addition and elimination reactions. Lyase-catalyzed reactions involve the breaking of a bond between a carbon atom and another atom such as oxygen, sulfur, or another carbon atom. They are found in cellular processes, such as the citric acid cycle, and in organic synthesis, such as in the production of cyanohydrins.[2]

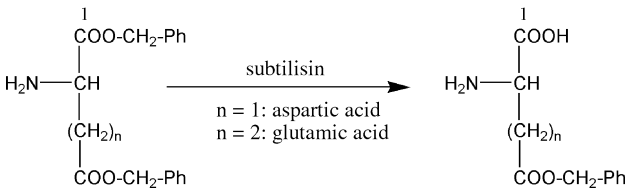

Fig. 6 Regio-selective ester-hydrolysis catalyzed by subtilisin.

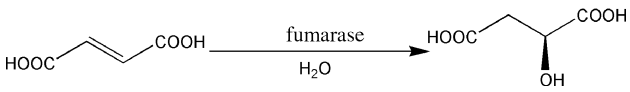

Fig. 7 Enzymatic synthesis of (*S*)-malic acid.

Several industrial processes using lyases as catalysts have been reported. Perhaps the most prominent lyase-catalyzed process is the production of acrylamide from acrylnitrile. This process is carried out by the Nitto Chemical Company of Japan at a scale of more than 40,000 tons per year.[20] Another example is the use of a fumarase for the production of (*S*)-malic acid from fumaric acid. As shown in Fig. 7, a water molecule is added to the double bond in fumarate by means of an addition reaction. The result is a cleavage of the carbon–carbon double bond, and a formation of a new carbon–oxygen bond. A third example is biocatalytic production of a cyanohydrin from a ketone. This reaction is catalyzed by a lyase called oxynitrilase. It consists of the cleavage of one carbon–oxygen bond, and the addition of a HCN molecule. The chirality of the product is based on the form of the enzyme used (*R*-oxynitrilase or *S*-oxynitrilase).[2]

Isomerases

Isomerases catalyze isomerization reactions such as racemization and epimerization. They have not been used in many industrial applications. However, one of the most successful enzyme based biocatalytic processes involves an isomerase: the use of glucose isomerase for the production of high-fructose corn syrup (HFCS) (Fig. 8). High-fructose corn syrup is used as an alternative sweetener to sucrose in the food and beverage industry. The isomerization of glucose to HFCS on an industrial scale is carried out in continuous fixed-bed reactors using immobilized glucose isomerases. The total amount of HFCS produced by glucose isomerase exceeds a million tons per year.[21]

Ligases

Ligases catalyze reactions that involve the creation of chemical bonds with nucleotide triphosphates. They

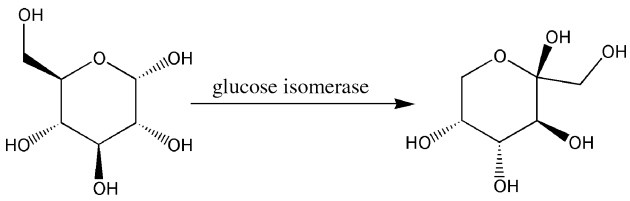

Fig. 8 Enzymatic synthesis of high-fructose corn syrup.

are important in certain cellular processes, such as connecting nucleotides in DNA replication. However, similar to isomerases, ligases have very few industrial applications.[2] It is important to note that DNA ligases are essential tools in recombinant DNA technology and are used almost in every biology-related laboratory.

INDUSTRIAL APPLICATIONS OF WHOLE-CELL BASED BIOCATALYSIS

Whole-cell based biocatalysis utilizes an entire micro-organism for the production of the desired product. One of the oldest examples for industrial applications of whole-cell biocatalysis is the production of acetic acid from ethanol with an immobilized *Acetobacter* strain, which was developed nearly 200 yr ago.[1] The key advantage of whole-cell biocatalysis is the ability to use cheap and abundant raw materials and catalyze multistep reactions. Recent advances in metabolic engineering have brought a renaissance to whole-cell biocatalysis. In the following sections, two novel industrial processes that utilize whole-cell biocatalysis are discussed with emphasis on the important role played by metabolic engineering.

Lactic Acid

L-lactic acid has long been used as a food additive and has recently received great attention because it can be used as an important feedstock for the production of other chemicals such as polylactic acid (PLA), acetaldehyde, polypropylene glycol, acrylic acid, and pentadione.[22] Among them, PLA is the most important product as it can be used to manufacture thermoformed containers, packaging, nonwovens, paper-coated articles, and film products.[23] Lactic acid can be produced from sucrose, whey (lactose), and maltose or dextrose from hydrolyzed starch using *Lactobacillus* strains.

Compared to other polymeric materials such as polyethylenes, polylactic acid has several advantages including an increased hydrophilicity, resistance to ultraviolet light, ability to be dyed with dispersion dyes, a range of melting temperatures between 120°C and 170°C, and low flammability and smoke generation. Most importantly, polylactic acid is biodegradable and is derived from renewable resources, utilizing energy from the sun and lowering the fossil fuel dependence for production.[23]

In recognition of the superior properties and the huge potential market of polylactic acid, Cargill Inc. and The Dow Chemical Company started a joint venture Cargill Dow LLC to produce lactic acid using fermentation (whole-cell biocatalysis) several years ago. A production plant was built in Blair, NE, in 2001 and it now produces 140,000 metric tons of polylactic acid per year. It is predicted that the eventual cost of polylactic acid will be between $0.50 and $0.75 per pound (http://www.cargilldow.com).

One of the drawbacks in the current commercial fermentation process is that the predominant form of the product is the deprotonated lactate rather than lactic acid, requiring more expensive and wasteful product purification steps. This is because the *Lactobacillus* fermentation operates at a minimum pH of 5.0–5.5 which is above the pK_a of lactic acid (3.87). To overcome this limitation, a powerful strain improvement method, genome shuffling, was used to improve the acid tolerance of a poorly characterized industrial strain of *Lactobacillus*.[24] A population of strains with subtle improvement in pH tolerance was isolated using classical strain improvement methods such as chemostats, and were then shuffled by recursive pool-wise protoplast fusion to create mutant strains that grow at substantially lower pH than does the wild-type strain.

1,3-Propanediol

1,3-Propanediol is an intermediate that is widely used in the synthesis of polyesters and polyurethanes. Polymers based on 1,3-propanediol are very useful in the carpet and textile industry because of their good light stability and biodegradability.[25] The conventional methods for producing 1,3-propanediol rely on petroleum derivatives and are quite capital intensive and/or generate waste streams containing environmental pollutants. Thus, the use of micro-organisms to produce 1,3-propanediol from glucose represents an attractive alternative.

Both the biological production of 1,3-propanediol from glycerol and that of glycerol from glucose have been known for many years.[13] However, there is no single micro-organism that could convert basic carbon sources such as glucose to the desired 1,3-propanediol end-product. Such a micro-organism is highly desired in the process as it requires less energy input and uses an inexpensive starting material.

A team of researchers from DuPont and Genencor has successfully used metabolic engineering techniques to engineer such a micro-organism. The conversion of glucose to 1,3-propanediol requires the combination of two natural pathways: glucose to glycerol and glycerol to 1,3-propanediol. The best natural pathway for the production of glycerol from glucose was found in the yeast *Saccharomyces cerevisiae*, which consists of two enzymes: dihydroxyacetone-3-phosphate dehydrogenase and glycerol-3-phosphate phosphatase. The best natural

pathway for production of 1,3-propanediol from glycerol was found in *Klebsiella pneumoniae*, which consists of glycerol dehydratase and 1,3-propanediol dehydrogenase. The genes encoding these two natural pathways were cloned and expressed in *E. coli*. *E. coli* was chosen as the production strain because it has been used in large-scale production on an industrial level, it has many genetic tools, and its metabolism and physiology are well characterized. This engineered *E. coli* was found to produce over 120 g/L of 1,3-propanediol in 40 hr fed-batch fermentation.[13]

CONCLUSIONS

Biocatalysis has become an important tool for industrial chemical synthesis and is on the verge of significant growth. In the past several decades, many biocatalytic processes have been implemented to produce a wide variety of products in various industries. Most of them use naturally occurring enzymes or micro-organisms as catalysts. With the help of innovative biocatalyst discovery methods and advances in protein engineering and metabolic engineering, the time and cost of developing new biocatalysts can be reduced significantly. Most importantly, the biocatalysts can be readily tailored to their specific applications and process conditions through protein engineering and metabolic engineering. It is possible that in the future they can be rationally designed to act specifically in any chemical reaction of interest, fulfilling the holy grail of catalysis: catalysis by design. In addition, the use of biocatalysts in organic solvents in combination with the integration of biocatalysis and chemical catalysis will continue to broaden the scope of the applications of biocatalysts. New advances in genomics, proteomics, and bioinformatics will fuel the development of biocatalysis as an integral part of industrial catalysis.

Biofilms

T. Reg. Bott
School of Engineering, Chemical Engineering, University of Birmingham, Birmingham, U.K.

INTRODUCTION

The term ''biofilm'' refers to a colony of living matter, usually microorganisms including algae, fungi, or bacteria, together with extracellular material attached to a solid surface. In natural conditions it will almost certainly contain several different microbial species, and also depending on the prevailing conditions, the biofilm may also contain adventitious particulate matter. In processing operations, biofilms can be an asset or a hindrance. In some cases, the biofilm is essential for achieving the objective of the process, e.g., the use of trickle filters for the removal of contamination to improve the quality of potable water.[1] On the other hand, the effectiveness of a cooling water system can be reduced by the presence of biofilms on heat transfer surfaces.[2]

Biofilm formation is a natural phenomenon, so that wherever suitable conditions exist, it would be anticipated that a biofilm would develop. Essential, of course, are the presence of nutrients to sustain life and a suitable temperature. Biofilms are formed on surfaces; so the availability of a suitable surface that may be colonized by microorganisms is vital. The structure and the composition of the biofilm are greatly dependent on the environment in which it grows. The composition of the fluid (usually water) in contact with the biofilm, including organic matter, oxygen, and trace elements, its pH, and its flow conditions across solid surfaces, all affect the rate of growth and the robustness of the biofilm structure that develops. The removal of waste products from the vicinity of the biofilm will also depend on the structure of the biofilm, in terms of porosity and thickness, and the flow conditions internal and external to the biofilm. The structure of the biofilm will also influence the availability of nutrients within the biofilm, because of its effect on the penetration of the fluid carrying the nutrients within the biofilm. The biofilm activity may affect the surface on which it resides. For example, the pH near the base of the biofilm may be different from that of the bulk fluid external to the biofilm, because of the metabolism of the microorganisms. This may give rise to corrosion or deterioration of the surface. Clearly, this is an important consideration in relation to the integrity of processing equipment.

The initiation and continued growth of a biofilm is an extremely complex process, subject to many internal and external influences. A discussion of these factors forms the basis of this entry.

MICROBIAL ACTIVITY

Bacteria may be regarded as more versatile than algae or fungi because they are not limited by the need for light or a consumable substrate. In addition, there is considerable variation among bacteria, which is due, in part at least, to the differences in the properties of cell surface polymers.[3] Fletcher[4] suggests that the bacteria attached to a surface appear to be metabolically different from their planktonic or ''free swimming'' counterparts.

Algae utilize carbon dioxide and inorganic chemicals as their primary source of nutrients, and light (usually sunlight) to photosynthesize sugars. The associated biofilms are generally composed of single cells or filamentous organisms, but other forms can exist depending on the conditions. In natural conditions, algal biofilms are found on rocks or stones, in rivers, or on the seashore. Colonies can also reside on man-made structures such as bridge supports standing in water or offshore oil rigs.

Fungi require a fixed organic source of carbon. The rigid cell wall limits them to being saprophytic on organic substrates or as parasites on animals, plants, algae, or even other fungi. In fact, fungi may be found on any solid that provides an organic substrate, provided that the local conditions are satisfactory.

Microbial cells are surrounded by a cell wall, which retains the cell contents, and is the primary barrier between the cell surface and the environment in which it exists. The quality of the cell wall, in terms of selective permeability, maintains the necessary levels of nutrients, trace elements, and cell internal pH. The cell membrane is the site of transfer processes: water is able to pass through this membrane, in or out of the cell, depending on the thrust of the osmotic pressure. The chemistry of the cell wall affects its properties in terms of surface electric charge and the availability of binding ions.

In many organisms, the cell wall is rigid, giving a characteristic shape to individual cells such as rod, filament, or sphere. The rigidity of the cell wall allows the development of structures that may be beneficial for the maintenance of a coherent biofilm. Some cells, however, do not have a rigid cell wall and, therefore, require an intrinsic mechanism to control osmotic

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120030621

pressure for the prevention of damage by excess water intake. A few freshwater organisms can dispose of water or imbibe it through contractile vacuoles. Certain algae can control the condition of soluble metabolites to counter the effects of osmotic pressure.

Microorganisms can produce extracellular materials, such as slimes of polysaccharides and mucilages, which may help to maintain attachment to the solid substrate, provide a source of nutrients if the nutrient availability declines for any reason, or enhance protection of the cells.

Clearly, the availability of nutrients will determine whether or not a biofilm can form and develop. In common with all living matter, the elements that constitute microorganisms are associated with organic chemistry in the widest sense, including carbon, hydrogen, oxygen, nitrogen, sulfur, phosphorus, and other inorganic molecules. The requirements are a source of energy, carbon, and reducing chemicals. Although CO_2 is an increasing component of the atmosphere, it is used as a nutrient source of carbon only by algae, via photosynthesis. The usual source of carbon for microorganisms is carbohydrates, especially polysaccharides because of their abundance. Nevertheless, other sources used include fats, hydrocarbons such as methane, and proteins. Cellulose is preferred by some fungi.

The inertness of atmospheric nitrogen precludes its availability for microorganisms. The usual source is nitrogen-containing compounds such as amino acids, ammonia, nucleotides, uric acid, and urea.

Sulfur is plentiful in naturally occurring compounds. Inorganic sulfates can be reduced via the sulfide and incorporated into amino acids. Hydrogen sulfide is used as a source of sulfur by some microorganisms. Organic sulfur may represent an alternative sulfur-containing nutrient.

Trace elements, including potassium, magnesium, and iron, are required by microorganisms, while calcium, sodium, and silica may be necessary for the growth of some species. There may also be a requirement for traces of zinc, copper, cobalt, manganese, and molybdenum.

The metabolism of microorganisms gives a basis for classification:[2]

1. Phototrophs obtain their energy directly from the sun.
2. Chemotrophs acquire their energy from the oxidation of organic as well as inorganic compounds.
3. Autotrophs are capable of synthesizing their cell carbon from simple compounds such as CO_2.
4. Heterotrophs require fixed sources of carbon.
5. Lithotrophs produce the reducing equivalents required for cell synthesis from inorganic substances like H_2S and ferrous iron.
6. Organotrophs obtain chemical reduction from the oxidation of organic molecules.

Movement to a favorable location for nutrient assimilation is achieved by the use of flagella, as with some bacteria, or by the use of fibrils, as with some algae cells to glide across surfaces.

During metabolism, a single cell will take in nutrients allowing the synthesis of macromolecules that provide the basis for growth. As the cell increases in size, it will eventually divide. Cell division in bacteria is well ordered; the daughter cells that result from the division are uniform in dimension and genetic character. The time to reach full size can be very short (as low as a few hours) depending on the prevailing conditions, particularly temperature and nutrient availability.

Cell division in some fungi starts with the production of a ''bud'' on the cell surface. Of course, the bud is much smaller than the original cell, but it grows till it reaches adult dimensions, and the reproductive process is repeated. There is a limit to the number of buds that can be produced by a single parent cell, as only one can be grown at a particular point on the surface of the cell. Fungi grow almost exclusively through what is known as apical growth, though they can also reproduce by means of sexual and asexual cycles.

For the development of algal biofilms, as with bacteria, few cells are needed to attach to a surface, as cell division rapidly gives rise to colonies that eventually coalesce to form a compact biofilm.[5]

THE IMPORTANCE OF A SURFACE

It would appear that many microorganisms tend to reside on a surface, in discrete colonies, or in a film. It has been suggested[3] that under natural conditions, i.e., in rivers or lakes, 90% of the microorganisms in the biosphere exist in biofilms. Of fundamental importance is that the microorganisms contained in a developing biofilm are exposed to a continuous supply of nutrients. The disturbance of the surface of the water source (e.g., a lake) in contact with the atmosphere ensures there is aeration, which would be advantageous for aerobic organisms. Furthermore, the movement of the water would assist the removal of waste products of the metabolic processes in the cells. The advantages experienced by the sessile cells (those attached to a surface) may be contrasted with the depravation of the planktonic cells (those suspended in water) where nutrient availability at the cell surface is largely because of Brownian diffusion, the cells moving with the water flow along the water streamlines.

Other advantages that accrue for biofilms on surfaces[4] include protection from short-term fluctuations in pH, salt and biocide concentrations, and dehydration. Because of the mass-transfer resistance of the biofilm to the transport of nutrient, conditions will change throughout the biofilm depth. Where several

different microorganisms are present, it is possible for symbiosis to occur. Symbiosis may be defined as a mutually beneficial partnership between organisms of different kinds. Examples include the utilization and breakdown of less readily degradable substances by specialized organisms, which provides a source of nutrients for other microorganisms, e.g., the degradation of cellulose by fungi. The creation of ecological niches, such as anaerobic zones under aerobic biofilms, allows the growth of anaerobic cells in otherwise aerobic environments.

COLONIZATION OF SURFACES

It is generally accepted that the colonization of a surface by microorganisms is a multistage process, as suggested by Characklis.[6] Five steps are involved.

Formation of an Organic Conditioning Layer

A conditioning layer on the virgin solid surface, newly immersed in water, is created by the adsorption of macromolecules. Chamberlain[7] has studied the importance of these adsorbed macromolecules in the attachment of microbes to solid surfaces. The adsorbed macromolecules on surfaces are generally organic in character, although there may be other compounds included in the adsorbed layer, such as metallic hydroxides and mineral particles. Because macromolecules frequently possess multiple attachment points, either functional groups or segments of more hydrophobic character, their attachment is likely to be irreversible. In freshwater systems, such as cooling water circuits, the macromolecules involved, including humic acids and polysaccharides, are likely to be derived from formally living matter. The humic components originate primarily from lignin-type materials and may contain carboxylic and phenolic residues that impart high reactivity. These components are generally highly aromatic. In seawater used for cooling purposes, humic compounds are somewhat different in character and generally comprise complex condensation molecules with polysaccharide, peptide, and lipid components. In contrast to fresh water systems, the marine humic compounds are generally aliphatic in character. In food-processing streams, the macromolecules are often proteins or glycoproteins, which may bring about the attachment of casein and other milk proteins to stainless steel, the usual material of construction in food processing equipment. The rate of adsorption of macromolecules is, in part at least, controlled by their concentration in the water, their relative affinities for the material with which the surface is made, and the hydrodynamics of the flow across the surface.

Transport of Microorganisms to a Surface

The transport of microbial cells dispersed in the liquid stream toward the surface is strongly influenced by the regime of flow across the surface, i.e., laminar or turbulent (see item elsewhere in this encyclopedia). The liquid immediately in contact with the solid surface may be regarded as being stationary, because of the viscous drag exerted by the solid surface. The velocity of the liquid layers gradually increases at distances at right angles to the surface. When close to the surface, these layers are slow moving and constitute what is generally known as the viscous or laminar sublayer. In simple terms, if the bulk flow is turbulent, a boundary layer exists between the slow-moving laminar sublayer and the turbulent bulk flow. For microorganisms to approach the surface and become attached to the conditioning layer, they have to pass from the turbulent bulk liquid, through the boundary layer and into the viscous sublayer. Initially, the cells are carried by eddy diffusion (i.e., resulting from the turbulence in the bulk liquid), but as they approach and enter the viscous sublayer, the eddy diffusion is damped out. Within the viscous sublayer itself, the transport mechanism is caused by molecular diffusion or Brownian motion. The thickness of the viscous sublayer is strongly dependent on the velocity in the bulk liquid. The greater the bulk flow, the thinner the viscous sublayer; i.e., the resistance to the transport of the cells to the surface is lower, and hence a more rapid build-up of cells on the surface is possible. Frictional drag forces become significant in the viscous sublayer, which slows the cells as they move towards the surface. Complex interactions between the cells and the effects of the flow conditions are also likely to affect the approach velocity; for instance, the disturbance of the laminar sublayer by the turbulence in the bulk flow.

Thermophoresis, where particles move in response to a temperature gradient, may also affect the movement of cells in relation to a surface. Because cells have a large water content, gravity will have little effect on settlement. As already stated, cells may respond to chemical stimuli that influence movement in relation to surfaces, and it is possible that the conditioning layer, because of its composition, attracts cells by chemotaxis, thereby facilitating colonization.

Attachment to a Surface

The attachment of particles in a fluid suspension to a solid surface is extremely complex and involves long-range attraction forces to bring the particles to the surface and provide a basis for further interaction. The forces involved may include van der Waals forces

and electrostatic forces. Because of the complexity, simplifying assumptions are made in an attempt to provide a reasonable explanation of the phenomena involved.

The majority of solid surfaces, when immersed in an aqueous solution, acquire an electrical surface charge. As a result, an electrical potential between the surface and the bulk fluid is created. There is an attraction between oppositely charged ions (counterions) in the fluid and the surface. At the same time, similarly charged ions (coions) are repelled away from the surface. The electric discontinuity created at the surface is generally known as the ''electrostatic double layer.'' Fig. 1 is a simplified illustration of the situation that applies to a spherical colloid particle immersed in water. The diffuse electrostatic double layer plays an important role in the interaction between the solid surface and microorganisms and colloids in suspension. Indeed, microorganisms in suspension have been called ''living colloids,'' the ''bridging'' may take the form of chemical bonding with the adsorbed macromolecules on the surface. The basic concepts of particle adhesion theory may be modified where microorganisms are the adhering particles. Mozes,[8] applying adhesion theory to the formation of biofilms, makes the following observations in relation to microbial cells in suspension:

1. It is not a homogeneous, rigid, smooth, and spherical ideal colloid particle.
2. It is not inert and in equilibrium with its environment.
3. It may be capable of independent movement.
4. It may respond physiologically to contact with a surface.

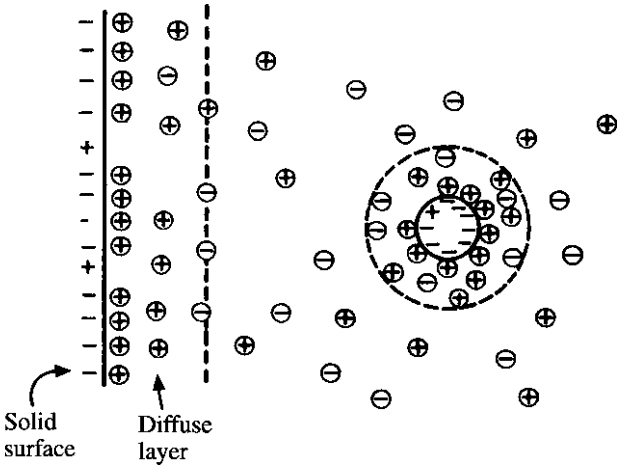

Fig. 1 An idealized representation of an electrostatic double layer and a solid colloidal particle. (From Ref.[2].)

Both reversible and irreversible attachments are possible. Microbial cells can be held in close proximity to a surface by the long-range forces, but still be capable of Brownian motion. Under the flow conditions, mild shear forces, brought about by flow and disturbances in the viscous sublayer, may also be present. These effects may restrict or prevent attachment. It is anticipated that this could be the situation if no conditioning molecules were residing on the surface and would explain the reason for the observed delay in biofilm formation under flowing conditions. Any adhesion of cells under these conditions could be said to be reversible.

Once there is a bonding between the conditioning molecules and the microbial cells, removal by shear forces becomes more difficult and the attachment can be regarded as irreversible. As the biofilm develops, however, shear forces caused by the fluid flow may be capable of removing cells from the surface. The extent of this removal is dependent on the quality of the biofilm and the bulk flow velocity. Furthermore, the establishment of irreversible attachment is dependent on the quality of the surface involved. Rough surfaces are known to facilitate the formation of biofilms. If the crevices on the surface are relatively large, a bacterium cell that is only 1 or 2 μm in size, could easily ''hide'' in a crevice and be unaffected by the shear forces. Under these circumstances, it is possible that there is a greater opportunity to form a bond with the conditioning molecules. Once these ''survivors'' are attached, the biofilm can begin to develop and irreversible attachment established. In the food industry, great care is taken to make sure that the surfaces of equipment in contact with food products are exceptionally smooth to reduce the risk of the formation of biofilms that could adversely affect food quality.

Nutrient Transport and Assimilation

After colonization of the surface, the microorganisms utilize the available nutrients to grow, multiply, and synthesize both intracellular products and extracellular polymeric substances that constitute the substance of the biofilm. Significant amounts of biofilm can be produced under ideal conditions, and even if planktonic cells are no longer present in the flowing water, the sessile cells already on the surface can provide the basis for biofilm development.[9]

The transport of nutrients from the bulk water to the developing biofilm depends on the concentration difference of nutrients between the bulk water and the surface of the biofilm. A concentration driving force is established by the removal of nutrients by the growing biofilm, assuming that the nutrient concentration in the bulk is maintained. As with the initial mass

transfer of cells to the surface, the boundary layers adjacent to the biofilm constitute a resistance to the transport of nutrients to the biofilm; the rate of growth may be limited by this resistance. The extent of the resistance will depend on the flow conditions outside the boundary layers. In broad terms, the higher the bulk velocity, the lower the resistance to mass transfer of nutrients.

As the biofilm develops, the nutrient availability to the bulk biofilm may become affected. The biofilm, despite its voids and channels, offers a further resistance to mass transfer. The cells within the biofilm consume nutrients that diffuse through the biofilm in response to the difference in concentration between nutrients at the biofilm surface and the cells attached to the conditioning layer. As a consequence, it is entirely possible that cells in the region of the solid surface are likely to become starved of nutrients. The properties of the biofilm may be different, therefore, in the layers where nutrient is available compared with the regions where there is little or no nutrient. For instance, the lack of oxygen may encourage anaerobic species to develop (some bacteria can exist as aerobes or anaerobes), with attendant changes to the quality of the biofilm.

Biofilm Removal

As is apparent from the foregoing discussion, the growth of the biofilm is a complex interaction between the flowing fluid and the physiology of the biofilm structure. Furthermore, the properties of the biofilm may change with time as it grows, resulting in the removal of part of the biofilm by the shear forces acting on the outer layers of the biofilm. The process is generally referred to as ''sloughing.''

THE STRUCTURE OF BIOFILMS

Concepts on the detailed structure of biofilms prior to the invention of the confocal scanning laser microscope were largely the results of intuition and speculation, because, in general, the biofilm had to be removed from the environment in which it was formed. Such a procedure could lead to the damage of the biofilm and loss of moisture that would change its appearance.

With the invention of newer methods of investigation, detailed examinations of fully hydrated biofilms, where water flows across the surface of the biofilm, could be made. The results of the observations revealed a heterogeneous structure consisting of cell clusters separated by interstitial voids and channels.[10] Real-time video imaging of biofilms growing on surfaces subject to fast flowing water revealed the presence of

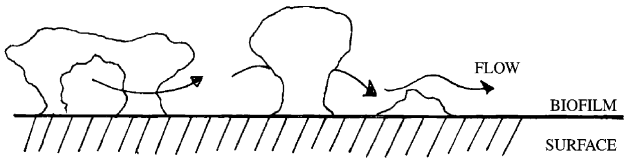

Fig. 2 Schematic concept of flow within a biofilm. (From Ref.[10].)

''streamers'' oscillating rapidly in the flow.[11] These streamers, which oscillate in response to the effects of turbulence in the flowing water, may assist the assimilation of nutrients by the destruction of the laminar sublayer around the colony. In other words, the resistance to the mass transfer of the nutrients is reduced.

The cell clusters can be composed of a single species that is likely to be the result of the initial colonization of the surface. It is possible to have groups of cells containing a mixture of various species, and this might be the result of synergy, i.e., an interactive association between two populations of microorganisms, not necessarily for survival, but for each group's benefit. Extracellular polysaccharide may be present around the clusters or less densely distributed in the spaces between the microcolonies. The result is a random array of channels through which water can flow. Fig. 2 illustrates the possible flow pattern between clusters of cells. Clearly, this water flow has implications for the delivery of nutrients to the cells in the lower regions of the biofilm.

Under high flow rates of fluid, when shear forces are strong, it is possible that the surviving cells lie so that the removal forces they experience are reduced to a minimum,[12] and the biofilm is less prone to sloughing.

THE DEVELOPMENT OF BIOFILMS

The discussion so far has dealt with scientific background to the formation of biofilms. It is of interest therefore to examine, as far as possible, the pattern of development in industrial process operations. The work described here is related to fresh water fouling by biofilms and carried out in a pilot scale laboratory apparatus, but it gives an indication of the effects of the principal operating variables on biofilm development with time. Biofilms in cooling water systems reduce the cooling efficiency because they are prone to occur on heat transfer surfaces, where, in general, conditions are conducive to development. The organisms involved are usually bacteria. Unless corrective action is taken, the biofilms so produced can cause serious operating problems with attendant higher operating costs.

The change in biofilm accumulation on a surface with time, under flowing water conditions, would be expected to follow the idealized curve in Fig. 3. Three regions can be seen in the diagram:

1. Initiation and growth, which is related to the laying down of the conditioning macromolecules on the surface.
2. After the colonization, there is a period of rapid growth, where the conditions, in terms of temperature, availability of nutrients, and their transport to the biofilm, are conducive to sustained growth.
3. The rate of growth gradually falls off, till a stable thickness of biofilm is reached, which might vary from a few micrometers to several millimeters, depending on the prevailing conditions.
4. The leveling off of the biofilm growth is attributed to a balance between growth and removal, depending on nutrient availability and temperature on the one hand, and shear forces caused by water flow on the other.

Under practical operating conditions, it will be seen that this ideal representation of biofilm development with time will be modified. Fig. 4 demonstrates that practical data roughly follow the idealized curve, but with considerable fluctuation of. The reason for this "saw tooth" appearance is attributed to the growth and partial sloughing of parts of the biofilm because of the shearing action of the flowing water at the surface of the biofilm. It is interesting to note that there is little effect on the development of the biofilm by the elimination of the planktonic bacteria in the flowing water. Once the surface has been colonized, development continues provided that a nutrient supply is maintained. An understanding of the effect of different variables on biofilm growth is essential for devising

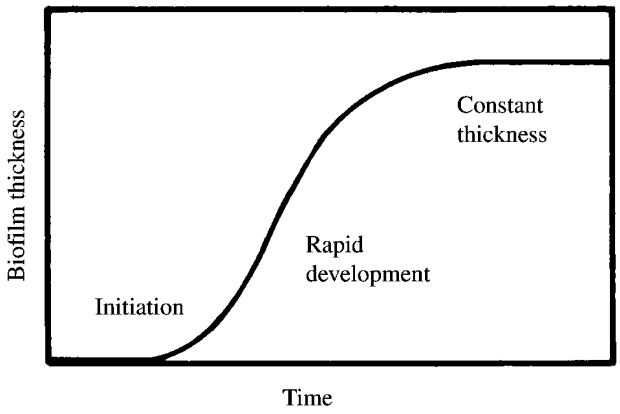

Fig. 3 Idealized concept of biofilm growth on a surface with time. (From Ref.[2].)

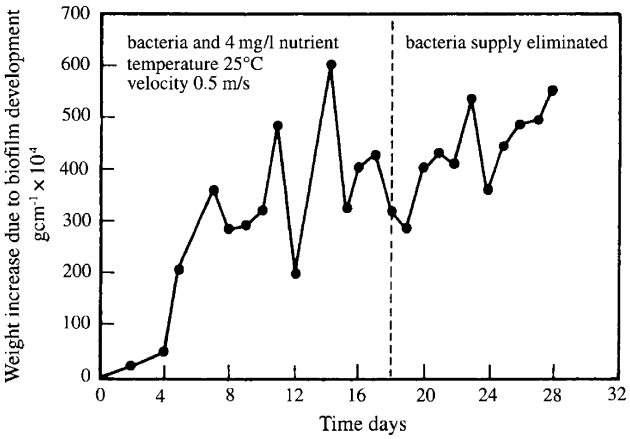

Fig. 4 Practical biofilm growth curve on the inside of an aluminum tube. (From Ref.[9].)

methods for biofilm control where biofilms pose an operational problem, in cooling water circuits, for instance, or in enhancing growth where a biofilm is the key to the effectiveness of the process, such as water purification.

MEASUREMENT OF BIOFILM ACCUMULATION

Very relevant to the representation of biofilm growth data is how to measure biofilm accumulation. There are various methods available, but a detailed discussion is outside the scope of this encyclopedia. For many years, direct weighing was employed, i.e., to determine the biofilm accumulation by weighing a tube or insert plate before and after contamination with microorganisms. The technique is very unsatisfactory for a number of rather obvious reasons. The removal of the test surface from the rest of the system for weighing may damage the biofilm, and the adventitious moisture associated with the biofilm is likely to give misleading information. Furthermore, the method does not lend itself to continuous tracking of the change in biofilm accumulation with time. Another method that has been used is to carry out a cell count on a unit area of test surface, but, apart from being labor intensive, this method also has the same problems of direct weighing. A number of methods have been developed to overcome the problem.[13] Some of the data reproduced here involve the use of infrared absorbance as a measure of biofilm thickness.[14]

THE AVAILABILITY OF NUTRIENTS

It is to be expected that the availability of nutrients is crucial to the development of biofilms. The effects of

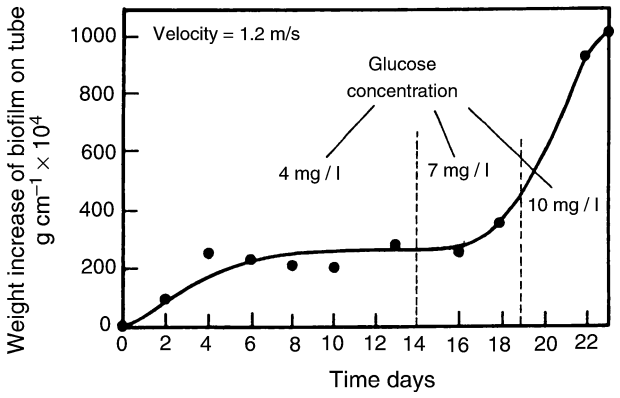

Fig. 5 The change in biofilm accumulation on the inside of a tube with three different nutrient concentrations expressed in terms of glucose concentration. (From Ref.[9].)

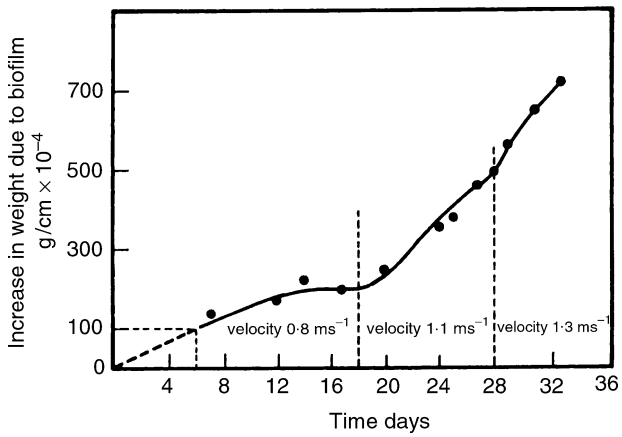

Fig. 7 The effect of velocity on biofilm growth at constant concentration. (From Ref.[9].)

the changes in nutrient concentration on biofilm growth are shown in Fig. 5. Fig. 6 demonstrates the importance of trace elements on biofilm development. Until trace elements were added to the system, little or no growth was evident.

THE EFFECT OF BULK WATER VELOCITY

The effects of changes in bulk water velocity are basically twofold. Higher velocities represent greater turbulence in the bulk flow and a reduction in the thickness of the boundary layers adjacent to the biofilm residing on the solid surface. As the velocity increases, the availability of nutrients, for a given concentration, to the biofilm increases because of the lower resistance to mass transfer of nutrients to the biofilm. It would be expected that this would be evident in the higher rate of biofilm growth. As the velocity increases, however, the attendant shear forces acting on the biofilm also increase. It would be expected that this would be manifest in a reduction of biofilm accumulation, till a new plateau is reached, i.e., the competing effects of increased growth because of greater nutrient availability and the removal of biofilm by the increased velocity. The result is apparent in Fig. 7.

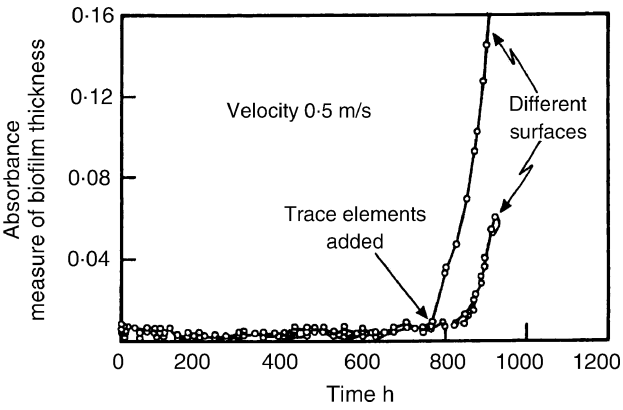

Fig. 6 The effect of adding trace elements to the nutrient on the growth of a biofilm on the inside of a glass tube, using infrared monitoring. (From Ref.[15].)

THE EFFECT OF TEMPERATURE

Microorganisms have an optimum growth temperature, when, provided that there are sufficient nutrients available, the growth is maximum. The optimum temperature is different for different species, on account of various metabolic characteristics. It is usually in the range of 20–50°C, with many in the range of 35–40°C. Fig. 8 shows the very pronounced effect of a relatively small temperature change on the development of a biofilm of *Escherichia coli*.[16]

THE EFFECT OF SURFACE

Mott and Bott[17] illustrated the effect of different materials on the accumulation of *Pseudomonas fluorescens* biofilms on the inside of tubes under identical operating conditions (see Fig. 9). The differences between the effects of the materials occur for two reasons: roughness and surface electrical properties. The quality of the surface, in terms of roughness, on which microorganisms attach, can affect the biofilm accumulation as discussed earlier. The effect of roughness is illustrated in Fig. 9 by the difference of biofilm accumulation between electropolished and "as received" 316 stainless steel. The rougher stainless steel is seen to be more hospitable to biofilm growth.

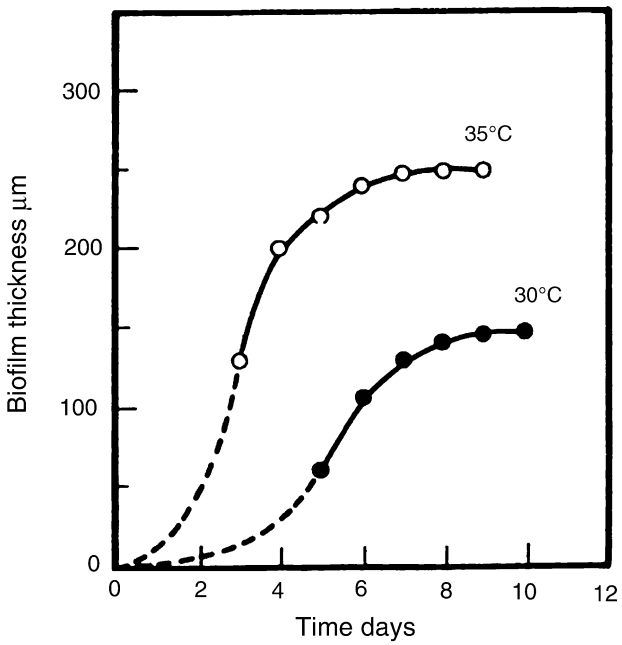

Fig. 8 The effect of temperature on the growth of a biofilm of *E. coli*. (From Ref.[16].)

In the light of these results, modification of the surface is a possible way of changing biofilm accumulation, i.e., to reduce roughness where the biofilm represents a nuisance or to use a rough surface where the biofilm performs a useful function.

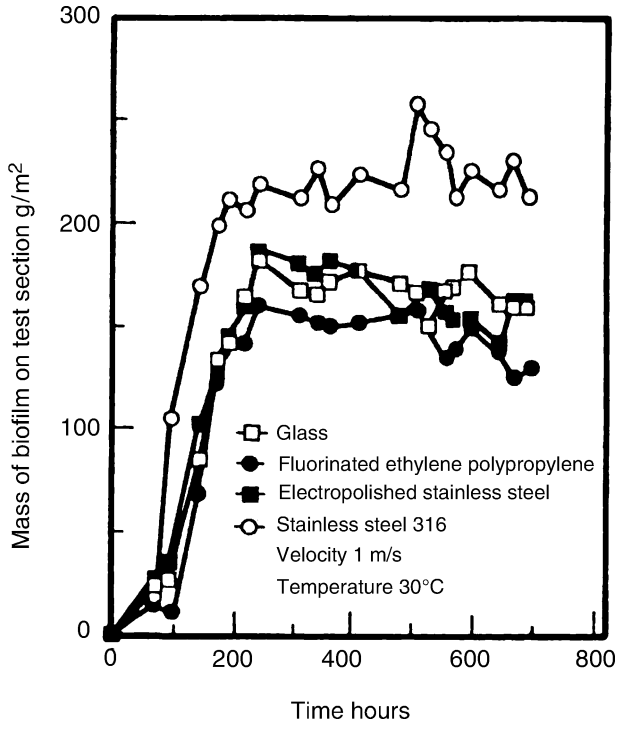

Fig. 9 Development of a biofilm of *P. fluorescens* on different materials. (From Ref.[7].)

CONTROL OF BIOFILMS

Reference in the discussion so far has been made to the need of controlling biofilm growth, a requirement that arises often. Where it is required to enhance growth, such as the treatment of wastewater, it is simply a question of ensuring that the operating conditions are optimum for the species present. There may be, of course, limited opportunity for this approach by virtue of the existing conditions of the process. It is unlikely that there would be much opportunity, for instance, to raise the temperature of the incoming stream because of the difficulties this would present and the costs involved.

Of greater significance is the need to control the growth of biofilms, as encountered in the use of naturally occurring water for cooling purposes. Some mention has been made in the preceding discussion, but it is useful to summarize the opportunities available. At the onset, it is important to stress that the tactic adopted will very much depend on the operating conditions and particularly on the quality of the water utilized. The obvious choice of method for controlling biofilm growth is to "dose" the cooling water with a biocide that will kill the microorganisms present in the system. For many years, this was the technique employed and the preferred biocide was chlorine, as it was very effective, available, and relatively cheap. As the cooling water is usually discharged back after use to the source from which it was obtained, e.g., a lake, river, or canal for fresh water systems, or the sea where this was more convenient, it has led to concern for the environment. Although chlorine is still used in many cooling systems, it is coming under increasingly tighter control to reduce the threat to the environment. As a consequence, there has been considerable investment in the search for a reliable alternative.

Perhaps the solution lies in the use of physical method, i.e., to avoid the use of chemicals altogether. The earlier discussion had indicated that velocity plays an important part in the development of biofilms, so that higher velocities might be used for biofilm control, as this would increase the removal forces. Although a realistic possibility, the technique is likely to be costly in terms of energy usage, because of the serious increase in pressure drop through the system that this would entail. In general terms, it has to be remembered that pressure drop increases as the square of velocity increases. A common technique in the power industry is to circulate sponge rubber balls with the cooling water through the steam condensers. It has to be said, however, that the opportunities for physical control have not been fully explored. Some physical methods for control that were described in a recent article are now being investigated.[18] They include the use of ultrasound and inserts in heat exchanger tubes, and the circulation of polymer fibers. The latter technique

would appear to show promise because the fibers reach all parts of the system in the same way as dissolved chemical biocides do, thereby keeping all parts of the system clean, provided that the fluid velocity is maintained. The other two techniques tend to give more localized control, in particular in heat exchangers, where the biofilm growth is likely to be most prevalent owing to the favorable temperature. An alternative physical strategy is to use modified surfaces to reduce the adherence of the microorganisms to the surface to facilitate removal by the shear forces. The extra cost of treatment of the surface such as electropolishing or ion implantation could be high. The alternative of coating the surfaces with, say, a polymer could invoke questions of its integrity over long periods of time.

In response to the environmental issues, the so-called ''environment friendly'' biocides have been or are being developed. The concept is that after a relatively short time, they decompose to innocuous breakdown products, some of which could be nutrients for biological activity that gives safe disposal. Although this suggests a contradiction in terms, there need not be any difficulties, provided the problem is recognized and handled properly. The cost of these biocides is relatively high, partly because the dose required is, in general, much higher than the traditional chemicals such as chlorine. For this reason, the dosing strategy requires careful attention.[19] The advantages of this approach include optimizing the chemical use and minimizing the maintenance costs. Some biocides that have been used for a number of years are naturally environment friendly and include the oxidizing agents, ozone and hydrogen peroxide, which breakdown to oxygen and water, respectively. A major difficulty with ozone is that it has to be generated as required, because it cannot be stored. Hydrogen peroxide is sometimes a constituent of proprietary biocide formulations.

CONCLUSIONS

Biofilms are common in natural environments and may include bacteria, algae, and fungi. Microorganisms prefer to reside on surfaces because the surface offers a certain degree of protection. But at the same time, they have a ready access to nutrients contained in the fluid passing over the surface. The important variables that affect the stability of the biofilm are temperature and the velocity of the fluid in contact with the biofilm. There is an optimum temperature and an optimum velocity to sustain the maximum biofilm thickness, provided that there is an adequate supply of nutrients. In processing, biocides can either be an aid or a disadvantage, for instance, as seen in wastewater treatment and fouling of heat exchangers in cooling water circuits, respectively. Where biofilms are an impediment to processing, control is implemented by chemical or physical means.

Biofuels and Bioenergy

Dinesh Gera
Fluent Incorporated, Morgantown, West Virginia, U.S.A.

INTRODUCTION

Biofuel is any gas, liquid, or solid fuel derived either from recently living organisms or from their metabolic by-products, including dedicated energy crops and trees, agricultural food and feed crop residues, aquatic plants, wood and wood residues, animal wastes, and other waste materials. It is a renewable energy, unlike other fossil fuel sources such as coal, petroleum, or nuclear energy. Biomass (any plant-derived organic matter) is a subset of biofuels, and it is used repeatedly in this entry. The term ''bioenergy'' refers to the production of energy (liquid, solid, and gaseous fuels) and heat using the biofuels or biomass.

Biomass is a very heterogeneous and chemically complex renewable resource. Understanding this natural variability and range of chemical compositions is essential for scientists and engineers conducting research and developing energy technologies using biomass resources. Biomass that is available for energy has a potential to produce an array of energy-related products, including liquid, solid, and gaseous fuels; electricity; heat; chemicals; and other materials.

Most scientists now agree that temperatures around the world are rising, and global warming may be occurring. There will be high societal costs if unchecked growth in atmospheric concentrations of greenhouse gases continues. Bioenergy and bio-based industrial feedstocks offer sound, economically friendly, and environmentally beneficial ways to reduce the pace at which CO_2 and other global warming gases accumulate in the atmosphere. The utility of bioenergy and its coproducts can play a major role in mitigation strategies for reducing greenhouse gases. Potential environmental benefits from biomass include offsetting these greenhouse gas emissions and sequestering carbon, improving water quality, and reducing soil erosion through the use of perennial cropping systems on marginal lands and by recovering wastes and capturing methane emissions.

The relative performance of biomass energy systems in reducing net greenhouse gas emissions depends on the sustainability of the sources of biomass feedstock, the energy requirements of the conversion systems, and the overall conversion efficiencies. Unlike fossil fuels, biomass production systems recapture emissions of carbon dioxide. It has been well documented that biomass energy and product systems have the potential to substantially reduce net greenhouse gas emissions. These vary greatly across biomass systems. A 1999 life cycle analysis indicated a 95% reduction in carbon dioxide emissions from a woody crop fired integrated gasification combined-cycle system relative to the average coal-fired power system. Direct-fired biomass systems, using residues that otherwise would have gone to landfills, generated even greater reductions in greenhouse gas emissions by avoiding methane production. The United States Department of Agriculture (USDA) and the Department of Energy (DOE) studies have shown that compared to gasoline, greenhouse gas emissions can be reduced on a per-gallon basis by 20–30% with the use of corn ethanol and 85–140% with that of cellulosic ethanol.[1]

This entry is organized into three major parts. The first identifies the biomass resources in the form of conventional forestry, agricultural crops and residue, and oil-bearing plants, among others. The second describes the conversion processes of bioresources into biofuels, and it is followed by the end product usage of biofuels in producing electricity in power plants.

BIORESOURCES

A variety of fuels can be made from biomass resources, including liquid fuels such as ethanol, methanol, biodiesel, Fischer–Tropsch diesel; gaseous fuels such as hydrogen and methane, and solid fuels such as switch grass, walnut shells, and sawdust, among others. Examples of biofuel include alcohol (from fermented sugar), black liquor from the paper manufacturing process, and soybean oil. Biofuel contains no petroleum, but it can be blended at any level with petroleum fuel to create a biofuel blend. It can be used in conventional heating equipment or diesel engines with no major modifications. Biofuel is simple to use, biodegradable, nontoxic, and essentially free of sulfur and aromatics. A typical blend of 20% biofuel with 80% of convention petroleum or fossil fuel has demonstrated significant environmental benefits. Biofuel is the only alternative fuel to have fully completed the health effects testing of the Clean Air Act. The use of biofuel in a conventional heating system or diesel engine results in a substantial reduction of unburned

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120018027

hydrocarbons, carbon monoxide, and particulate matter compared to the emissions from heating oil or diesel fuel. In addition, the exhaust emissions of sulfur oxides and sulfates (major components in acid rain) from biofuel are essentially eliminated compared to heating oil or diesel fuel.

Bioresources include any organic matter available on a renewable basis, including dedicated energy crops and trees, agricultural food and feed crops, agricultural crop wastes and residues, wood wastes and residues, aquatic plants, animal wastes, municipal wastes, and other waste materials.

Herbaceous energy crops: These are perennials that are harvested annually after taking 2–3 yr to reach full productivity. They include such grasses as switchgrass, miscanthus (also known as elephant grass or e-grass), bamboo, sweet sorghum, tall fescue, kochia, wheatgrass, and others.

Woody energy crops: Short-rotation woody crops are fast-growing hardwood trees harvested within 5–8 yr after planting. These include hybrid poplar, hybrid willow, silver maple, eastern cottonwood, green ash, black walnut, sweetgum, and sycamore.

Industrial crops: Industrial crops are developed and grown to produce specific industrial chemicals or materials. Examples include kenaf and straws for fiber, and castor for ricinoleic acid. New transgenic crops are being developed that produce the desired chemicals as part of the plant composition, requiring only extraction and purification of the product.

Agricultural crops: These feedstocks include the currently available commodity products such as cornstarch and corn oil, soybean oil and meal, wheat starch, other vegetable oils, and any newly developed component of future commodity crops. They generally yield sugars, oils, and extractives, although they also can be used to produce plastics and other chemicals and products.

Aquatic crops: A wide variety of aquatic biomass resources exist, such as algae, giant kelp, other seaweed, and marine microflora. Commercial examples include giant kelp extracts for thickeners and food additives, algal dyes, and novel biocatalysts for use in bioprocessing under extreme environments.

Agriculture crop residues: Agriculture crop residues include biomass (primarily stalks and leaves) that are not harvested or removed from the fields in commercial use. Examples include corn stover (stalks, leaves, husks, and cobs), wheat straw, and rice straw. With approximately 80 million acres of corn planted annually, corn stover is expected to become a major biomass resource for bioenergy applications.

Forestry residues: Forestry residues include biomass that is not harvested or removed from logging sites in commercial hardwood and softwood stands, as well as material resulting from forest management operations, such as precommercial thinnings and removal of dead and dying trees.

Municipal waste: Residential, commercial, and institutional postconsumer wastes contain a significant proportion of plant-derived organic material that constitutes a renewable energy resource. Waste paper, cardboard, wood waste, and yard wastes are examples of biomass resources in municipal wastes.

Biomass processing residues: All processing of biomass yields by-products and waste streams collectively called residues, which have significant energy potential. Residues are simple to use because they have already been collected. For example, processing of wood for products or pulp produces sawdust and a collection of bark, branches, and leaves/needles.

Animal wastes: Farms and animal processing operations create animal wastes that constitute a complex source of organic materials with environmental consequences. These wastes can be used to make many products, including energy.

Biofuels can be converted into all three natural forms, i.e., liquid, gas, and solid, from bioresources, using the biochemical, photobiological, and thermochemical processes described in the following section.

BIOMASS CONVERSION PROCESSES

Biochemical conversion processes: Enzymes and micro-organisms are frequently used as biocatalysts to convert biomass or biomass-derived compounds into desirable products. Cellulase and hemicellulase enzymes break down the carbohydrate fractions of biomass into five- and six-carbon sugars, a process known as hydrolysis. Yeast and bacteria ferment the sugars into products such as ethanol. Biotechnology advances are expected to lead to dramatic biochemical conversion improvements.

Photobiological conversion processes: Photobiological processes use the natural photosynthetic activity of organisms to produce biofuels directly from sunlight. For example, the photosynthetic activities of bacteria and green algae have been used to produce hydrogen from water and sunlight.

Thermochemical conversion processes: Heat energy and chemical catalysts are used to break down biomass into intermediate compounds or products. In gasification, biomass is heated in an oxygen-starved environment to produce a gas composed primarily of hydrogen and carbon monoxide. In pyrolysis, biomass is exposed to high temperatures in the absence of air, causing it to decompose. Solvents, acids, and bases can be used to fractionate biomass into an array of products including sugars, cellulosic fibers, and lignin.

Biofuels exist in all three natural forms, that is, gas, liquid, and solid:

1. Gas fuel
    a. Methane—Methane can be produced by the natural decay of garbage dumps over time. Additionally, biomass can be gasified to produce a synthesis gas composed primarily of hydrogen and carbon monoxide, also called syngas or biosyngas. Hydrogen can be recovered from this syngas, or syngas can be catalytically converted to methanol. It can also be converted using the Fischer–Tropsch catalyst into a liquid stream with properties similar to diesel fuel, called Fischer–Tropsch diesel. However, all of these fuels also can be produced from natural gas or coal using a similar process.
2. Liquid biofuels
    a. Bioalcohols are ethanol and methanol, when they are not produced from petroleum. A significant amount of ethanol is produced from sugar beets and corn using the fermentation process. Ethanol is the most widely used biofuel today, with a current capacity of 1.8 billion gallons per year based on starch crops such as corn. Ethanol produced from cellulosic biomass is currently the subject of extensive research and development, and demonstration efforts. It is currently being used as an automotive fuel and a gasoline additive.
    b. Straight vegetable oil (SVO) is a waste product of the food service industry, also called fryer grease. It can be used to run a conventional diesel engine if the oil is clean and heated to the appropriate temperature before being injected into the engine. Using SVO as a fuel greatly lowers health and environmental hazards caused by using petroleum fuels while boosting energy security.
    c. Biodiesel is produced through a process in which organically derived oils are combined with alcohol (ethanol or methanol) in the presence of a catalyst to form ethyl or methyl ester using transesterification. The biomass-derived ethyl or methyl esters can be blended with conventional diesel fuel or used as a neat fuel (100% biodiesel). Biodiesel can be made from soybean or canola (rapeseed) oils, animal fats, waste vegetable oils, or microalgae oils. It can be used in unaltered diesel engines. Biodiesel can be mixed with petroleum diesel. Vehicle performance on biodiesel is almost similar to vehicle performance on conventional petroleum diesel.
3. Solid fuel
    a. Biomass, such as switch grass, walnut shells, and sawdust, is currently used as the cofiring fuel in industrial boilers to reduce the nitrogen oxide (NO_x) emissions.

GLOBAL BENEFITS AND IMPACTS

A 1999 biofuel life cycle study, jointly sponsored by the USDOE and the USDA concluded that biofuel reduces net CO_2 emissions by 78% compared to petroleum fuels from biofuel's closed carbon cycle.[1] The CO_2 released into the atmosphere when biofuel is burned is recycled by growing plants, which are later processed into fuel.

Scientific research confirms that biofuel has a less harmful effect on human health than petroleum fuel. Biofuel emissions have decreased levels of polycyclic aromatic hydrocarbons (PAHs) and nitrited PAH compounds (nPAH), which have been identified as cancer causing compounds. Test results indicate that PAH compounds were reduced by 50–85%. Targeted nPAH compounds were reduced by 90%. Biofuel is nontoxic and biodegradable. In addition, the flash point (the lowest temperature at which it can form an ignitable mix with air) is 300°F, well above petroleum fuel's flashpoint of 125°F.

Several developed countries have introduced policies encouraging use of biofuels made from grain, vegetable oil, or biomass to replace part of their fossil fuel use in transport. These initiatives generally have at

least three goals: 1) to prevent environmental degradation by using cleaner fuel; 2) to reduce dependence on imported, finite fossil fuel supplies by partially replacing them with renewable, possibly domestic, sources; and 3) to provide a new demand for crops to support producer incomes and rural economies.

The use of biomass for power could have impacts on local air pollution. As an example, direct combustion and cofiring of biomass offers improvements in conventional air pollutants, NO_x, sulfur dioxide (SO_2), particulate matter (PM_{10} and $PM_{2.5}$), carbon monoxide (CO), and volatile organic chemicals (VOC) relative to direct-firing of coal. It follows, then, that certain emissions from advanced coal energy systems, which are now under development by the USDOE, also may be moderated by biomass cofiring or cogasification. The USDOE is conducting research on biomass gasification systems that most likely would reduce the overall emissions relative to most conventional fossil systems.

Because the impact of conventional pollutants is primarily local or regional, facility location is also a significant environmental consideration. Utilization of bio-based chemicals may help to reduce risks to human health from environmental releases and workplace exposure to toxic chemicals, particularly those derived from petroleum-based feedstocks. Substitution of bio-based products for petroleum-based end products has the potential to reduce pollution from virtually all stages of production, from extraction of the raw material to final product manufacturing and product disposal. Substituting bio-based products for inorganic-based products, e.g., wood for steel, biocement for cement, and cotton insulation (formaldehyde-free) for fiberglass, can have even more substantial effects on reducing greenhouse gas emissions, as the inorganic-based products are extremely energy intensive to produce. Substituting a biochemical for a petrochemical that has different properties can reduce the pollution generated by the production of the petrochemical, and also may reduce the environmental impact associated with using the chemical in manufacturing final consumer products. Finally, even substituting a biochemical for an identical petrochemical can reduce the upstream impacts associated with the extraction of the material.

Using the advanced bioethanol technology available, it is possible to produce ethanol from any cellulose/hemicellulose material, which means any plant or plant-derived material. Many of these materials are not just underutilized and inexpensive, but also create disposal problems. For example, rice straw and wheat straw are often burned in the field, a practice that is becoming limited by air pollution concerns. Also, much of the material now going into landfills is cellulose/hemicellulose material and could be used for bioethanol production. Technology is now available to convert the municipal solid waste to ethanol. Wastes from many paper mills, food processing, and other industries also may be converted to bioethanol.

Another possible bioethanol feedstock is corn stover (corn stalks and leaves). Because of the stover's large volume and proximity to current ethanol production facilities and because it is already there for the taking, biofuels program analysts expect stover to be one of the primary feedstocks for advanced bioethanol production. Currently, stover is left in the fields in some cases and plowed under in others. Appropriate levels of stover harvesting will need to be carefully determined to avoid losing stover's value for erosion control and soil enrichment. In many areas though—particularly in northern areas where springtime soil warming is of concern—stover is routinely plowed under—mostly to get rid of it. Harvesting part of that stover might allow farmers to switch to a no-till operation, which soil scientists recognize to be far better from a soil erosion and fertilizer use perspective.

The total bioenergy potential of the base year, 1990, was estimated at 225 EJ (1 EJ = 1 exajoule = 10^{18} J) or 5.4 billion (10^9) tons of oil equivalent (Gtoe).[2] For comparison, the actual use of bioenergy in 1990 was 46 EJ or 1.1 Gtoe. By the year 2050, this potential was estimated to have grown to between 370 and 450 EJ (8.8 and 10.8 Gtoe). The slowest growth is expected to occur in the ''crop residues'' category (because of increasing the harvesting index). To put the estimated totals into perspective, the estimated global energy value from photosynthesis is 4000 EJ.[2]

SOME ISSUES IN BIOMASS HANDLING

Material handling, collection logistics, and infrastructure are important aspects of the biomass resource supply chain.

Biomass material handling: Materials handling systems for biomass constitute a significant portion of the capital investment and operating costs of a bioenergy conversion facility. Requirements depend on the type of biomass to be processed as well as the feedstock preparation requirements of the conversion technology. Biomass storage, handling, conveying, size reduction, cleaning, drying, and feeding equipment, and systems require special attention. Biofuels can be stored in existing fuel tanks. Biofuel is completely compatible with petroleum fuels.

Biomass collection logistics and infrastructure: Harvesting biomass crops, collecting biomass residues, and storing and transporting

biomass resources are critical elements in the biomass resource supply chain.

Biomass feedstock production shares many of the potential environmental effects associated with other agricultural systems, including soil erosion, fertilizer, and pesticide runoff. However, biomass production systems using perennial crops, such as trees and grasses, that are being developed by the Agricultural Research Service, the Forest Service, the Oak Ridge National Laboratory, land grant universities, and others will lower overall chemical use and reduce soil erodable from rates associated with conventional monoculture crop production. Positive environmental effects have been documented where biomass (perennial crop) production replaces conventional crop production on marginal, highly erodable lands. Additional research is needed to optimize the management systems for a wide variety of soil and climate conditions. Utilization of biomass products such as compost also can serve as a component of an overall strategy to reduce, reuse, and recycle solid waste. For example, promoting composting is entirely consistent with efforts to enhance recycling. In providing incentives to promote biomass energy from waste, it will be important to understand and mitigate potential instances where diverting waste for energy might have impacts on programs and incentives to promote waste reduction and recycling. It is important to keep in mind that the established, national hierarchy for materials utilization places reuse and recycling above the use of materials for energy recovery. Improvements in handling and management of solid waste, such as the capture and use of landfill gas, can reduce emissions of methane, a powerful greenhouse gas, as well as other pollutants.

THERMOCHEMICAL PROPERTIES OF BIOMASS FEEDSTOCKS AND FUEL

Biomass feedstocks and fuels exhibit a wide range of physical, chemical, and agricultural/process engineering properties. Despite their wide range of possible sources, biomass feedstocks are remarkably uniform in many of their fuel properties (see Table 1), compared with competing feedstocks such as coal or petroleum. For example, there are many kinds of coals whose gross heating value ranges from 20 to 30 MJ/kg (million joules per kilogram; 8600–12,900 Btu/lb). However, nearly all kinds of biomass feedstocks destined for combustion fall in the range 15–19 MJ/Kg (6450–8200 Btu/lb). For most agricultural residues, the heating values are even more uniform—about 15–17 MJ/Kg (6450–7300 Btu/lb); the values for most woody materials are 18–19 MJ/Kg (7750–8200 Btu/lb). Moisture content is probably the most important determinant of heating value. Air-dried biomass typically has about 15–20% moisture, whereas the moisture content for oven-dried biomass is around 0%. Moisture content is also an important characteristic of coals, varying in the range of 2–30%. However, the bulk density (and hence energy density) of most biomass feedstocks is generally low, even after densification—between about 10% and 40% of the bulk density of most fossil fuels—although liquid biofuels have comparable bulk densities.

Table 1 Thermochemical properties of various bioenergy feedstocks and fuels

		Heating value (MJ/kg)	Ash (%)	Sulfur (%)	Potassium (%)	Ash melting temperature (°C)
Bioenergy feedstocks	Corn stover	17.6	5.6			
	Sugarcane bagasse	18.1	3.2–5.5	0.1–0.15	0.73–0.97	
	Hardwood	20.5	0.45	0.009	0.04	900
	Softwood	19.6	0.3	0.01		
	Hybrid poplar	19.0	0.5–1.5	0.03	0.3	1350
	Bamboo	18.5–19.4	0.8–2.5	0.03–0.05	0.15–0.5	
	Switch grass	18.3	4.5–5.8	0.12		1016
	Miscanthus	17.1–19.4	1.5–4.5	0.1	0.37–1.12	1090
Liquid biofuels	Bioethanol	28		<0.01		
	Biodiesel	40	<0.02	<0.05	<0.0001	
	Black liquor	11–13	40–45	3–8	0.1–8	
Fossil fuels	Coal (low rank; lignite/sub-bituminous	15–19	5–20	1.0–3.0	0.02–0.3	~1300
	Coal (high rank; anthracite/bituminous	27–30	1–10	0.5–1.5	0.06–0.15	~1300
	Oil	42–45	0.5–1.5	0.2–1.2		

(From Refs.[3,4].)

Most biomass materials are easier to gasify than coal, because they are more reactive, with higher ignition stability. This characteristic also makes them easier to process thermochemically into higher-value fuels such as methanol or hydrogen. Ash content is typically lower than for most coals, and sulfur content is much lower than for many fossil fuels. Unlike coal ash, which may contain toxic metals and other trace contaminants, biomass ash may be used as a soil amendment to help replenish the nutrients removed by harvest. A few biomass feedstocks stand out for their peculiar properties, such as high silicon or alkali metal contents. These feedstocks may require special precautions for harvesting, processing, and combustion equipment. Note also that mineral content can vary as a function of soil type and the timing of feedstock harvest. In contrast to their fairly uniform physical properties, biomass fuels are rather heterogeneous with respect to their chemical elemental composition.

Among the liquid biomass fuels, biodiesel (vegetable oil ester) is noteworthy for its similarity to petroleum-derived diesel fuel, apart from its negligible sulfur and ash content. Bioethanol has only about 70% of the heating value of petroleum distillates such as gasoline, but its sulfur and ash contents are also very low. Both of these liquid fuels have lower vapor pressure and flammability than their petroleum-based competitors—an advantage in some cases (e.g., use in confined spaces such as mines) but a disadvantage in others (e.g., engine starting at cold temperatures).

It should be mentioned here that almost all fuels suitable for traditional transport vehicles are compounds containing predominantly carbon and hydrogen. In the case of fossil derived fuels, the only other constituent elements, such as nitrogen and sulfur, are generally regarded as undesirable contaminants. Compounds such as tetraethyl lead are typically added to modify fuel properties so as to reduce the tendency of the fuel to ''knock'', while others, such as nitromethane, are added to specialty fuels to improve power output. However, biofuels differ chemically from fossil-based fuels in that they usually contain oxygen in addition to carbon and hydrogen. Like fossil fuels, they also may contain other elements, notably nitrogen, which is an undesirable impurity. Table 2 compares the approximate compositions and properties for selected transport fossil fuels and biofuels.

Biofuels are highly volatile and have a relatively high hydrogen (H) content. The portion of the volatiles in biofuels is around 70–80%. The carbon content and heat values are low compared to fossil fuels. Biofuels, including black liquor, are renewable fuels, which do not increase the carbon dioxide (CO_2) burden globally. The age of biofuels ranges from a few months to several thousands of years. Different energy plants and annual crops, which are grown on fields, are the most short-lived biofuels, with their age varying from a few months to some years. A characteristic feature of solid biofuels is their low sulfur (S) and sodium (Na) contents, but relatively high chlorine (Cl) and potassium (K) contents. The net heating value (LHV) of most biofuels is in the range of 6–10 MJ/kg in as fired conditions. This range is only about one-third of the heating value of coal.

The relatively low sulfur content in most solid biofuels may introduce corrosion problems in the superheaters. The inhibiting tendency of sulfur to limit superheater corrosion has already been recognized in the 1970s. It is generally known that when the sulfur to chlorine molar ratio (S/Cl) in the fuel is higher than 2.0, corrosion is diminished significantly. The best way to prevent molten phase corrosion is to keep the superheater metal temperature below the first melting temperature of deposits, in practice below 500°C when firing biofuels.

Table 2 Approximate compositions and properties for selected transport fossil fuels and biofuels

Fuel	Approximate average formula	Average molecular weight	Energy density (MJ/L)	CO_2 emissions (G/MJ)
Natural gas	$\sim CH_{3.85}$	18.2	38.2 MJ/m^3	51.3
LNG	$\sim CH_{3.85}$	18.2	25.0	51.3
CNG	$\sim CH_{3.85}$	18.2	38.2 MJ/m^3	51.3
LPG	$\sim C_3H_{7.8}$	49	25.7	60.2
Gasoline	$\sim C_{5.4}H_{10.7}$	80	35.2	65.8
Automotive diesel	$\sim C_{15.2}H_{22.2}$	212	38.6	65.8
Methanol	CH_3OH	32.04	15.8	60.8
Ethanol	C_2H_5OH	46.07	23.4	64.3
RME biodiesel	$\sim C_{13}H_{29}O$	201	33.3	85.0

(From Ref.[5].)

Biofuels can be combusted with various technologies, but only a few of them have gained a well-established position. The moisture content of biofuels is relatively high (compared to fossil fuels), which places certain requirements on the combustion systems designated for these fuels. In this context, the following technologies are available: 1) grate-firing technology, which is the oldest but still widely used technology for bark and for straw combustion; 2) bubbling fluidized bed technology, which is the most suitable for high moisture fuels; and 3) pulverized fuel injection technology in tangentially fired (t-fired) boilers. The first two technologies are getting obsolete; hence, a combustion example with the t-fired industrial boiler is demonstrated in the following section.

END PRODUCT USAGE OF BIOFUEL

Cofiring Biofuel with Coal in an Industrial Boiler

Because coal-fired boilers are a significant source of power generation in the United States and abroad, cofiring biomass at levels of 2–15% (heat basis) could provide a significant increase in bioenergy utilization while taking advantage of the existing utility infrastructure. Cofiring biomass with coal results in NO_x reduction and helps in reducing the unburned carbon in ash. Some utility companies have had success when cofiring 6 mm (0.25 in.) topsize biomass at full load.[6] In such situations, the computational fluid dynamics (CFD) modeling can provide insight into the behavior of the 6 mm particles as opposed to the smaller sizes. For example, Table 3 illustrates the complex behavior when cofiring a dry switchgrass in a 150 MWe t-fired pulverized coal utility boiler with four burner levels at 13.5 m, 12.0 m, 10.5 mm, and 9.0 m from the ground (A, B, C, D, where D is the lowest level near the bottom ash hopper, and A is the uppermost level) as shown in Fig. 1. Using an eastern bituminous low-sulfur coal in this CFD simulation, switchgrass is evenly distributed among the burners at a total 10% energy basis cofiring level, using a broad size distribution of about 5% plus 6 mm, 14% plus 4 mm, 37% plus 2 mm, 60% plus 1 mm, and 23% minus 0.5 mm with a mean particle size of 2 mm. Table 1 presents the fate of biomass particles—whether particles distribute to the fly ash or bottom ash, their effective biomass particle residence time (from burner injection level to either the convective section entrance or the bottom ash hopper), and combustion efficiency (CE)—as viewed from one corner of the boiler.

In this CFD simulation, pulverized coal and switchgrass achieve an average residence time of over 3 and 4 sec, respectively, with average CEs of 99.9% and 99.3%, respectively. Although switchgrass particles are an order of magnitude larger than pulverized coal, they achieve high CEs because of their high volatile content along with residence time enhancements. Table 1 shows that the smallest switchgrass particles behave in an expected fashion, with longer residence times observed for particles injected in the lower furnace, with essentially complete burnout as particles enter

Table 3 Computational fluid dynamics biomass particle size impacts—residence time, CE, and fly ash/bottom ash partitioning for 10% switchgrass cofiring at full load in a four-level burner 150 MWe t-fired boiler

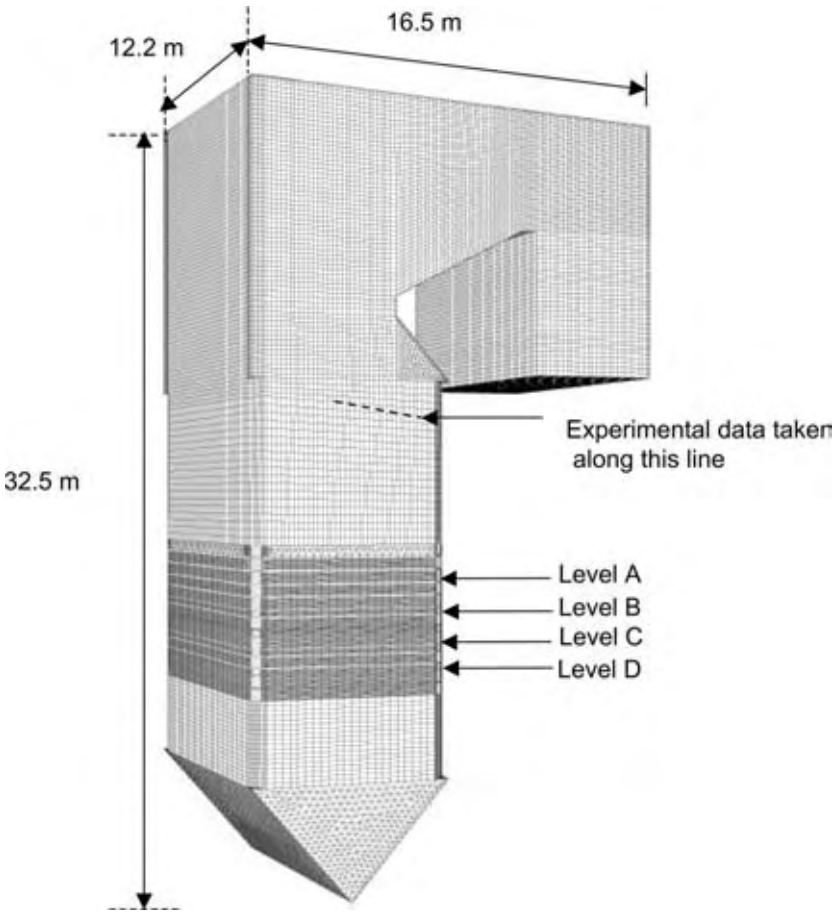

Fig. 1 Schematic of an industrial t-fired (150 MW_t) boiler.[6]

the convective pass and report to fly ash. However, the larger switchgrass particles behave quite differently as the relative contributions of gravity, buoyancy, and drag forces alter particle trajectories and effective residence times inside the turbulent flow field of the t-fired boiler. This behavior can be seen by the presence of still-burning sparklers entering the convective pass for intermediate particle sizes, and at larger sizes, still-burning sparklers that simply drop into the bottom ash. While the overall CE of 99.3% for switchgrass is very good, the presence of still-burning sparklers could be an issue from the standpoint of boiler operations and bottom ash handling.

CONCLUSIONS

In response to now incontrovertible evidence of human-induced global warming caused by the emission of atmospheric warming gases, renewable bioenergy generation is the potential vehicle to offset the greenhouse gases in the future. It is anticipated that the new electrical capacity from future power plants may come from energy crops and forestry residue combustion. Interestingly, combustion of biofuels releases CO_2, but because biofuels are made from plants that absorb CO_2 from the atmosphere, release is recaptured when new biomass is grown to produce more biofuels. Depending on how much fossil energy is used to grow and process the biomass feedstock, substantially reduced net greenhouse gas emissions result. Making biodiesel from soybeans reduces net emissions nearly 80%. The combination of reducing both gasoline use and fossil electrical production can mean a greater than 100% net greenhouse gas emission reduction and less dependence on foreign oil. As with any fossil-fuel combustion, no matter how much is spent on improved technology and emission controls, gasoline and diesel use in motor vehicles will, by definition, contribute to global climate change. To whatever extent biofuels are used instead, global warming will be reduced. Biofuels are highly volatile and hence can be used in big particle sizes as a reburning fuel. Cofiring biomass with coal in the existing power plants can significantly reduce the NO_x emissions, and hence there will be less fear of acid rain.

INTRODUCTION

Bioinformatics is the science of accumulating, analyzing, storing, assimilating, and transmitting large quantities of biological data. The completion of genome sequencing projects for a large number of organisms has kindled a quest to understand the complex programs encoded in the sequences. Because these programs are executed through coded proteins, a tremendous amount of effort is now directed toward identifying and characterizing all the proteins, their interactions, and the genetic structure defining them. Consequently, there is a great demand for computational tools to efficiently analyze and assimilate the large amount of biological data into knowledge. Particularly important are computational tools that utilize genomic, transcriptomic, proteomic, and metabolomic data to reconstruct biological pathways and networks so as to facilitate the understanding of their function and interaction.

The availability of complete genomes of microbes has revealed their remarkable industrial potential. Microbial genomic data are paving the way for novel and improved vaccines and therapeutics, better-tasting and healthier foods and beverages, stronger biodefense, efficient bioprocess alternatives, and a cleaner environment (Table 1). Bioinformatics tools will greatly facilitate a holistic understanding of the functioning of these microbes and enable their manipulation to perform desired tasks with unprecedented precision, flexibility, and efficiency. Therefore, the recent advances in bioinformatics have created a stir in the chemical process industry. The purpose of this entry is to provide an overview of bioinformatics tools and their applications toward understanding metabolic networks, which are likely to have a major impact on the chemical process industry.

Genome research is yielding enormous amounts of information at a rate that continues to increase. The nature of this information varies from static (i.e., sequences/structures of DNA and protein molecules) to dynamic (i.e., gene expression patterns and proteomic data). A large number of public databases now house these data. In the following section, the nature of biological information and some public databases for storing biological data are described. A major challenge is the computational integration of highly diverse data types, ranging from qualitative information such as gene function and protein modification sites to more quantitative information such as gene expression patterns and flux through metabolic networks.[8]

Pathway modeling, the computational representation of genetic and metabolic pathways, effectively builds on existing tools that analyze raw sequence data. It has been extensively utilized to understand the mechanism underlying the complex behavior of biological networks and even to design synthetic networks with desired properties. One such technique, namely, metabolic flux balance analysis, has been successfully applied to define the capabilities of biological systems on a genome scale and to develop an understanding of physiological function in microbes. Because bioinformatics applied to metabolic flux balance analysis shows great promise in revolutionizing the chemical process industry, an entire section is devoted to the basic principles underlying this technique and the methods for its implementation.

BIOLOGICAL INFORMATION

The sequencing of the genomes of numerous organisms has created a large amount of primary nucleotide sequence data that are stored in numerous public databases. Recent efforts to understand the function of gene products (proteins) and their complex interactions have resulted in a steadily increasing amount of biological information. As a result, there are now databases for almost all biological functional elements—from genes and gene expression to protein structure for many common organisms (Table 2). The management of this biological information has been possible because of the tremendous advances in computing capabilities in recent times. In conjunction with the development of modern database technology, the World Wide Web has become the natural medium for managing and distributing genomic data. The database at the National Center for Biotechnology Information (NCBI: http://www.ncbi.nih.gov) is the largest repository for molecular biology information. In addition to biological data, the web site has a large software collection for analyzing nucleotide and protein sequences.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120016148

Table 1 Examples of industries that will benefit significantly from advances in bioinformatics

Industry	Microbes	Reference
Health		
Genome sequence helps understand how the species achieves virulence, and identify genes and potential vaccines	*Neisseria meningitis* *Streptococcus agalactiae*	[1] [2]
Food		
Genome sequence enables their engineering to produce better-tasting and safer foods such as cheddar cheese and cabernet sauvignon	Lactic acid bacteria	[3]
Biodefense		
Knowledge of the complete genome sequence can help develop rapid detection techniques of potential bioterror agents causing deadly diseases	*Brucella suis*	[4]
Chemicals		
Genomic sequence helps in metabolic engineering to produce expensive chemicals by altering natural pathways	*Escherichia coli*	[5]
Environment		
Analysis of genomic sequence provides an understanding of physiological function and the ability to engineer bacteria to clean up hazardous waste and the environment	*Deinococcus radiodurans* *Rhadocyclus tenius*	[6] [7]

A major task now is to develop computational tools to analyze these data in the databases so as to create knowledge. There are several ongoing programs to understand the molecular machines and their molecular level controls for both individual microbes and communities of microbes sufficiently so that we can engineer them to address national needs. The computational tools required to achieve this end range from sequence analysis algorithms (comparative genomics) to statistical mechanical methods for describing macromolecular motions, structures (structural bioinformatics), and interactions (docking). A final goal is to integrate the output from these diverse tools into comprehensive computational models to perform mechanistic-based cellular simulations. Toward this goal, new technologies are required to integrate the resulting data and build multidimensional models at the cell and cell community levels that reflect the results of functional genomics studies (Fig. 1). In what follows, a relatively well-developed technique for modeling and analyzing biological systems, namely, pathway modeling, is described.

BIOLOGICAL PATHWAY MODELING

Biological systems function by transmitting and processing information in genetic, protein, and metabolic networks. Therefore, a large chunk of postgenomic research is devoted to understanding the complex interactions that are responsible for the functioning of biological networks.[9] There are two principal approaches to modeling biological systems. Kinetic modeling attempts to derive the properties of enzymatic pathways from knowledge of the kinetic parameters associated with the activity of each component and the order in which those components act.[10] Steady-state or static modeling searches for global properties of networks based on generic properties of the system such as stoichiometry and Boolean logic.[11]

Kinetic Modeling

In the first approach, a set of rate expressions are derived to describe the temporal variation of the species as a function of the activities of the binding and catalytic events (for example, using detailed mass action laws or Michaelis–Menten kinetics). This approach has been extensively used in areas such as metabolic control analysis.[12] Early studies addressing the connection between genotype and phenotype were undertaken using this technique. In particular, the phenomenon of dominance because of near-neutrality of gene activity was explained; a dominant phenotype is not affected by minor perturbations in the genotype.[12] According to the analysis, if a microbe has evolved to optimize its growth rate, then metabolic flux should be as high as possible, and the activity of each enzyme (which is a function of its level of expression as well as catalytic rate constant set by the protein structure) will take on a value that places it close to the point at which the maximal flux reaches a plateau.[12] Under these conditions, halving the dosage of the enzyme will

Table 2 Some biological databases

have little effect on the total flux, and hence the gene tends to be dominant.[12] In addition, slight changes in activity because of new mutations and polymorphisms will not greatly affect flux, so the genetic variants should have little effect on fitness, and their dynamics will be in accordance with the expectations of neutral theory. A considerable body of experimental data from *Escherichia coli* in particular corroborates this conclusion.[13]

A complete metabolic network for the human red blood cell (hRBC, see Fig. 2) was analyzed using kinetic information available in the literature.[10] The mass balance equations describing the temporal variation of the metabolite concentrations, x, are represented as

$$\frac{\mathrm{d}x}{\mathrm{d}t} = \mathbf{S}\mathbf{v}(x) \tag{1}$$

where $\mathbf{v}$ is the vector of enzymatic reaction rates and $\mathbf{S}$ is the stoichiometric matrix for the enzymatic reactions. The dynamic model was analyzed using phase plane analysis, temporal decomposition, and statistical analysis. The results revealed that the formation of pseudoequilibrium concentration states was a characteristic feature of hRBC metabolism. The analysis

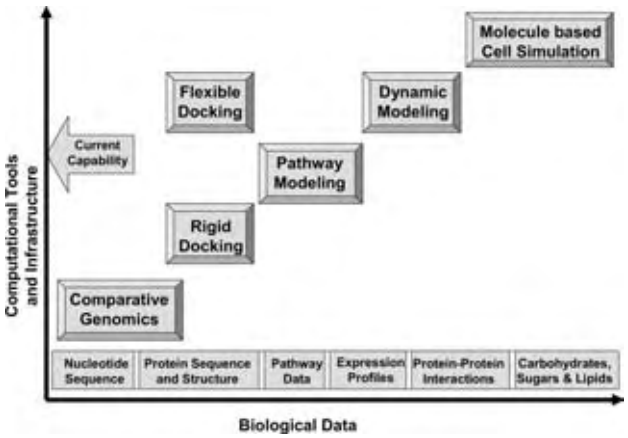

Fig. 1 The amount of biological information is growing steadily. From nucleotide sequence to protein–protein interactions, a large amount of data are being generated for each biologically functional element. Computational tools are now available to perform analysis of the data for these elements and convert them into knowledge. To address the complex interactions between various functional elements, there is a need to develop new computational analysis, modeling, and simulation capabilities. Research is currently under way to create the mathematics, algorithms, and computer architectures required to understand each level of biological complexity.

enabled the definition of physiologically meaningful pools of metabolites.[10] Analysis of this nature elucidates the nuances underlying the functioning of biological networks and the results can greatly improve understanding and facilitate manipulation.

Models based on mass action kinetics have proven useful in describing cellular processes such as receptor–ligand binding, signal transduction, and cellular behavior.[14] Biochemical networks involved in cellular signaling pathways possess rich dynamical characteristics. Experimental elucidation of the dynamic behavior of these pathways is a daunting task. Therefore, there is great interest in developing theoretical models of biochemical networks involved in signaling pathways. In conjunction with experimental data, these models reveal that signaling pathways can display ultrasensitivity, flexible bistability, and oscillatory behavior.[15]

The processes occurring during cell division in prokaryotes and eukaryotes represent a classic example of a tightly controlled oscillatory biochemical network. Models of biochemical networks involved in cell division have proven extremely useful in testing various hypotheses regarding the underlying mechanism. Specifically, it was found that toggle-like switching of the dynamics of the network arising from positive feedback is the driving force for cell division transitions into and out of mitosis.[16]

Networks of signaling pathways are also implicated in performing temporal decoding functions involved

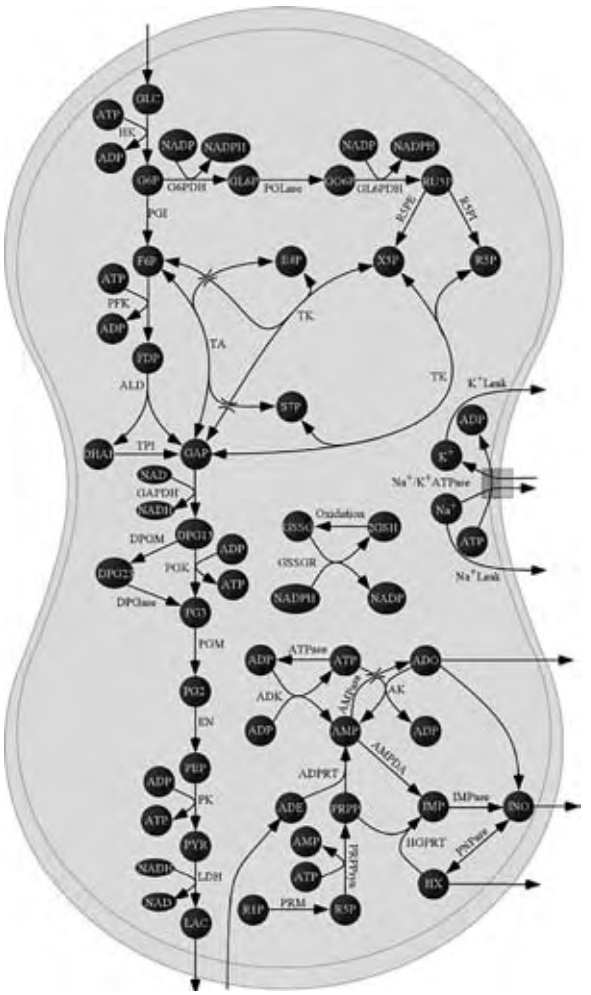

Fig. 2 The red blood cell has played a special role in the development of mathematical models of metabolism given its relative simplicity and the detailed knowledge about its molecular components. The model comprises 44 enzymatic reactions and membrane transport systems and 34 metabolites and ions. The model includes glycolysis, the Rapaport–Leubering shunt, the pentose phosphate pathway, nucleotide metabolism reactions, the sodium/potassium pump, and other membrane transport processes. Analysis of the dynamic model using phase planes, temporal decomposition, and statistical analysis shows that hRBC metabolism is characterized by the formation of pseudoequilibrium concentration states: pools or aggregates of concentration variables. (From Ref.[10].)

in bacterial chemotaxis. Using mass action kinetic models of the networks, it is possible to understand information processing (temporal tuning) by the network. Such models predict two primary mechanisms for temporal tuning of pathways: a weighted summation of responses of pathways with different timing, and the presence of biochemical feedback loops with emergent dynamics.[17]

Kinetic models of biological systems show great potential in guiding the manipulation biological

systems to precisely perform the desired tasks. Examples of such applications are the engineering of synthetic gene circuits and metabolic engineering.[10,18] Hasty et al. demonstrated that gene circuits engineered using computational modeling and experimental molecular biology can lead to insights into some of the basic modules that comprise complex, naturally occurring gene networks.[18] Drawing an analogy with established techniques in electrical engineering, the gene circuit approach uses mathematical and computational tools in the analysis of a proposed circuit diagram, while novel experimental techniques are used to construct the networks to perform the desired task. Using this technique, it is possible to design basic building blocks of gene circuits, namely, autoregulatory toggle switches (Fig. 3), logic gates, and oscillators.

The lack of kinetic information makes it difficult to develop detailed models of biological systems. Therefore, most studies attempt to model subnetworks to gain an insight into biological function. In most cases, reasonable values are assigned to biochemical parameters to develop a first-generation model. The results of this model are compared with available experimental data to test the underlying hypothesis. The model may then be used to design experiments, the results of which can help fill the knowledge gaps in the model.

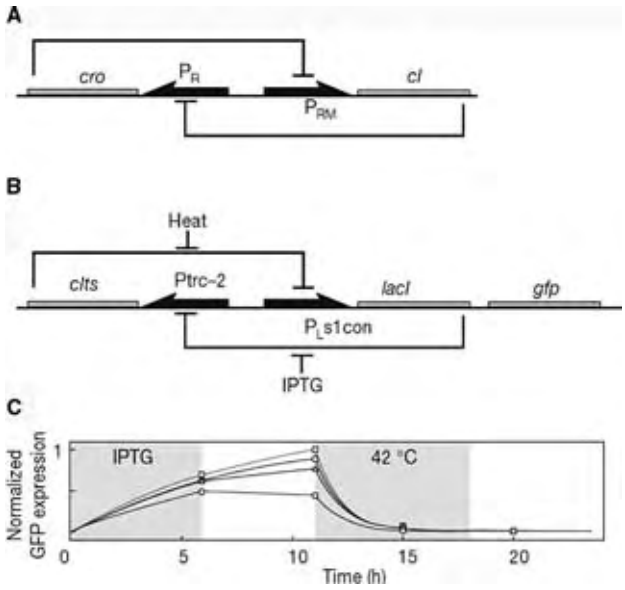

Fig. 3 Genetic toggle switch: (A) The P_R and P_{RM} system in λ phage. Cro controlled by P_R represses P_{RM} whereas CI controlled by P_{RM} represses P_R (B) The synthetic genetic toggle switch uses the promoter Ptrc-2 to control the production of a temperature-sensitive version of the CI protein (expressed by *cIts*); CI acts to repress the promoter P_Ls1con. Conversely, P_Ls1con controls transcription of the gene *lacI*, whose product LacI (lactose repressor) represses Ptrc-2. (C) Experimental results showing bistability of a genetic toggle switch in *E. coli*. The response of green fluorescent protein (GFP) is shown, which corresponds to expression of the *cI* gene. Shaded regions indicate periods of induced switching. (From Ref.[18].)

Steady-State or Static Modeling

The second broad class of genomic modeling eschews any explicit reference to the kinetic properties of defined pathways, and instead aims to find generic systems properties that emerge from the logic and connectivity of interacting networks. The approach has been applied to study genetic regulatory networks as well as metabolic networks.

The universal properties of gene regulatory networks may be described using a combination of Boolean switches.[11] In such a model, each gene interacts with k other genes. Using such a model, Kauffman illustrated the underlying mechanisms responsible for order, adaptation, and coevolution.[11] The particular biological behavior that was predicted to occur was found to be a function of the degree of interaction within the network, embodied in k. A notable observation was that, for very large values of k, a phase transition from order to chaos occurs. Therefore, there is a limit to the degree of interconnectivity that can be supported by biological networks. The application of this modeling technique to the genome-wide analysis of metabolic networks has received lot of attention in recent times. The basic principles underlying this technique and the methods for its implementation are described in the forthcoming section, followed by a description of applications in the field of metabolic engineering.

METABOLIC FLUX BALANCE ANALYSIS

Metabolic networks can be quantitatively and qualitatively studied without enzyme kinetic parameters by using a constraints-based approach.[19] Metabolic networks must obey the fundamental physicochemical laws, such as mass, energy, redox balances, diffusion, and thermodynamics. Therefore, when kinetic constants are unavailable, cellular function can still be mathematically constrained based on the mass and energy balance. Flux balance analysis (FBA) is a mathematical modeling framework that can be used to study the steady-state metabolic capabilities of cell-based physicochemical constraints.[19]

The FBA approach is attractive as it does not require kinetic parameters. Additionally, the stoichiometric parameters that are required for FBA are constant and unambiguously unknown. The stoichiometric coefficients are invariant and can be identified

from genome sequence information using bioinformatics. Therefore, like all static modeling attempts, this approach greatly benefits from comparative genomics: the presence of homologs of known enzymes can be used to reconstruct the biochemical pathway.[20] Functional mapping based on homology is possible because of the evolutionary conservation of proteins, and about 70% of gene products from each of the sequenced genomes having homologs in distant genomes.[20] Thus, the functions of many newly sequenced genes can be predicted simply by comparing different genomes and by transferring functional annotation of proteins from better-studied organisms to their homologs from lesser-studied organisms. Once these functions are known, a putative metabolic network can be constructed and bioinformatics tools can be applied to analyze the network.

FBA is attractive as a predictive tool. That is, once the model is constructed, one can predict the metabolic behavior under a number of different conditions.[21] The basic principle underlying FBA is the steady-state conservation of mass, energy, and redox potential. A dynamic mass balance can be written around each metabolite (X_i) within a metabolic network. Fig. 4 shows a hypothetical network with the fluxes (V) affecting a metabolite (X_i). The dynamic mass balance for X_i is:

$$\frac{dX_i}{dt} = V_{syn} - V_{deg} - V_{use} \pm V_{trans} \quad (2)$$

where the subscripts syn and deg refer to the synthesis and degradation reactions. The V_{trans} and V_{use} metabolic fluxes correspond to the uptake/secretion and utilization reactions, respectively. Eq. (2) can be rewritten as:

$$\frac{dX_i}{dt} = V_{syn} - V_{deg} - V_{use} + b_i \quad (3)$$

where b_i is the net transport of X_i into the defined metabolic system. The growth and the maintenance requirements (V_{use}) can be represented as fluxes in the metabolic network, which are mathematically indistinguishable from other metabolic reactions. The stoichiometry and magnitude of the growth and maintenance fluxes can be estimated from the literature or measured.[22,23] For a metabolic network that contains m metabolites and n metabolic fluxes, all the transient material balances can be represented by a single matrix equation:

$$\frac{d\mathbf{X}}{dt} = \mathbf{S} \cdot \mathbf{v} + \mathbf{b} \quad (4)$$

where $\boldsymbol{X}$ is an m dimensional vector defining the metabolite concentrations, $\mathbf{v}$ is the vector of n metabolic fluxes, $\mathbf{S}$ is the $m \times n$ stoichiometric matrix, and $\mathbf{b}$ is the vector of metabolic transport processes.

The time constants characterizing metabolic transients are typically very rapid compared to those of cell growth and process dynamics; therefore, the transient mass balances can be simplified to consider only the steady-state behavior.[24] Eliminating the time derivative in Eq. (4) and rearranging the equation yields:

$$\mathbf{S} \cdot \mathbf{v} + \mathbf{I} \cdot \mathbf{b} = 0 \quad (5)$$

Eq. (5) states that at steady-state (or pseudo-steady-state), all the formation fluxes of a metabolite must be balanced by the degradation fluxes.

Not all metabolites are capable of being transported into or out of the cell; therefore, the $\mathbf{I} \cdot \mathbf{b}$ term can be simplified by removing the rows in the $\mathbf{b}$ vector that correspond to metabolites that are not transported, thus forming a vector $\mathbf{b}_r$. Additionally, the corresponding columns in $\mathbf{I}$ are eliminated, thus forming the matrix $\mathbf{U}$. Furthermore, the stoichiometric matrix can be partitioned such that the metabolic reactions within the system boundary are defined by $\mathbf{S}_{reactions}$, $\mathbf{S}_{use}$, representing the internal fluxes and the biomass/maintenance requirement fluxes, respectively. The $\mathbf{U}$ matrix allows certain metabolites to be transported into and out of the system. Eq. (5) can therefore be rewritten as:

$$\begin{aligned} &\mathbf{S} \cdot \mathbf{v} + \mathbf{U} \cdot \mathbf{b}_r = 0 \\ &[\mathbf{S}_{reactions} | \mathbf{S}_{use} | \mathbf{U}] \begin{bmatrix} \mathbf{v}_{reactions} \\ \mathbf{v}_{use} / \mathbf{b}_r \end{bmatrix} = 0 \end{aligned} \quad (6)$$

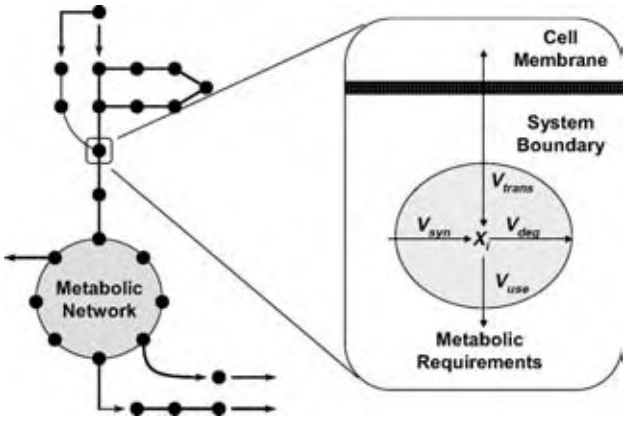

Fig. 4 Flux balance models use material balances around each metabolite in a metabolic network. The concentration of each metabolite, X_i, is affected by various fluxes, V_j. V_{trans} is the uptake or secretion flux, while V_{use} is the flux required for growth and maintenance. V_{syn} and V_{deg} refer to the fluxes resulting from the metabolic synthesis and degradation of the metabolite.

where

$$\mathbf{S}' = [\mathbf{S}_{\text{reactions}}|\mathbf{S}_{\text{use}}|\mathbf{U}]$$

$$\mathbf{v}' = \left[\frac{\mathbf{v}_{\text{reactions}}}{\mathbf{v}_{\text{use}}/\mathbf{b}_r}\right]$$

Therefore, we generate the following equation:[21]

$$\mathbf{S}' \cdot \mathbf{v}' = 0 \tag{7}$$

Every metabolite inside the system boundary corresponds to a row in the stoichiometric matrix; however, some of these metabolites are intracellular, while the rest are extracellular (see Fig. 4). The stoichiometric matrix is arranged such that the m_{i} internal metabolites are entered first, and the m_{e} external metabolites second ($m = m_{\text{i}} + m_{\text{e}}$). When the stoichiometric matrix is arranged in this manner, the $\mathbf{S}_{\text{use}}$ and the $\mathbf{U}$ matrices take on the following form:

$$\mathbf{U} = \left[\frac{0}{I}\right]$$

$$\mathbf{S}_{\text{use}} = \left[\frac{\mathbf{S}^u_{\text{use}}}{0}\right] \tag{8}$$

where $\mathbf{U}$ is an $m \times m_{\text{e}}$ matrix, $\mathbf{I}$ is the $m_{\text{e}} \times m_{\text{e}}$ identity matrix, and $\mathbf{S}^u_{\text{use}}$ is a matrix with m_i rows.

Eq. (7) defines the mass, energy, and redox potential constraints on the metabolic network, thus effectively defining the capabilities of the metabolic network. Flux distributions (the flux vector, $\mathbf{v}$) that satisfy Eq. (7) are possible metabolic phenotypes. However, this estimation of the metabolic capabilities is conservative and can be further reduced by adding additional constraints.

Additional Constraints

Eq. (7) defines the mass, energy, and redox balance constraints on the metabolic system. However, additional physicochemical constraints are typically placed on the metabolic network. For example, the value of the flux through each of the metabolic reactions can be constrained based on reversibility, transport limitations, and/or maximum allowable fluxes. Irreversibility constraints are enforced by placing a lower limit of zero on the respective irreversible metabolic reactions:

$$0 \leq v_j \leq \beta_j \tag{9}$$

In the absence of additional information, β_j (metabolic flux upper limit) is set to infinity. The constraints in Eq. (9) can be representative of a maximum allowable flux through an irreversible reaction by setting β_j to a finite value. The flux limitations may be known from enzyme expression levels and $V_{\max}$ data. The following equation can be used if information regarding the metabolic flux range is known, rather than simply specifying the maximal flux levels:

$$\alpha_j \leq v_j \leq \beta_j \tag{10}$$

The restriction of the flux through certain reactions can be used to model the regulatory events occurring within the cell. Further, any experimental information can be simulated by appropriately assigning values to α and β. It is also possible to incorporate regulatory information using this methodology. For instance, setting fluxes to zero or some low level can represent the repression of certain enzymes, such as *ppc* and *pps* during growth on glucose. Thus, the use of additional constraints provides increased flexibility in analyzing the metabolic network by incorporating additional knowledge about a particular cell.

Commonly, restrictions are placed on the transport fluxes (corresponding to the various uptake processes). For example, when specific information regarding an uptake rate is not known, the maximal uptake rate is set by using the constraints defined by Eq. (10) (β is defined as the maximal uptake rate or $\mathbf{b}_r$ element). However, often in experimental systems, the uptake rates have been measured, and the flux value can be fixed by using the formalism described by Eq. (10). Transport reactions for metabolites that are not present in a simulated culture condition are constrained to zero ($0 \leq v_j \leq 0$).

Solution Method

Typically, the number of metabolic fluxes is greater than that of mass balances (i.e., $n > m$) resulting in a plurality of feasible flux distributions or flux vectors that satisfy Eq. (7). This range of solutions is indicative of the flexibility in the metabolic network. Although infinite in number, the solutions to Eq. (7) are in the null space of the matrix $\mathbf{S}$.[25] However, in the analysis of metabolic systems, we are interested in the feasible set.[26] The feasible set is the region of intersection between the null-space of $\mathbf{S}'$ and the linear inequality constraints Eqs. (9) and (10). The feasible set defines the capabilities of the metabolic genotype of a given organism [more accurately than just considering the solutions to Eq. (8), as discussed above], because it defines all the metabolic flux distributions that can be achieved with a particular set of genes.[19] Each flux distribution is a specific metabolic phenotype that is expressed under particular conditions.

There are two fundamentally different methods to define a specific metabolic phenotype or flux vector.

First, one can experimentally measure as many fluxes (or more) as the dimension of the null-space, so as to uniquely calculate the remaining fluxes.[24] This approach is called metabolic flux analysis. Alternatively, an objective of the metabolic network can be chosen to computationally explore the best use of the metabolic network by a given metabolic genotype. Herein, we pursue the second option. The solution to Eq. (7) subject to the linear inequality constraints can be formulated as a linear programming (LP) problem, in which one finds the flux distribution that minimizes a particular objective. Mathematically, the LP problem is stated as:

Minimize Z, where

$$Z = \sum c_i \cdot v_i = \langle \mathbf{c} \cdot \mathbf{v} \rangle \quad (11)$$

where Z is the objective that is represented as a linear combination of metabolic fluxes v_i. Herein, the vector $\mathbf{c}$ is defined as the unit vector in the direction of the growth flux, v_{growth}. The optimization can also be stated as the equivalent maximization problem, i.e., by changing the sign on Z.

Objective Function

This general representation of Z enables the formulation of a number of diverse objectives. These can be design objectives for a strain, exploitation of the metabolic capabilities of a genotype, or physiologically meaningful objective functions, such as maximization of cellular growth rate. For instance, growth can be defined in terms of biosynthetic requirements based on cellular biomass composition, as defined in the literature.[22] Thus, biomass generation is defined as a reaction flux draining the intermediate metabolites in the appropriate ratios, and the negative of this flux is defined as the objective function to be minimized, Z. The diversity of metabolic objectives that can be represented by Eq. (11) provides the necessary flexibility to answer a number of important questions.

APPLICATIONS

Flux balance analysis has been used for over 15 yr to study the metabolic flux distribution.[19] Initially, the applications of FBA were primarily educational; however, recently, the utility has grown. The FBA has been applied to study the effect of gene deletions, the design of bacterial metabolism for industrial and environmental applications, or for the computational exploration of cellular physiology.[19] Metabolic engineering has been successfully applied to engineer micro-organisms to produce valuable biochemicals for the pharmaceutical industry. For example, Stafford et al. successfully used *Rhodococcus* sp. to convert indene into precursors of the HIV protease inhibitor, and Chang et al. engineered *E. coli* to produce optically pure isomers of lactate.[27,28] The FBA will likely find additional applications in the near future.

Traditionally, to identify the function of a protein the first step was to obtain a mutant and study its properties. This same procedure can also be applied to whole-cell models. A detailed understanding of the metabolic network is possible by understanding the behavior of the system without a key component. The FBA has been used to predict the whole-cell metabolic flux distribution for a number of mutants under different conditions.[19] The results of the computational gene deletion analysis indicate that the model accurately predicts the qualitative growth behavior in over 85% of the cases. Genome enabled studies, such as the analysis of large sets of mutants in parallel and whole-cell transcript profiling, can be further aided by the interpretation of the data from a metabolic model.[19]

The FBA can provide insights for engineering metabolic networks. For example, FBA can be used to identify the important fluxes for the production of a metabolite or protein. Once the key points are identified, the manipulations can be carried out using molecular genetics. In the past two decades, the ability to make precise manipulations of the cellular genetic content has greatly outpaced our ability to predict the effect of these changes. Through techniques such as FBA, metabolic engineers have identified tools and techniques that can overcome this limitation. Thus, in the near future, metabolic engineers and bioinformatists will be able to harness the power of having completely sequenced genomes and a descriptive mathematical model for their particular system of interest.

Finally, mathematical modeling in biology can provide valuable insight into the integrative behavior of cellular networks. For example, FBA can be used to predict the metabolic by-products in *E. coli* that are formed during aerobic and anaerobic metabolism.[19] Furthermore, FBA has been utilized to generate several novel hypotheses regarding the function of the *E. coli* metabolic network. These were demonstrated to be consistent with available experimental data.[21]

HIGH-THROUGHPUT EXPERIMENTS

An area that is receiving considerable attention is the development of computational tools to meaningfully analyze data obtained using high-throughput experiments. These techniques have the potential to reveal important information otherwise buried within a sea

of data. Gene expression, defined by the levels of cellular mRNA, is the first aspect of gene function amenable to genome-scale measurements with readily-available technology. It is now possible to carry out massively parallel analysis of gene expression on tens of thousands of genes from a given sample.[29] A number of techniques have been developed to perform statistical analysis of the measurements, including public databases and proprietary software. The most popular method for analyzing gene expression profiles is hierarchical clustering. This approach is extremely effective in identifying groups of coregulated genes, and is incorporated into the Cluster/TreeView software (http://rana.lbl.gov/EisenSoftware.htm). A particularly impressive application of this strategy was the compendium of expression profiles approach in which over 300 different strains and conditions were contrasted.[29] This technique can be used to study the coregulation of groups of genes under different conditions and upon treatment with drugs. Compared to the method of assessing gene function by coregulation, the compendium approach has a significant advantage in that it does not rely on the regulatory characteristics of the gene of interest. Furthermore, the same compendium used to characterize mutants can also be used for other perturbations, including treatments with pharmaceutical compounds, and potential disease states as well. For instance, the compendium mentioned here was used to identify a novel target for the commonly used drug dyclonine.[29]

The results of incisive analysis of data obtained from high-throughput experiments have the potential to provide important information regarding the underlying structure of the biological networks. Information about the architecture of biological networks can provide tremendous insights into their structure and function. Moreover, such data are extremely useful in the development of dynamic models of these pathways. For example, using a network clustering method to analyze high-throughput protein–protein interaction data obtained using two-hybrid screens, it is possible to unravel the signaling-protein modules (Fig. 5).[30] In Fig. 5, the data are seen to decompose into well-defined clusters. For example, Ras-pathway proteins form a single cluster. The organization of a pathway into separate protein clusters reflects the existence of more than one module within the pathway. The results indicate that pathway models can then be developed in a modular manner.

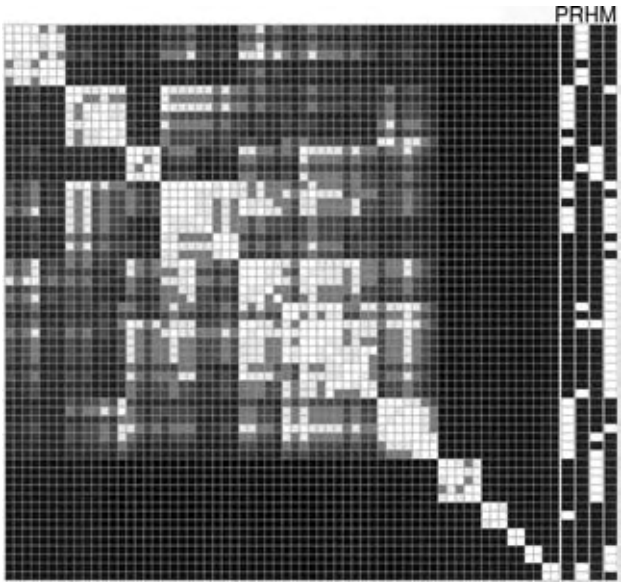

Fig. 5 Diagram showing the clustering of proteins involved in the yeast signaling network. From a global two-hybrid screen, 64 proteins that have at least one interaction with another signaling protein were selected. A symmetrical matrix of these 64 proteins was clustered identically in both dimensions. The cluster tree is not shown. Each row or column represents a protein. Each feature is the intersection of two proteins and is a grayscale representation of pairwise protein association (see text). Direct interactions are white. Indirect interactions of increasing distance (weaker association) are progressively darker. All features on the diagonal (self-associations) are white. Columns to the right of the clustered network represent Munich Information Center for Protein Sequences (MIPS)-defined signaling pathways [P, polarity-PKC; R, Ras; H, HOG; M, mating/filamentation MAPK (mfMAPK)]. White bars in the MIPS pathway columns indicate protein members of the pathway. (From Ref.[30].)

CONCLUSIONS

Recent advances in molecular biology have created a wealth of information from which it is possible to understand biological function at the molecular level. Toward this end, computational tools are being rapidly developed to process this information and convert it into knowledge. The availability of biological information about microbes and the ability to effectively process that information to define the initial capabilities in both normal and perturbed states have tremendous potential in the chemical process industry. Industries that will greatly benefit include the pharmaceutical, biotechnology, health, food, defense, biochemical, and environmental.

A significant effort in the information processing direction has been devoted to reconstructing, analyzing, and understanding the biological pathways involved in gene regulation, signaling, and metabolism. Techniques are now available to model biological subnetworks and, in some cases, even complete networks. Their applications have revealed that biological networks exhibit complex dynamical behavior,

including ultrasensitivity, flexibility, bistability, oscillatory behavior, and temporal tuning. A good understanding of these functions will be extremely useful in engineering biological systems to perform the desired tasks and, therefore, will have tremendous applications in process design, development, and optimization.

The flux balance approach is an elegant technique for analyzing biological pathways in that the approach allows metabolic networks to be quantitatively and qualitatively studied without knowledge of specific enzyme kinetic parameters. A combination of FBA and bioinformatics provides a rapid, economical, and predictive in silico screening method for potential strategies to produce a desired compound.

In the near future, there will be tremendous progress in the development of sophisticated computational tools to assimilate biological information into quantitative models. Such models will facilitate a deeper understanding of biological function, thereby allowing their precise engineering to perform the desired tasks. A major challenge in modeling and simulating systems biology is integrating high- and low-level models so that a more accurate picture of the entire biological process can be obtained. Integrating models of protein structure and function with those of biochemical pathways promises to provide insights into the complexities of biological function.

High-throughput experiments will also significantly benefit from powerful computational tools to extract biologically meaningful information from a large amount of data. The results of these experiments will be extremely useful in providing information about the underlying structure of biochemical pathways and in refining mathematical and computational models. With the development of sophisticated bioinformatic tools for understanding and manipulating biological function with amazing precision, there is considerable excitement in the chemical process industry.

INTRODUCTION

Since the energy crisis of the 1970s, the development of low-cost, sustainable, and renewable energy sources has been a major focus of research. Fuel-grade ethanol is a transportation energy source that can be produced from biomass. Biomass resources for ethanol include sugar-based crops such as beets and cane, starch-based crops such as corn and potatoes, and lignocellulosic feedstocks such as wood, corn stover, and grasses.

This entry provides an overview on the processes and limitations for making ethanol from biomass using either a fermentable sugar platform or a fermentable producer gas platform. Fig. 1 shows a simplified schematic of the platforms that are described later. Two of the platforms convert biomass (sugar, starch, or lignocellulose) into fermentable sugars, while the other platform converts lignocellulose into fermentable producer gas. Since an azeotrope occurs in the distillation process (3–5% water remains), further dehydration of ethanol can be accomplished through azeotropic distillation or molecular sieve dehydration.

The advantages and disadvantages of using ethanol as a transportation fuel are also described along with the issues that must be resolved in providing a consistent supply of high-quality and low-cost biomass for the production of ethanol. Several technological barriers remain in producing ethanol, including high enzyme costs, the inability of microbial strains to simultaneously and efficiently utilize a variety of sugar substrates, and the low ethanol yield in producer gas fermentation. However, with the development of inexpensive routes for production, low-cost ethanol could soon become a reality.

ETHANOL AS A BIOFUEL

In 2001, 80% of worldwide energy was supplied by fossil fuels, with only 1.4% being supplied by sustainable biomass used for electricity, heat production, and transportation. With regards to transportation energy, 97% was supplied by fossil fuels in industrialized nations.[1] Due to concerns over the depletion of fossil fuels, utilizing renewable resources would be beneficial for supplementing energy needs currently obtained from fossil fuels.

Fuel-grade ethanol (bioethanol) and other valuable commercial products can be produced by utilizing renewable resources (i.e., biomass) as a starting raw material. Over the last few years, there has been a tremendous growth in the U.S. ethanol industry fueled by a growing demand for renewable fuels. In 2002, the total ethanol produced in the United States was 2 billion gallons, representing a 20% increase over 2001 and a 45% increase over 1999.[2] The potential world ethanol production from biomass is 130 billion gallons per year, with lignocellulosic biomass contributing to 90% of this amount. This production capacity is 16 times higher than the current ethanol production in the world and could replace 32% of the global gasoline consumption.[3] As a supplement to gasoline, ranging from 10% (E10) to 95% (E95), ethanol is beneficial for environmental and economic/national security reasons.

Environmental Benefits

The Clean Air Acts Amendments of 1990 mandated the addition of oxygenates to gasoline to reduce the formation of harmful ground-level ozone (photochemical smog) in urban areas. In addition, the reduction of toxic gaseous pollutants and volatile organic compounds from emissions of motor vehicles was mandated. Methyl tertiary butyl ether (MTBE) has traditionally been used as an oxygenate in gasoline due to its high octane number, low sulfur content, and relatively low production cost as compared to other high-octane components.[4] However, in recent years, MTBE has been shown to be a potential carcinogen in humans and animals and a source of ground- and surface-water contamination. MTBE is currently being eliminated through political

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120039776

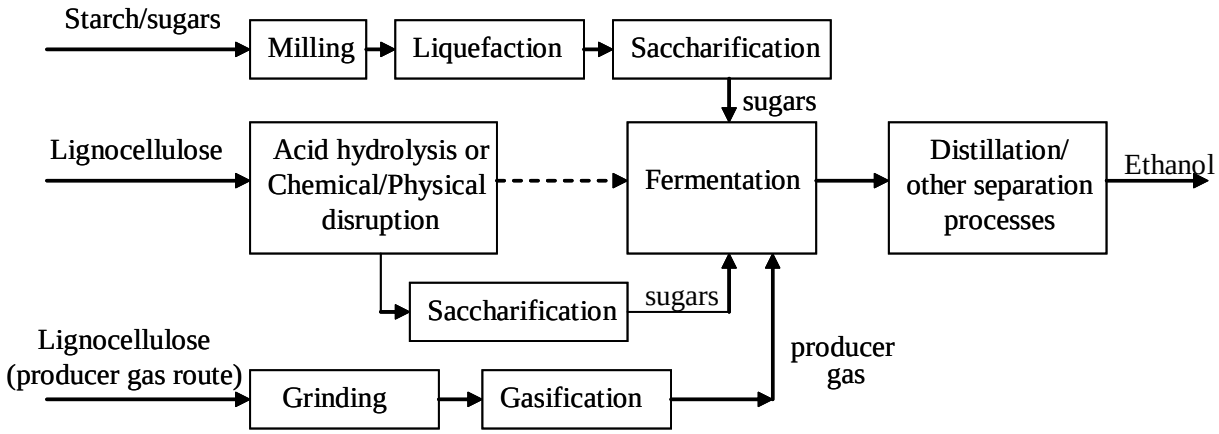

Fig. 1 Processes for biomass conversion to ethanol.

means, although efforts are being made to prevent the ban.[5] Ethanol is a very strong candidate to replace MTBE despite higher production costs, since it is environmentally friendly and can be produced domestically from renewable sources.

The addition of ethanol to gasoline reduces harmful vehicle emissions and facilitates the reduction or removal of toxic air components, which are commonly found additives in gasoline.[2] Emissions of carbon dioxide (CO_2), the primary greenhouse gas contributing to global warming, have increased steadily, and the transportation sector alone accounts for 33% of total emissions.[6] It is estimated that an 85% ethanol fuel would reduce greenhouse gas emissions between 15% and 30%.[7] Ethanol-blended fuels would reduce particulate emissions, primarily a concern in diesel engines, by as much as 40%.[2]

Economic/National Security Benefits

Currently, the United States imports about 57% of its oil, creating a US$ 66 billion trade deficit; the deficit is expected to rise to US$ 170 billion by 2020.[8] Projections show that oil imports could grow to 68% in 2025, thus increasing the dependence on crude oil from potentially unstable regions around the world.[2] It is estimated that a 10% ethanol blend would reduce oil requirements by 3%, while a 95% ethanol blend could reduce the oil requirement by as much as 44%.[9] Thus, it is beneficial to increase local energy production via fuels from renewable sources to prevent sudden energy disruptions, which could have severe economic ramifications.

Drawbacks

There have been ongoing arguments over the use of ethanol as a fuel. Ethanol can be corrosive to some metals, gaskets, and seals in car engines. The heating value of ethanol is 76,000 Btu/gal compared to 115,000 Btu/gal for gasoline; hence, more ethanol is required to travel the same distance. There have been conflicting reports on the preceding statement, since some argue that there is statistically no mileage difference due to the higher combustion efficiency of ethanol compared to gasoline.[10] Some argue that the cost of ethanol is too high for it to be used as an additive or a replacement to gasoline and that the ethanol industry will not survive without tax incentives.[11] Arguably, ethanol as a fuel will not be able to compete with gasoline unless less expensive routes for ethanol production are investigated and developed.

BIOMASS RESOURCES

The major sources of biomass feedstock are low-cost residues, wastes, and byproducts such as corn stover, wheat and rice straw, municipal solid waste, sawdust, dedicated energy crops such as switchgrass, hybrid poplars, and hybrid willows, and corn starch. The total estimated availability of usable biomass in the world is about 2 billion dry tons per year.[3] Thus, considerable effort has been devoted towards developing energy crops to meet the estimated increase in energy usage. An estimated 549 million acres of land will be available to cultivate such energy crops (based on estimates by the Oak Ridge National Laboratory—Biofuels Feedstock Development Program). The use of herbaceous energy crops, such as switchgrass, for the production of ethanol also offers a significant energy gain compared to corn. The ratio of total available energy to the total energy input for harvesting and handling is 4.43 and 1.21 for switchgrass and corn, respectively, translating to energy gains of 343% and 21% respectively.[12] In addition to its energy gain, switchgrass

has been chosen as the model crop for biomass utilization because of its high productivity over a wide geographic range, ability to grow on marginal lands, low water and nutrient requirements, and environmental benefits such as improved soil conservation.[13]

One of the primary reasons for the slow acceptance of biomass to ethanol conversion is the lack of a reliable and sustainable lignocellulosic supply infrastructure to maintain a commercial conversion facility. There are many issues that must be resolved in providing a consistent supply of high-quality, low-cost biomass.[14]

- *Feedstock quality*. To operate round the year, most conversion facilities need to utilize a variety of biomass feedstocks. Therefore, changes in feedstock quality, including physical and chemical characteristics, must be taken into account in the design, operation, and performance of a commercial plant.
- *Harvesting and collection*. Crop residues must be collected soon after the principal crop has been removed to reduce field losses and avoid contamination. Other feedstocks such as perennial grasses are harvested only during selected months of the year. The timing of harvest and collection of crop residues and energy crops often necessitates the use of storage facilities.
- *Transportation*. Movement of biomass from the original source to a processing facility can be very costly because of its relatively low bulk density. For example, the bulk density of coal is over three times that of most standard biomass packages.
- *Storage*. The quantities required for a commercial conversion facility demand the use of storage facilities even if only used as a supply buffer at the facility itself. For dry biomass, protection from the elements is often required to maintain acceptable moisture levels and to minimize storage losses. In addition, fire protection is an important consideration when storing large quantities of biomass at one site.

BIOMASS TO ETHANOL: FERMENTABLE SUGAR PLATFORM

A majority of ethanol produced from biomass utilizes the fermentation of sugars that are obtained from polysaccharides prevalent in the biomass. Feedstocks include sugar-based crops such as beet and cane, starch-based crops such as corn and potato, and lignocellulosic plants such as wood, corn stover, and grasses. Fermentation increases in difficulty from sugar crops to starchy crops to lignocellulosic plants as a result of the increasing complexity and heterogeneity of sugar components of these biomass resources. Sugar crops contain the simplest sources of sugars in the form of sucrose (Fig. 2), a disaccharide consisting of

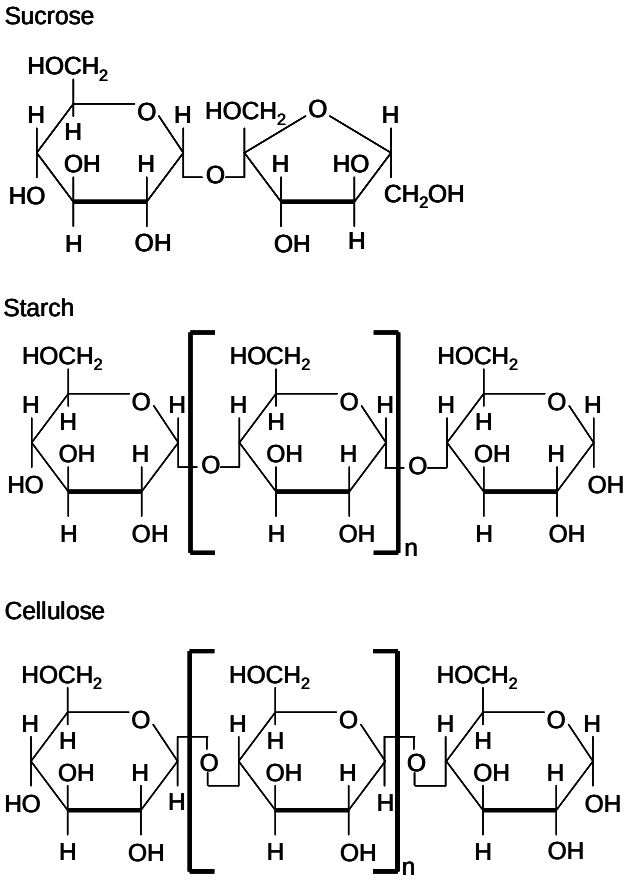

Fig. 2 Sugar units of biomass.

glucose and fructose (both are six-carbon sugars). Starch is a polysaccharide that serves as the nutritional reservoir in plants and is composed of glucose residues in α-1,4 linkages that must be converted to single glucose units for fermentation. Starch consists of either an unbranched form (Fig. 2) or a branched form containing additional α-1,6 linkages of glucose every 20–30 glucose units.

Lignocellulosic materials are characterized by varying amounts of cellulose, hemicellulose, lignin, and small quantities of other extractives. Typically, the composition by weight is 40–50% cellulose, 20–40% hemicellulose, and 10–30% lignin.[15] Cellulose (Fig. 2) is an unbranched polysaccharide that serves a structural role in plants and is composed of glucose residues joined by β-1,4 linkages, which are stronger and more difficult to break than the starch linkages. Hemicellulose is a branched polysaccharide, consisting primarily of five-carbon sugars such as xylose and arabinose in addition to six-carbon sugars such as glucose and mannose. These complex sugars must be converted to single sugar units for fermentation. Lignin is a group of amorphous, high molecular weight compounds that cannot be fermented.

Fermentation of Sugar and Starch Crops

Most current commercial ethanol production is from the fermentation of sugar and starch crops. Yeast can rapidly convert sucrose to ethanol with a theoretical carbon conversion of 67%. The production of ethanol from corn grew to about 1.9 billion gallons in 2001.[16] This accounted for 90% of the total ethanol production and an estimated 615 million bushels of corn (6.2% of total corn produced) were consumed. The remaining 10% of ethanol production was by fermentation of grain sorghum, barley, wheat, cheese whey, and potatoes.

The basic steps for the conversion of sugar and starch crops to ethanol are: 1) The biomass either undergoes a grinding process (dry milling) or is chemically treated (wet milling) to reduce the size of the feedstock; 2) if starch crops are used, the starch is converted to sugars by enzymatic treatment—called saccharification; 3) the sugars are fermented to ethanol by yeast; and 4) the ethanol is purified from the fermentation broth by distillation (Fig. 1). The remaining solid residue is used for cattle feed or, in some cases, as a fuel for boilers. The process for the starch/sugar feedstock can either be a dry mill process, in which the entire feedstock is fed to the fermentation unit, or a wet mill process, in which feedstock components are separated and the starch is fed to the fermentation unit. For the dry milling process, a liquefaction step occurs, in which a caustic solution and enzymes are added in a heated environment to obtain a slurry solution.

Such fermentation processes are often used in geographic locations in which the crops are grown in abundance, due to the low transportation costs of the feedstock supply. Low volumetric productivities and long fermentation times are disadvantages of the processes, which often have a high cost and require federal subsidies.[17] Therefore, to expand ethanol production throughout the United States, alternative raw materials, such as underutilized biomass and low-cost cellulosic feedstock, are being investigated.

Fermentation of Sugars from Lignocellulosic Biomass

Due to abundant quantity and competitive prices, lignocellulosic feedstocks have a greater potential for ethanol production than starch and sugar crops. Importantly, lignocellulosic feedstocks do not interfere with food security[3] and can be cultivated on marginal lands. The most common lignocellulosic materials are corn stover, grasses, wood chips, paper wastes, and agricultural residues. Since cellulose and hemicellulose are complex sugars not directly utilized by yeast or bacteria, they need to be reduced to fermentable sugars. Several processes have been utilized to obtain the fermentable sugars, including: 1) acid hydrolysis followed by fermentation; 2) acid and enzymatic hydrolysis followed by fermentation; 3) physical/chemical disruption and enzymatic hydrolysis followed by fermentation; and 4) pretreatment followed by simultaneous saccharification and fermentation.

Acid hydrolysis followed by fermentation

In the dilute acid process, biomass is treated with dilute sulfuric acid (2–5%) at about 160°C under a pressure of about 10 atm[18] to break down the cellulose and hemicellulose components to fermentable sugars. The lignin fraction is separated from the hydrolysate. The five- and six-carbon sugars are then fermented to ethanol by using genetically engineered organisms such as *Escherichia coli*,[19] *Saccharomyces cerevisiae*,[19] and *Zymomonas mobilis*.[20] A drawback is that this process results in low glucose yields (50–60%) from cellulose and hence gives low ethanol yields.[21] A concentrated acid solution (10–30%) can also be utilized at 100°C and atmospheric pressure to hydrolyze the hemicellulose and cellulose.[22] The benefits of the concentrated acid hydrolysis process over the dilute acid hydrolysis process are the lower operating temperatures and pressures, as well as higher glucose yields. A challenging issue in both the dilute acid hydrolysis and concentrated acid hydrolysis processes is the disposal of lignin, although it can be used as a fuel. Also, a major disadvantage is the formation of toxic by-products, such as furfural and hydroxymethyl furfural, that can affect the conversion rates.

Acid and enzymatic hydrolysis followed by fermentation

For the enzymatic process, the feedstock is first pretreated with a dilute acid to break down the lignocellulose into lignin, hemicellulose, and cellulose. Enzymes called cellulases and xylanases are then used to break down the cellulose and hemicellulose fractions into six- and five- carbon sugars, respectively. Without the dilute acid treatment, the enzymes would not be able to come in efficient contact with the cellulose and hemicellulose. The sugars are then fermented to ethanol using organisms such as *E. coli*,[19] *S. cerevisiae*,[23] and *Z. mobilis*.[20] The pretreatment of lignocellulose with dilute acid followed by enzymatic breakdown of cellulose and hemicellulose has shown to maximize the overall process yields as compared to processing with dilute acid alone. The disadvantage of this method is its high cost and requirement of enzymes,

although the costs have been greatly reduced over the last several years.[24] Also, this process is complicated by the accumulation of soluble products such as cellobiose and cellotriose, which act as competitive inhibitors of hydrolysis.[19]

Physical/chemical disruption and enzymatic hydrolysis followed by fermentation

Several processes, other than dilute acid hydrolysis, have been used to make biomass accessible to enzymatic breakdown for the generation of fermentable sugars. For ammonia disruption, the lignocellulose is exposed to ammonia at a high pressure and a temperature ranging from 25°C to 90°C.[25] The elevated pressure and temperature causes swelling and decrystallization of the biomass. The pressure is then suddenly lowered, causing the biomass to explode. This makes the biomass accessible to enzymes that hydrolyze the cellulose and hemicellulose to fermentable sugars, as noted above. For steam disruption, the biomass is fed into a high-pressure cylinder and treated with steam. The biomass is then passed into a flash tank, causing an explosion due to the sudden pressure change. The explosion causes autohydrolysis of the hemicellulose to xylose. The cellulose is treated with enzymes to form glucose. A disadvantage of the process is that volatile organics (e.g., furfural) are formed, which are toxic to the microbial catalysts. Additional processes that break down the biomass to allow enzymatic treatment include mild alkaline extraction with $Ca(OH)_2$ or NaOH.[26] In all cases, the sugars obtained from the process are fermented to ethanol using the organisms identified in the previous enzymatic method.

Pretreatment followed by simultaneous saccharification and fermentation

To eliminate the separate steps of formation of fermentable sugars followed by fermentation, the simultaneous saccharification and fermentation process has been developed following pretreatment with acid or physical/chemical disruption methods.[27] Since glucose is an inhibitor of cellulase activity, this process effectively removes the glucose and provides higher yields.

Major disadvantages of the processes mentioned include the current need for economic subsidies, the high cost of enzymes, and the formation of waste streams (such as acid pretreatment materials and toxic compounds found in acidic hydrolysates of biomass), although utmost efforts are being made to eliminate these drawbacks.[24,28] When biomass is utilized, lignin (approximately 10–40 wt% of biomass) cannot be broken down into fermentable components. Thus, 10–40% of the biomass is not incorporated into products. However, utilization of the lignin waste stream is currently being explored. Developments in conversion technologies over the last two decades have reduced the cost of bioethanol production from US$ 5.00/gal to approximately US$ 1.20/gal.[29]

BIOMASS TO ETHANOL: FERMENTABLE PRODUCER GAS PLATFORM

A large variety of biomass substrates, including solid municipal waste and waste paper, can be converted to producer gas via gasification. Producer gas can then be converted to ethanol by chemical catalysts, but microbial catalysts offer several advantages, since they require significantly lower temperature and pressure conditions (usually atmospheric conditions) and are less susceptible to varying feed gas compositions. Chemical catalysts are more susceptible to poisoning, and their specificity is lower compared to microbial processes, although faster conversion times are often possible.

A large number of bacterial strains have been isolated that have the ability to ferment producer gas (the CO, CO_2, and H_2 components) to ethanol, acetic acid, and other useful liquid products. *Clostridium ljungdahlii* was the first recognized organism to form ethanol from components of producer gas.[30] The organism favors the production of acetate at a higher pH (5–7), but ethanol is the dominant product at pH between 4 and 4.5. Recently, an additional clostridial acetogen was isolated and was shown to produce ethanol from producer gas generated from biomass.[31,32] Other organisms that can produce ethanol from producer gas, although not as the major product, include *Butyribacterium methylotrophicum*[33] and *Clostridium autoethanogenum*.[34]

Formation of Producer Gas via Gasification

Gasification is a heterogeneous thermochemical process in which a carbon-based feedstock, usually fed in a ground or pelletized form, is converted to a gaseous product by means of a gasification agent. The gaseous product, termed producer gas, consists primarily of CO, CO_2, N_2, methane (CH_4), H_2, and water. Trace amounts of higher hydrocarbons, ash, tar, and other contaminants are also present. Gasification can be classified into indirect and direct gasification. Direct gasification involves the use of an oxidizing agent, either air or oxygen, to partially oxidize the feedstock, while indirect gasification occurs in the absence of oxygen. Steam is a common gasifying agent for indirect gasification. The type of gasifier used depends on many

factors, such as the type and size of biomass, the desired composition of producer gas, and the scale of operation.

Common gasifier configurations include fixed-bed gasifiers, moving-bed gasifiers, and fluidized-bed gasifiers. Though simple and inexpensive to operate, fixed-bed gasifiers have disadvantages such as channeling and limited scale-up capacity. Fluidized-bed gasifiers offer excellent heat and mass transfer rates between biomass and the gas stream and have been used for a variety of feedstocks such as sawdust, sugarcane bagasse, rice husk, woodchips, and solid waste. They offer a reliable alternative for small-particle feedstocks such as switchgrass, which have a tendency to agglomerate in other types of gasifiers. Fluidized-bed gasifiers can also be scaled up easily for industrial operations.[35] Unlike other processes described previously for conversion of biomass to ethanol, in which the lignin fraction of lignocellulose remains unutilized, it is possible to convert all the carbon present in lignocellulosic substrate to a gaseous mixture using gasifiers.

Pathways of Producer Gas Fermentation

For acetogens, such as the ones identified for producer gas fermentation, ethanol synthesis is reported to follow the Wood–Ljungdahl pathway.[36] The overall stoichiometry for the formation of ethanol (C_2H_5OH) from CO, CO_2, and H_2 is

$$6CO + 3H_2O \rightarrow C_2H_5OH + 4CO_2 \quad (1)$$

$$6H_2 + 2CO_2 \rightarrow C_2H_5OH + 3H_2O \quad (2)$$

With CO as the sole substrate carbon source, one-third of the carbon from CO can theoretically be converted to ethanol [Eq. (1)]. Since reducing equivalents are necessary to fuel the reductive metabolic pathway, some of the CO is oxidized to produce reducing equivalents (via carbon monoxide dehydrogenase) and CO_2; the carbon is not available for ethanol formation. Although ethanol can be theoretically produced from CO alone, previous studies have shown that an external supply of CO_2 is required in addition to CO to sustain cell growth and ethanol formation, although CO_2 is generated during the fermentation process.[37]

For a 3:1 H_2/CO_2 ratio, all of the carbon can theoretically be converted to ethanol [Eq. (2)], although such as ratio does not occur with biomass gasification. However, it is important to note that CO_2 can be used by acetogens if H_2 is present. For an equimolar mixture of H_2 and CO, two-thirds of the carbon from CO can theoretically be converted to ethanol as shown in Eq. (3) [a combination of Eqs. (1) and (2)].

$$6CO + 6H_2 \rightarrow 2C_2H_5OH + 2CO_2 \quad (3)$$

In both these latter cases, reducing equivalents are produced from H_2 via the hydrogenase enzyme, resulting in greater carbon conversion to ethanol. Thus, the theoretical yield of carbon in the producer gas towards ethanol production depends upon the composition of the producer gas.

Since biomass is generally of the form $(CH_2O)_n$, the potential exists for a significant amount of H_2 to be formed in addition to the CO and CO_2. According to the biomass structure, the amount of H_2 cannot be in excess of the CO and CO_2 such that the theoretical carbon conversion is not greater than 67% [see Eq. (3)]. Process inefficiencies and reactions in the gasifier, such as the water gas shift reaction and formation of tars, results in lower carbon conversion. However, unlike the fermentation of sugars obtained from biomass, in which the theoretical carbon conversion is 67% of the non-lignin component of biomass (based on glucose to ethanol), the lignin in the gasification process can contribute to the carbon source. It is important to note that optimization issues must still be addressed before comparisons can be made between the gasification–fermentation process and the fermentation process involving biomass-generated sugars.

Fermentation of Producer Gas

Commercialization of producer gas fermentations is currently hindered by low productivity in the bioreactor. Several factors, such as low cell density, lack of regulation of metabolic pathways to yield only the desired product, inhibition of the biological catalysts by products and substrates, and low gas–liquid mass transfer, need to be addressed to establish the economic feasibility of producer gas fermentations.[33]

The transport of gases to the bulk liquid through the liquid film around gas bubbles is the rate-limiting step in most fermentation processes that involve sparingly soluble gaseous substrates. Producer gas fermentations are primary examples of such mass transfer limited fermentations. At mild temperatures, CO and H_2 have aqueous solubilities of 60% and 4%, respectively, compared to oxygen on a mass basis. These low solubilities result in low concentration gradients and, hence, low mass transfer rates.[33] Higher mass transfer rates can be achieved by the use of an agitator system. Increasing the operating pressure can also increase the gas mass transfer rate in producer gas fermentations. Microbubble dispersions, bubbles with

diameters of about 50–100 μm, have been used to provide a large gas transport area at low power consumption.[33]

Continuous stirred-tank reactors (CSTRs) have been routinely employed for producer gas fermentations. A two-stage reactor system has also been used to maximize ethanol production and minimize the formation of byproducts. Carbon monoxide and hydrogen conversions of 90% and 70%, respectively, were observed in the first reactor, while they were about 70% and 10% in the second reactor. High ethanol-to-acetate ratios were achieved by the use of such a dual reactor system.[38] Bubble columns are also commonly used for industrial fermentations. A comparative study was performed between a CSTR and a bubble column reactor for CO fermentation using *Peptostreptococcus productus*. Higher conversion rates of CO were observed with the bubble column without the use of any additional agitation.[39] Producer gas fermentation with packed bubble columns and trickle bed reactors has also been studied. The trickle bed reactor has a low pressure drop and liquid hold-up, and the conversion rates were the highest compared to CSTRs and bubble columns.[40]

The alteration of fermentation conditions, such as pH, drastically affects product concentrations. Research with *C. ljungdahlii* has shown that at high pH values (5.5–6), acetate was the dominant product, while at a lower pH (4–4.5), there was a drastic shift towards the production of ethanol.[41] Inhibition by end products or intermediates is the principal factor that limits metabolic rates and final product concentrations in many fermentation processes. Product inhibition can greatly affect the economics of commercialization. With regards to ethanol inhibition, growth of *B. methylotrophicum* was inhibited at alcohol concentrations of 5 g/L.[42] However, a recently isolated clostridial strain was shown to tolerate ethanol concentrations up to 78 g/L.[31] Efforts have been made to eliminate the drawbacks of inhibition by improvement of bacterial strains to tolerate higher product concentrations and/or by use of novel separation coupled fermentation processes such as pervaporation, extraction, and membrane separation.

CONCLUSIONS

With regards to lignocellulosic processes, producer gas fermentation is still in the early research stages compared to fermentation of sugars from lignocellulose. Both processes have advantages and disadvantages with reference to the process barriers described previously. Unlike the commercialized sugar/starch ethanol process, the lignocellulosic processes are in the early stages of commercialization.[43] It is important to realize that a single process may not be the only solution, and that there is a strong potential for multiple processes to coexist depending upon the biomass feedstock.

The development of new processes for the conversion of low-cost renewable biomass to ethanol is important as a possible alternative to the fast-depleting petroleum resources. Despite the current low utilization of ethanol compared to gasoline, ethanol is fast becoming a choice as an additive to gasoline, considering its positive environmental impact due to lower toxic and greenhouse gas emissions. Although a federal subsidy presently contributes to the success of ethanol as a fuel, its future certainly looks promising. The cost of ethanol could be reduced dramatically if the current research efforts to utilize low-cost biomass are successful. Several technological barriers remain, such as the high cost of enzymes, the inability of microbial strains to simultaneously and efficiently utilize a variety of sugar substrates, and the low ethanol yield in producer gas fermentation. However, with the development of inexpensive routes for production, low-cost ethanol could soon become a reality.

INTRODUCTION

Biomaterials science is a multidisciplinary endeavor incorporating chemical engineering, medicine, biology, chemistry, materials science, bioengineering, and biomechanics. The past few years have witnessed an explosion in the field of biomaterials, with an expansion of both the compositions and the applications of medical implant materials. As the prevalence of chronic diseases such as diabetes, cardiovascular disease, and neurodegenerative disease increases, there will be an even greater need for innovative biomaterials. This entry reviews the current status of the field of biomaterials, and highlights new developments in biomaterials. The entry will provide an overview of medical applications of biomaterials, and will describe current classes of biomaterials, including metals, ceramics and glasses, and polymeric materials. The entry will then discuss the next generation of biomaterials, including surface-modified biomaterials, smart biomaterials, bioactive materials, biomimetic materials, patterned biomaterials, and tissue engineering and regenerative medicine.

DEFINITIONS

A commonly used definition of a biomaterial, endorsed by a consensus of biomaterials experts, is "a nonviable material used in a medical device, intended to interact with biological systems."[1] An essential characteristic of biomaterials is biocompatibility, defined as "the ability of a material to perform with an appropriate host response in a specific application."[1] The goal of biomaterials science is to create medical implant materials with optimal mechanical performance and stability, as well as optimal biocompatibility.

OVERVIEW OF BIOMATERIALS APPLICATIONS

Biomaterials are used in diverse clinical applications. Table 1 lists several examples of applications of biomaterials in medicine.[2] Note that metals, ceramics, polymers, glasses, carbons, and composite materials are listed.

TYPES OF BIOMATERIALS

Metals

Metals and alloys have long been used in surgical and dental applications where materials with high strength are required. Metals are excellent for providing specific mechanical properties, including strength and ductility; however, corrosion of metallic implants in biological environments remains a concern. Corrosion not only limits device lifetime but also causes release of toxic metal ions that are often carcinogenic or mutagenic.[3,4] Thus, much of the current research focuses on minimizing and reducing corrosion of metallic biomaterials. Blackwood has recently reviewed common types of corrosion encountered in metal implants in vivo, as well as physiological parameters relevant to corrosion.[3] For surgical implants, relevant parameters are chloride content, pH, and dissolved oxygen levels in blood.[3] In vitro tests of corrosion resistance are typically performed in aqueous solutions containing 0.9% NaCl, with a pitting resistance number greater than 26 desirable for implanted materials.[3] Differences between in vitro and in vivo response are often attributed to dissolved oxygen content, sulfur-containing amino acids present in blood, and pathological changes associated with implantation such as generation of hydrogen peroxide and lowered pH (as low as 4) at the implant site.[3] Corrosion is an even greater concern in dental applications, because of the high acidity and chloride ion levels in many foods. Additionally, the corrosiveness of saliva is highly dependent on oral hygiene.[3] Thus, while reasonable in vitro models for saliva are available, it is difficult to predict in vivo corrosive resistance of dental materials.

Most metallic biomaterials fall into one of four categories: stainless steels, titanium and titanium-based alloys, cobalt–chromium alloys, and amalgams.[3] Additionally, research is under way on a number of

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120040342

Table 1. Examples of clinical applications of biomaterials

Application	Types of materials
Orthopedic	
Joint replacements (hip, knee)	Titanium, Ti–Al–V alloy, stainless steel, polyethylene
Bone plate for fracture fixation	Stainless steel, cobalt–chromium alloy
Bone cement	Poly(methyl methacrylate)
Bony defect repair	Hydroxyapatite
Artificial tendon and ligament	Teflon™, Dacron™
Cardiovascular	
Blood vessel prosthesis	Dacron™, Teflon™, polyurethane
Heart valve	Reprocessed tissue, stainless steel, carbon
Catheter	Silicone rubber, Teflon, polyurethane
Pacemaker	Polyurethane, silicone rubber, platinum electrodes
Ophthalmologic	
Intraocular lens	Poly(methyl methacrylate)
Contact lens	Silicone-acrylate, hydrogel
Corneal bandage	Collagen, hydrogel
Dental	
Dental implant for tooth fixation	Titanium, alumina, calcium phosphate
Neurologic	
Cochlear implant	Platinum electrode
General surgery	
Skin repair template	Silicone–collagen composite
Sutures	Silk, nylon, poly(glycolide-*co*-lactide)
Adhesives and sealants	Cyanoacrylate, fibrin
Organ replacement	
Heart–lung machine	Silicone rubber
Artificial kidney (hemodialyzer)	Cellulose, polyacrylonitrile
Artificial heart	Polyurethane

(Adapted from Ref.[2].)

next-generation metallic biomaterials, including rare earth materials and shape-memory alloys. Of the stainless steels, type 304 had been used previously in medical applications, but problems with localized corrosion and tumor formation were sometimes reported.[3] Type 316L SS is currently the most widely used in biomedical applications.[5] This is an iron–chromium–nickel alloy with a low carbon content, where chromium provides corrosion resistance. The resistance to pitting corrosion can be improved if nitrogen additions are made.[3] More recently, additional corrosion-resistant stainless steels have been developed, including 316LVM grade with a typical composition of 18Cr14Ni3Mo. For dental materials, which must be extremely corrosion resistant, ultraclean high nitrogen austenitic stainless steels are recommended, such as 21Cr10Ni3Mo0.3Nb0.4N.[3] Finally, mixing different grades of stainless steels is not recommended, as this can lead to galvanic corrosion and failure. In general, stainless steels display better mechanical and formability properties but worse corrosion resistance than titanium-based alloys. Release of chromium presents a concern, although the levels of chromium are lower in stainless steels than in cobalt–chromium alloys.[3]

Titanium displays excellent biocompatibility and corrosion resistance; however, it does not have the high strength necessary for several biomedical applications.[3,5] The most popular material for load-bearing orthopedic applications is Ti6Al4V, a dual-phase alloy comprising an Al-stabilized η-phase and a V-stabilized β-phase.[5] Other alloys in use for medical applications include Ti2.5Al2.5Fe, Ti6Al7Nb, and Ti50Ta.[3,5] While all these alloys exhibit a higher tensile strength than titanium, their corrosion resistance is not as high.[3] They also display poor shear strength and thus should not be used for applications such as screws.[3]

Common cobalt–chromium alloys include CoCrMo, used in dentistry and artificial joint applications, and CoCrNiMo, used as a part of replacements for heavily loaded joints because of its very high tensile strength.[3] Other cobalt–chrome biomaterials include CoCrWNi, MP35N, and ASTM F1058 (40Co12Cr15Ni7Mo).[3,5] In all these materials, chromium is present at fairly high levels. Thus, the release of chromium upon corrosion is a concern, as chromium is a carcinogen.[3]

Amalgams are typically used in dental applications and are multiphase alloys. Silver–tin amalgam carries a risk of mercury release through corrosion of the

Sn_7Hg γ_2 phase.[3] Newer high copper amalgams reduce the risk of mercury release, as preferential corrosion of the η' phase, Cu_6Sn_5, typically occurs.[3] However, release of mercury can still occur even in these materials. Older silver–tin amalgams are based on a silver–tin alloy, while high copper amalgams are based on either a silver–copper–tin alloy or a mixture of silver–tin and silver–copper alloys.[3]

Next-generation metallic biomaterials include porous titanium alloys and porous CoCrMo with elastic moduli that more closely mimic that of human bone; nickel–titanium alloys with shape-memory properties for dental braces and medical staples; rare earth magnets such as the NdFeB family for dental fixatives; and titanium alloys or stainless steel coated with hydroxyapatite for improved bioactivity for bone replacement.[3,5,6] The corrosion resistance, biocompatibility, and mechanical properties of many of these materials still must be optimized; for example, the toxicity and carcinogenic nature of nickel released from NiTi alloys is a concern.[3]

Ceramics and Glasses

Many ceramic materials possess improved biocompatibility as compared to metals, and corrosion is typically not an issue. Ceramics often have high strength but display brittleness, poor crack resistance, and low ductility.[7] Several ceramic materials are bioinert, bioactive (forming bonds with the surrounding tissue such as bone), or bioresorbable (as in the case of some porous ceramics).[7]

Arguably, the most important ceramic biomaterial is hydroxyapatite (HAP), $Ca_{10}(PO_4)_6(OH)_2$, a synthetic analog of bone mineral.[7] Natural bone is a composite comprising small crystalline HAP platelets bonded to collagen.[7] Synthetic hydroxyapatite is known to be bioactive, forming a strong bond with adjacent bone tissue and inducing bone growth along the interface (termed osteoconduction).[6] Hydroxyapatite and its derivatives are used most often in orthopedic and dental applications, for applications such as repair of bone defects and tooth root implants.[7] As mentioned above, HAP powders and coatings are also sometimes used in conjunction with metallic implants to induce adhesion with the surrounding tissue and to promote bioactivity.[6] Solid HAP is very robust in physiological environments and can remain in the body for 5–7 yr, while porous HAP can be resorbed by the body after approximately 1 yr.[7] Over 30 yr of research and clinical practice suggest that HAP and its related compounds are generally nontoxic and produce little or no inflammation or foreign body response. There have been some unfavorable biological reactions reported with porous HAP; these have been attributed to irritation from sharp edges of the implant and micromovement of the implant.[7]

Materials derived from HAP include Mg-HAP, which has been investigated for bone restoration in osteochondrosis; carbonate-HAP, with potential applications in the deposition of calcium and in some root canal fillings; silver-HAP, of interest for infected bone defects; and fluorine-HAP, of interest in the treatment of tooth defects and as coatings for metallic biomaterials.[7] Closely related materials include tricalcium phosphate, $Ca_3(PO_4)_2$, and certain calcium-phosphate glasses (described below), which form microcrystals of HAP on their surfaces in vivo, and thus exhibit similar degrees of bonding to bone tissue as HAP and its derivatives.[7] Additionally, tricalcium phosphate and HAP can both be combined with glasses to optimize the resorption time in vivo or to tune the bioactivity. Many of these so-called ''glass-ceramics'' typically contain SiO_2 in concentrations from 12% to 50% by mass, and may also contain CaO, Na_2O, or P_2O_5; or less commonly K_2O, MgO, CaF_2, Al_2O_3, and B_2O_3. Glass-ceramic implants with a lower calcium concentration may be resorbed in the body in as little as 10–30 days.[7] Taken together, HAP, tricalcium phosphate, and related materials have been investigated for nearly every conceivable type of bone reconstruction, including skull restoration after surgery or trauma, tooth-root implants, and tooth fillings, maxillofacial reconstruction, joint reconstruction, repair of load-bearing skeletal elements, grafting and stabilizing skull bone, repair of alveolar clefts and augmentation of alveolar ridges, cervical spine fusion, and reconstructive surgery of the middle ear.[7] Additionally, because glass-ceramics containing approximately 45% SiO_2 display strong bonding with soft tissue, these materials are of interest for the restoration of tendons, ligaments, small blood vessels, and nerve fibers; as well as catheters for infected wounds and as microsurgical joints.[7] Finally, HAP is used as a component of composite materials for bone replacement applications, as reviewed recently.[8,9] Examples include collagen–HAP composites and polyethylene–HAP composites.

Another important class of ceramic biomaterials is based on Al_2O_3 (aluminum oxide or corundum). These materials are bioinert and are widely used for the knob of replacement hip joints and other joint endoprostheses.[7] Other uses include tooth-root implants, parts for osteosynthesis, maxillofacial implants, and skull surgery.[7] Aluminum oxide ceramics prepared for use as biomaterials must have a low concentration of impurities such as silicon oxide and alkaline earth oxides, which can interfere with the bioinertness of the implant.[7]

A third class of bioceramics are based on ZrO_2, stabilized by Y_2O_3 or CeO_2. These materials are close to aluminum oxide materials in terms of biocompatibility but exhibit a higher bend strength and crack resistance, though with lower compressive strength.[7] Zirconium dioxide ceramics can be used for many of

the same types of biomedical applications as aluminum oxide and is in fact replacing aluminum oxide in many applications.

Glass-based biomaterials have been reviewed recently by Hench, Xynos, and Polak; Stroganova, Mikhailenko, and Moroz; and Knowles.[6,10,11] As alluded to above, biocompatible glasses are often used in conjunction with ceramics or alone for applications involving bone and joint reconstruction. Bioactive glasses are more quickly dissolved and resorbed into the body than bioceramics; furthermore, the dissolution time can be tuned using a variety of techniques.[11] Much of the research in this area has involved the ternary Na_2O–CaO–P_2O_5 system, which is of interest for both tissue engineering and antibacterial applications.[11] Calcium phosphate glasses with additional components, such as SiO_2, K_2O, MgO, and Al_2O_3, have also been investigated for bone restoration applications.[10]

Polymers

The literature on polymeric biomaterials is vast. Polymeric materials typically are easier to process than metals or ceramics, and often have lower strength and moduli. Their microstructure and transport properties can often be tuned by varying processing conditions, polymer molecular weight, cross-link density, and environmental conditions (temperature, pH, ionic strength, etc.). For these reasons, they are used more often for soft tissue engineering and drug delivery applications. Polymer-based materials with biomedical applications include hydrogels, temperature, and pH-responsive gels, conventional thermoplastics, block copolymers, polysaccharides, and artificial proteins, to name a few. Several of these are described later in this entry (see sections Smart Biomaterials and Bioactive Biomaterials below) as well as in other entries in this Encyclopedia on hydrogels, functional biomaterials, and so on. To avoid repetition with these entries, here we summarize the major biomedical applications of different classes of polymers, and refer the reader who wishes to have more information to recent reviews as well as related entries in this Encyclopedia. Table 2 lists some important classes of polymeric materials along with their main biomaterials applications.[12]

THE NEXT GENERATION OF BIOMATERIALS

Surface-Modified Biomaterials

While traditional biomaterials have saved millions of lives, these materials still suffer from problems with infection, thrombosis, inflammation, and poor healing with resultant fibrous encapsulation of biomaterials. Implanted biomaterials induce an inflammatory foreign body reaction that prevents normal wound healing; the foreign body response may result from nonspecific protein adsorption to biomaterial surfaces. One approach to overcoming these problems is to engineer the tissue-biomaterial interface by modifying the biomaterial surface.[13] Biomaterial surfaces may be engineered to create nonfouling, or stealth, surfaces that inhibit protein adsorption. Poly(ethylene glycol) (PEG) has been attached to biomaterials to create nonfouling materials that repel protein adsorption and cell attachment in vitro; PEG-modified surfaces have been found to resist cell adhesion for up to 2 weeks in vitro. While PEG is effective, its nonfouling properties are dependent on surface chain density, and it is easily damaged by oxidants. Poly(ethylene glycol) oligomers in self-assembled monolayers have been applied to create precision surfaces that are highly protein resistant.[14] Additionally, PEG-like surfaces have been prepared by plasma deposition of tetraethylene glycol dimethylether (tetraglyme) to form a highly nonfouling cross-linked structure; these surfaces are resistant to protein adsorption, as well as adhesion of platelets, monocytes, endothelial cells, and bacteria in vitro. In addition to PEG and PEG-like surfaces, nonfouling surfaces have been constructed using phospholipids, including phosphatidyl choline, and saccharides. In general, a number of different strategies have been successful in reducing nonspecific protein adsorption to biomaterials in vitro, but this has not yet translated into success in vivo. For example, tetraglyme-coated implants still induce fibrous capsule formation when implanted subcutaneously in mice, and tetraglyme-treated implants exhibit significantly higher macrophage adhesion than untreated implants in vivo.[13] Better model systems that accurately capture the in vivo environment will be required for the development of nonfouling surfaces for implanted biomaterials.

Smart Biomaterials

In numerous medical device applications, it may be desirable to have biomaterials that can respond to changes in the surrounding environment. Environmental triggers can be used in implanted biomaterials to activate or deactivate drug delivery, cell attachment, or a change in mechanical properties. Smart biomaterials have been designed that are sensitive to changes in pH, temperature, and other physical and chemical stimuli.[15] Hydrogels that exhibit pH-dependent swelling behavior can be created from ionic networks. For example, hydrogels prepared from poly(methacrylic acid) grafted with poly (ethylene glycol) (PMAA-g-PEG) shrink at pH 2 because of formation of interpolymer complexes, but swell 3–25

Table 2 Important classes of polymeric biomaterials

Polymer	Main biomaterials applications
Proteins and protein-based polymers	
Collagen	Soft tissue engineering and implants, absorbable sutures, wound dressings, drug delivery
Albumin	Cell encapsulation and drug delivery
Poly(amino acids)	Oligomeric drug carriers, polyelectrolyte complexes for cell encapsulation
Polysaccharides and derivatives	
Carboxymethyl cellulose	Drug delivery, dialysis membranes, polyelectrolyte complexes for cell encapsulation, and cell immobilization
Cellulose sulfate	Complexes for cell encapsulation
Agarose	Supporting material for clinical analysis, cell immobilization
Alginate	Cell encapsulation and immobilization, immobilization of enzymes, controlled release, injectable microcapsules
Carrageenan	Microencapsulation, thermoreversible gelation
Hyaluronic acid	Lubrication applications
Heparin and heparin-like glycosaminoglycanes	Antithrombotic and anticoagulant properties; used in surgery
Dextran and derivatives	Drug delivery
Chitosan and derivatives	Gels, membranes, and microspheres for drug delivery; polyelectrolyte complexes for encapsulation
Aliphatic polymers	
Poly(lactic acid), poly(glycolic acid), and their copolymers	Biodegradable sutures, drug delivery systems, and tissue engineering scaffolds
Poly(hydroxy butyrate), poly(caprolactone), and their copolymers	Biodegradable matrices for controlled release and cell encapsulation
Polyamides	Sutures, dressings, hemofiltration membranes
Polyanhydrides	Biodegradable tissue engineering scaffolds and devices
Poly(ortho esters)	Surface-eroding materials for sustained release and ophthalmology
Poly(cyano acrylates)	Biodegradable surgical adhesives and glues
Polyphosphazenes	Drug delivery, hydrogels, and thin films
Thermoplastic polyurethanes	Permanent implants, prostheses, vascular grafts, catheters, and drug delivery devices
Polyethylene	Sutures, catheters, membranes
Poly(vinyl alcohol)	Gels and membranes for drug delivery and cell encapsulation
Poly(ethylene oxide) and copolymers	Used to render surfaces biocompatible and resistant to protein adhesion; copolymers with poly(propylene oxide) form thermoreversible gels for drug delivery
Poly(hydroxyethyl methacrylate)	Hydrogels for soft contact lenses, drug delivery, skin coatings
Poly(methyl methacrylate)	Dental implants, bone replacement
Polytetrafluoroethylene	Vascular grafts, clips, and sutures
Polydimethylsiloxanes	Implants in plastic surgery and orthopedics blood bags and pacemakers
Poly(vinyl methyl ether)	Temperature-sensitive materials; shape-memory materials
Poly(*N*-alkylacrylamides)	Temperature-sensitive gels

(Adapted from Ref.[12].)

times in size at a physiological pH 7.[16] Ionic strength-dependent and pH-dependent swelling has also been observed in gels of PMAA or poly(acrylic acid) with poly(hydroxyethyl methacrylate).[15] These gels can be loaded with drug and will trap the drug at low pH, then swell to release the drug at a high pH. Such gels may be promising for oral delivery of biopharamaceuticals, as the gel will protect the drug from the acidic pH of the stomach for subsequent successful delivery in the small intestine. Insulin-loaded PMAA-g-PEG gels have been

administered orally to diabetic mice, and the glucose levels of the mice decreased following gel administration, suggesting that the gel successfully protected and delivered the protein therapeutic.[17]

In addition to pH-sensitive gels, thermally sensitive biopolymers have been investigated; such materials can respond to changes in temperature from room temperature to body temperature. These hydrogels exhibit a lower critical solution temperature (LCST); the gels expand when cooled below the LCST and contract when heated above the LCST. Hydrogels of poly(N-isopropylacrylamide) (pNIPAAm) have an LCST of 32°C and have been studied extensively for drug release applications.[15] Temperature-modulated drug release from pNIPAAm hydrogels can be achieved via bulk squeezing: drug that is distributed inside the matrix is squeezed out when the hydrogel contracts with heating above the LCST. Another application of pNIPAAm hydrogels is the creation of surfaces for cell culture systems. Coatings of pNIPAAm are hydrophilic below the LCST and hydrophobic above the LCST. Because cells attach on hydrophobic surfaces and detach from hydrophilic surfaces, cells cultured on pNIPAAm surfaces can be nontraumatically lifted as intact sheets from these surfaces, simply by lowering the temperature.

Polymers of elastin-like peptide (ELP) also exhibit temperature-sensitive behavior.[13] The LCST of ELP can be controlled by varying the length of the ELP molecule or its amino acid composition to obtain transition temperatures ranging from 30°C to 90°C. The ELPs have been used for chondrocyte encapsulation and as drug carriers for cancer therapy. An additional thermoresponsive biomaterial is the biodegradable triblock copolymer poly(ethylene glycol)–poly(lactic acid-co-glycolic acid)–poly(ethylene glycol) (PEG–PLGA–PEG). This copolymer exhibits a sol-to-gel transition with increases in temperature.[15] This property may be important for drug delivery applications, as PEG–PLGA–PEG can be injected as a free-flowing solution at room temperature and then becomes a gel upon reaching body temperature. Hydrogels with certain compositions may demonstrate both pH- and temperature sensitivity. For example, hydrogel copolymers of MAA and NIPAAm sense small changes in pH and temperature. Controlled release of antithrombotic agents, including streptokinase and heparin, has been demonstrated with these dual-sensitivity hydrogels.[15]

Other stimuli in addition to pH and temperature have been investigated to create smart biomaterials. These include external physical stimuli such as light, magnetic fields, electric current, and ultrasound. Specific biochemical stimuli also may be used: calcium-responsive hydrogels, antigen-responsive hydrogels, and microbial infection-responsive hydrogels have all been designed for drug delivery applications.[14]

Bioactive Biomaterials

Several advances have been made in rendering materials biologically active.[18] Bioactivity may be used to impart pharmacological activity to a biomaterial, to modify the biocompatibility of a material, or to tune the lifetime and degradation of a biomaterial. One method for creating bioactive biomaterials is to incorporate pharmacological agents into materials. Polymeric implants that release therapeutic drugs are already in clinical use; examples include progesterone-releasing implants for fertility regulation, and lupron-releasing implants for prostate cancer treatment. Polymer-coated arterial stents that elute sirolimus and tacrolimus have revolutionized the treatment of coronary artery disease, by preventing restenosis following stent placement. Site-specific delivery of chemotherapeutics for brain cancer treatment has been achieved using polyanhydride disks loaded with carmustine (BCNU).[19] Biological growth factors may also be incorporated into materials, either through surface display or through controlled release systems. Polypeptide growth factors may regulate a variety of cellular responses, including cell migration, proliferation, survival, and differentiation. Growth factors have been exploited to create biomaterials that deliver angiogenic growth factors to induce vascular repair; neuronal survival and differentiation factors to treat neurodegenerative disease; transforming growth factor β to induce bone repair; bone morphogenetic protein-4 to enhance bone formation; and tissue growth factors to heal chronic ulcers.

Another approach to creating biological activity in biomaterials is to incorporate adhesion factors, including adhesion-promoting oligopeptides or oligosaccharides.[18] While traditional biomaterials promote cell adhesion via nonspecific adsorption of proteins, a greater degree over cell migration, cell adhesion, and cell-type selectivity can be achieved by incorporating adhesion-promoting factors directly into biomaterials. For example, the RGD tripeptide from fibronectin may be either immobilized on biomaterial surfaces or included directly into the backbone of polymer chains to induce cell adhesion, spreading, focal contact formation, and cytoskeletal organization. The YIGSR domain and the SIKVAV domain from laminin are migration-promoting peptides, and have been incorporated into gels to promote neuronal cell infiltration and nerve regeneration. The tetrapeptide REDV from fibronectin may be employed in vascular grafts to specifically support adhesion and migration of vascular endothelial cells, while also preventing the adhesion of clot-forming platelets. The protein osteopontin has been immobilized on poly(2-hydroxyethyl methacrylate) surfaces to promote endothelial cell adhesion.[13] These approaches to biomaterial modification are clinically relevant, as it has been shown in clinical studies that enhancement of cell

adhesion strength improves the performance of endothelial cell-seeded vascular grafts in high-flow regions.[20]

Still another method for engineering bioactive biomaterials is to design materials containing enzymatic recognition sites.[18] Incorporation of enzymatic cleavage sites into a biomaterial allows the degradation rate of the material to be tuned, and also allows the biomaterial to be proteolytically remodeled. For example, gels containing PEG chains with central oligopeptide sites that are substrates for collagenase or plasmin are degradable by cell-associated enzymatic activity.

Tissue Engineering and Regenerative Medicine

The goal of tissue engineering is to replace lost tissues or organs with polymer constructs that contain specific populations of living cells. Traditional strategies for replacing lost tissue include organ transplantation and mechanical device implantation; however, organ transplantation is limited by donor organ shortages and transplant rejection, and mechanical devices have limited durability and limited bioactivity. Tissue engineering has the potential to overcome these limitations by creating functional tissues that have the capacity for growth, remodeling, and self-repair. The general approach to creating engineered tissue is to harvest specific cell populations from the tissue of interest, seed the cells into a biodegradable polymer scaffold, and cultivate the cell/polymer construct in a bioreactor prior to implantation.[21] Upon implantation, the biodegradable polymer will degrade and gradually be replaced by regenerated tissue.

Successful tissue engineering requires appropriate selection of cells, polymers, and bioreactor conditions for the application of interest. Cells used in tissue engineering may be drawn from either primary tissues or cell lines; the bulk of tissue engineering experiments have utilized primary autogenous cells. Scaffold polymers for tissue engineering must be biodegradable, biocompatible, and readily processible into appropriate anatomical shapes. The most commonly used scaffold polymers are poly(glycolic acid) (PGA), poly(lactic acid) (PLA), and their copolymers (PLGA). Polyanhydrides, polycarbonates, and polyurethanes have also been investigated, and hydrogels, particularly algal polysaccharides, have been utilized as cell delivery matrices. Bioreactors for tissue engineering are designed to allow optimal conditioning of the cell/polymer construct to initiate tissue formation prior to implantation. It is desirable to achieve a high and uniform cell density throughout the polymer scaffold. The bioreactor is a dynamic tissue culture environment where gas and nutrient exchange are augmented by constant turnover of tissue culture medium, and where tissue-specific mechanical forces (stretch, pressure, shear forces) are recapitulated.[22]

The tissue engineering approach has been applied to many tissues including skin, cartilage, bone, liver, intestine, urologic tissue, cardiovascular tissue, and neural tissue.[19,22] Tissue engineered skin regeneration systems are already in clinical use to repair burns, wounds, and chronic ulcers. In one approach, neonatal dermal fibroblasts are placed on PLGA scaffolds and grown into sheets to create skin.[19] In another approach, a bilayer system is used, in which a lower dermal layer of human fibroblasts and an upper epidermal layer of human keratinocytes are seeded onto a bovine collagen matrix. Cartilage regeneration has been achieved by delivering chondrocyte suspensions to focal articular cartilage defects; an autologous chondrocyte product has been FDA approved for clinical application.[22] Cartilage tissue has also been engineered in the configuration of the ear, nasal septum, and trachea using PGA and PLGA constructs seeded with chondrocytes; such constructs have also been shown to close full-thickness cranial defects in animals. Clinical trials are under way to use chondrocyte/polymer constructs for cartilage replacement in humans. In the area of bone replacement, PGA meshes seeded with periosteal cells have been shown to generate new bone in animal models. For replacement of liver function, hepatocytes are seeded on PGA sheets; implantation of these sheets into liver enzyme-deficient animals results in partial correction of the enzyme deficiency. Copolymers of PGA and PLA scaffolds fabricated to contain vascular-like channels and seeded with cocultures of hepatocytes and endothelial cells demonstrate remodeling and formation of vascular channels in vitro, suggesting that complex tissue architecture can be achieved with an appropriate cell/polymer construct. For intestinal replacement, mixed enterocyte/stromal cell populations have been seeded onto PGA meshes; such constructs demonstrate formation of structures resembling intestinal villi and crypts when implanted in animals. In the urologic system, functional ureters have been created using tubular PGA constructs seeded with urothelial cells and smooth muscle cells, and functional bladder tissue has been created from PGA sheets seeded with urothelium and smooth muscle cells. For cardiovascular tissue engineering, endothelial cells have been seeded on both tubular polymer constructs to create blood vessels and leaflet-like constructs for heart valve reconstruction; tissue engineered heart valves are functional in large animals.[22,23] For neural regeneration, an electrically conducting polymer, polypyrrole, has been shown to provide a substrate for nerve regrowth in animal models.

CONCLUSIONS

Biomaterials have improved the lives of millions by providing material solutions to biomedical problems.

Biomaterials have been applied in a variety of clinical disciplines, including cardiovascular medicine, orthopedics, and ophthalmology, and new materials are in use or under development for virtually every organ system in the body. Traditional biomaterials have been designed from polymers, ceramics, and metals. The next generation of biomaterials will incorporate biomolecules, therapeutic drugs, and living cells. Innovative new biomaterials, including surface-modified biomaterials, smart biomaterials, bioactive biomaterials, and tissue-engineered materials, will have improved properties of biocompatibility, tunability, and biological functionality. Successful development of new biomaterials will require an increased understanding of cell–material interactions, as well as better model systems for the biological environment.

BioMEMS

L. James Lee
Department of Chemical Engineering, The Ohio State University, Columbus, Ohio, U.S.A.

INTRODUCTION

Miniaturization methods and materials are well developed in the integrated circuit industry. They have been used in other industries to produce microdevices, such as camera and watch components, printer heads, automotive sensors, micro-heat exchangers, micropumps, microreactors, etc., in the last 15 years.[1,2] These new processes are known as microelectromechanical systems (MEMSs), with a combined international market of over US$ 15 billion in 1998.[3] In recent years, MEMS applications have also been extended to the optical communication and biomedical fields. The former are called micro-optic electromechanical systems (MOEMSs), while the latter are known as biomicroelectromechanical systems (bioMEMSs). Potential MOEMS structures include optical switches, connectors, grids, diffraction gratings, and miniature lenses and mirrors. Major potential and existing bioMEMS products are biochips/sensors, drug delivery systems, advanced tissue scaffolds, and miniature bioreactors.

Future markets for biomedical microdevices for human genome studies, drug discovery and delivery in the pharmaceutical industry, clinical diagnostics, and analytical chemistry are enormous (tens of billions of U.S. dollars).[4] In the following sections, major bioMEMS applications and microfluidics relevant to bioMEMS applications are briefly introduced. Because of the very large volume of publications on this subject, only selected papers or review articles are referenced in this entry.

BIOMEMS APPLICATIONS

Biochips/Biosensors

Chip-based microsystems for genomic and proteomic analysis are the first bioMEMS products to have been commercialized. A large number of articles have been published in this field in recent years. Here, a brief introduction is given based on several recent review articles.[5–9] Biosensors are not necessarily microsystems.[10,11] MEMS techniques, however, may greatly enhance the performance of biosensors and reduce their cost. Microfabricated biosensors can be considered a division of biochips.[10–12]

Most molecular and biological assays and tests are very tedious, as shown in Fig. 1. They include the following steps: 1) obtaining a cellular sample (e.g., blood or tissue); 2) separating the cellular material of interest; 3) lysing the cells to release the crude DNA, RNA, and protein; 4) purifying the crude lysate; 5) performing necessary enzymatic reactions, such as denaturing, cleaving, and amplifying of the lysate by polymerase chain reaction (PCR); 6) sequencing DNA/genes using gel or capillary electrophoresis; and finally, 7) detecting and analyzing data. This process requires skilled technicians working in well-equipped biomedical laboratories, for periods of time ranging from many hours to several days to analyze a single sample. Much of today's diagnostic equipment is costly and bulky. It has limited use in medical diagnostics and is unsuited for emergency response at sites of care. To improve public health services, there is a great need to develop efficient and affordable methods and devices that can simplify the diagnostic process and be used as portable units. In recent years, the concept of integrating many analysis systems into one microdevice has attracted a great deal of interest in industry and academia. Such devices are called ''laboratories-on-chips.'' They combine a number of biological functions (such as enzymatic reactions, antigen–antibody conjugation, and DNA/gene probing) with proper microfluidic techniques (such as sample dilution, pumping, mixing, metering, incubation, separation, and detection in micrometer-sized channels and reservoirs) in a miniaturized device. The integration and automation involved can improve the reproducibility of results and eliminate the labor, time, and sample preparation errors that occur in the intermediate stages of an analytical procedure. The miniaturized devices also allow realization of low-energy and ''point-of-care,'' parallel detection from a very small sample size, and easy data storage and transfer through computers and the Internet.

Biochips used for genomic analysis range from those used for separations for DNA sequencing, to those used in microvolume PCR, to complete analysis systems. Sequencing separations of single-stranded DNA fragments on a microchip follow the same principles as in conventional capillary electrophoresis.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120030622

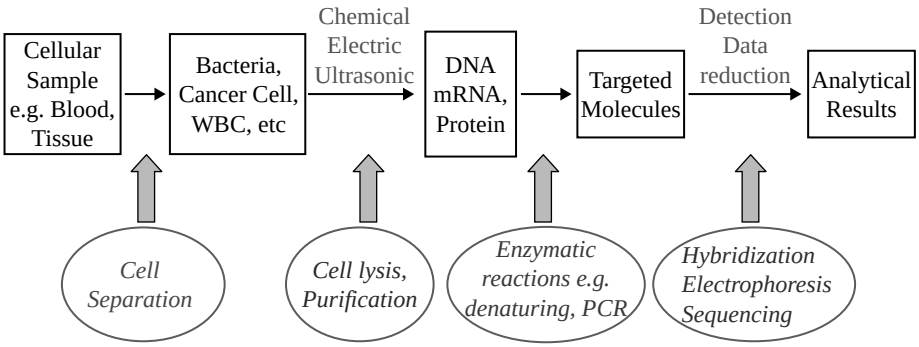

Fig. 1 Schematic of molecular diagnostics. *(View this art in color at www.dekker.com.)*

The process, however, is much faster because a higher electric field can be applied to the micrometer-sized separation channels without Joule heating problems. Automatic injection of a very small sample volume and parallel processing of a large number of separations can also be easily achieved. PCR allows amplification of a specific region of a DNA chain. PCR carried out on microchips is much more efficient than that on commercial PCR thermocyclers. In PCR, a sample solution is mixed, containing DNA, primers (synthesized short oligomers whose sequences flank the region of DNA to be amplified), a thermostable DNA polymerase enzyme, and the individual deoxyribonucleotides. Melting (or denaturization) of the double-stranded DNA molecules to single-stranded ones is done by heating the sample to ~95°C. The system is then quickly cooled to ~60°C for annealing; during this process, the added primers adhere to the single-stranded DNA. Finally, the sample is heated to ~72°C, at which temperature the polymerase is most active. During this extension period, complementary dinucleotide triphosphates are added to the growing strand using the target DNA as template. Each PCR cycle may double the amount of DNA of the required length. In the ideal case, 1 mol of targeted DNA fragments can be produced after 79 cycles. Practically, 20–50 cycles are needed to obtain a measurable quantity. Due to the high surface area/volume ratio associated with microdevices (it is important that PCR-friendly surfaces are produced in these devices), heat transfer is more efficient and temperature control is much easier than in large systems. PCR time can be easily reduced from hours to minutes, particularly in continuous-flow PCR chips.[6]

Miniaturized proteomic analysis devices include enzyme assays and immunoassays. The enzyme assay chip is mainly a sophisticated incubator and flow-through system. It can perform multiple functions typically required by the biochemist, namely, diluting substrate and buffer, mixing enzyme and substrate, incubating during conversion, and allowing for detection in a flow channel. Immunoassay chips are similar to enzyme assay chips, except that the main focus is antigen–antibody interaction for clinical diagnostics and drug discovery.

There are a small number of commercially available biochips in the market today. Most are microarray-based systems, with biomolecules such as DNA probes, enzymes, and antigens being immobilized on the chip surface (e.g., GenChip® from Affymetrix, NanoChip™ from Nanogen, Inc., and GeneXpert® from Cepheid), or simple microfluidic systems capable of DNA sequencing by either electrophoresis (e.g., LabChip® from Caliper, Inc., and LabCard™ from ACLARA BioSciences, Inc.) or PCR. DNA microarray chips and DNA sequencing microfluidic chips have contributed to the Human Genome Project.

In addition to commercially production, a great deal of research and development work on biochips has been going on both in industry and in academia. Genomic analysis of DNA and RNA continues to be the focus of interest, but more and more effort is being spent on proteomic analysis of proteins and peptides.[5–9] Several enzyme assays and immunoassays designed based on microarray-based systems with simple microfluidic control are close to commercialization. They can be a vital tool in clinic diagnostics, drug discovery, and biomedical research.

Completely integrated micro-total analysis systems (μ-TAS) that can perform all the functions mentioned in Fig. 1 would be very valuable for high-throughput drug screening and personalized healthcare. However, only model systems have been proposed by research groups at present.[9] The mass production of such complicated systems at low cost is a challenging issue. Silicon and glass have been the most popular materials for fabricating microchips, but polymers are increasingly being used because of the availability of flexible, low-cost, high-throughput manufacturing methods for the micro-/nanoscale features needed for these types of applications.

Sensitive detection in microfluidic analytical devices is a challenge because of the extremely small detection volumes available. In conventional capillary

electrophoresis, the most commonly employed detection method is UV absorption. In microscale biochips, laser-induced fluorescence (LIF) in conjunction with optical microscopy is currently the dominant detection technique because of its high sensitivity and noncontact nature. LIF microscopy, however, is costly, and the equipment size is quite large. To ensure wide application of the miniaturized biomedical devices, simple, portable, and low-cost detection methods are essential. Considerable efforts have been made lately to explore electrochemical methods, because the use of electrodes for detection leads to smaller instruments and cost reduction. Amperometry, conductimetry, and electrochemiluminescence are also likely methods to complement fluorescence detection for on-chip analysis.[13]

Drug Delivery

Self-regulated and controllable drug delivery systems

Most conventional drug delivery systems are based on polymers or lipid vesicles. Drug safety and efficacy can be greatly improved by encapsulating the drug inside or attaching it to a polymer or lipid. The three general mechanisms by which drugs are delivered from polymer or lipid systems are: 1) diffusion of the drug species through a polymer membrane; 2) a chemical or enzymatic reaction leading to cleavage of the drug from the system; and 3) solvent activation through swelling or osmosis of the system.[14] A major limitation of currently available delivery devices is that they release drugs at a predetermined rate. Certain disease states, such as diabetes, heart disease, hormonal disorders, and cancer, require drug administration either at a life-threatening moment or repeatedly at a certain critical time of day. Drug delivery technology can be taken to the next level by the fabrication of ''smart'' polymers or devices that are ''responsive'' to the individual patient's therapeutic requirements and deliver a certain amount of drug in response to a biological state. Given the miniature size of implantable devices, micromachining techniques will be essential for their manufacture. Currently, there are no commercial products based on the micromachined responsive drug delivery approach, and only some early research activity is seen in this direction.

The controlled release of drugs has been explored by adapting intelligent polymers, such as functional hydrogels, which respond to stimuli such as magnetic fields, ultrasound, electric current, temperature, and pH change.[15–17] These chemically synthesized materials are biocompatible and have good functionality. However, they often lack well-defined properties because of their inherent size and structure distribution resulting from chemical synthesis.[18] On the other hand, microfabrication technology developed for microelectronic applications is capable of mechanically creating devices with more precisely defined features, in a size range similar to that of polymeric and lipid materials.[19] Using hydrogels as switches or gates for controlled drug delivery and microfluidics has been explored recently by several researchers.[20,21] In a recent paper, Cao, Lai, and Lee[22] describe the design of a self-regulated drug delivery device based on the integration of both mechanical and chemical methods. A pH-sensitive hydrogel switch is used to regulate the drug release, while a constant release rate is achieved by carefully designing the shape of the drug reservoir.

Biocapsules, membranes, and engineered particles for drug delivery

Immunoisolation is the protection of implanted cells from the host's immune system by the complete prevention of contact of immune molecules with the implanted cells, generally by the use of a semipermeable membrane. To achieve this without preventing nutrients from reaching the cells or waste from being removed, it is necessary to have an absolute pore size just below the minimum size needed to block out the smallest immune molecule, immunoglobulin G (IgG). The polymer and ceramic membranes used currently in biomedical devices possess nanopores with nonuniform size distributions, which makes it difficult to control the passage of drugs and immunoglobulins (~30–50 nm in size) through these membranes.[23,24] Nonuniform porosity also requires the use of long, torturous flow paths, necessitating the use of thick membranes. Nanoscale resistance to flow in such thick membranes is high, so that high applied pressures (~1–4 MPa) are needed, which further complicates use.[25] These membranes also show incomplete virus retention.

Ferrari and co-workers[19] examined the feasibility of using microfabricated silicon nanochannels for immunoisolation. A suspension of cells was placed between two microfabricated structures with nanoporous membranes to fabricate an immunoisolation biocapsule. Characterization of diffusion through the nanoporous membranes demonstrated that 18 nm channels did not completely block IgG but did provide adequate immunoprotection (immunoprotected cells remained functional in vitro in a medium containing immune factors for more than two weeks, while unprotected cells ceased to function within two days). A major application of biocapsules containing nanochannels is immunoisolation of transplanted cells for the treatment of hormonal and biochemical deficiency diseases, such as diabetes.

Polymer microparticles have attracted much attention for drug delivery applications. Traditional microparticle

fabrication protocols, such as phase separation, emulsification, and spray drying, have been successfully used for the production of drug delivery microspheres.[26,27] However, due to the surface-driven manufacturing process of these methods, the structural complexity of the resulting particles is limited. These methods are also difficult to apply for producing a monodispersed particle size distribution. Size control of microparticles is an important factor, since there are many routes of drug administration. According to DeLuca et al.,[28] very large microparticles (>100 μm) with a broad particle size distribution are acceptable for embolization and drug delivery by implantation. Microparticles in the size range of 10–100 μm can be used for subcutaneous and intramuscular administration. Here, the particle size distribution is not a critical factor. Intravenous administration results in localization in the capillary vasculature and uptake by macrophages and phagocytes. Microparticles larger than 8 μm lodge predominately in the lung capillaries, whereas those smaller than 8 μm may clear the lung and be localized in the liver and spleen. Therefore, it is most important to control the size of the largest particle.

During inhalation administration to the lung, filtering of particles occurs in the upper airways by inertial impaction, with large particles (aerodynamic diameter $d_a > 5\,\mu m$) being deposited in the mouth and the first few generations of airways. Very small particles ($d_a < 1\,\mu m$) are dispersed by diffusion, and a large fraction of these particles remain suspended in the airflow and are exhaled. Microparticles with the optimal size range of 1–5 μm are deposited in the central and peripheral airways and in the alveolar lung region by a combination of inertial impaction and sedimentation.[29] Therefore, the size and distribution of microparticles for inhalation therapies must be closely controlled to achieve high efficiency. Inhalation is a noninvasive drug delivery route and has been used widely for the treatment of diseases such as asthma, cystic fibrosis, and chronic obstructive pulmonary disease. Potential applications of new inhalation products in the near future include the treatment of diseases such as diabetes, pain, and growth deficiency, where proteins and lipids-based drugs will be used. For these biomolecule-based drugs, processing conditions such as high temperature and long solvent contact time may result in drug denaturization, so particle formation methods must avoid such conditions. For certain envisioned functional features of drug delivery vehicles, such as targeted and controlled vector release on cancer tumors, ''highly engineered'' microparticles (i.e., each particle is essentially a microdevice) may be required. This is another limiting factor for the traditional microparticle fabrication methods.

Compared to conventional polymer microparticle fabrication methods, microfabrication offers greater control of particle features and geometries. The shape and size of the particles can be controlled tightly. Perhaps more importantly, the components and surface properties can be designed to achieve particular functions. Using soft lithography (this fabrication method is explained in a later section), Guan and Hansford[30] recently developed a simple method to fabricate nonspherical polymer microparticles of precise shape and size, which can serve as either drug delivery vessels or substrates for further processing to produce functional drug delivery devices. Fig. 2 shows a micrograph of thin, platelike microparticles fabricated using this method. Combining the surface micropatterning and surface-tension self-assembly of autofolding,[31,32] well-defined 3D micropolyhedra, e.g., cubes and pyramids, can be fabricated from metals.[33] In our laboratory, similar micropolyhedra are currently being developed using functional polymers (e.g., biodegradable polymers and functional hydrogels). Large protein and gene molecules may be wrapped in such well-defined microstructures and delivered to targeted sites by either pulmonary delivery or intravenous administration.

Tissue Engineering

Tissue engineering is the regeneration, replacement, or restoration of human tissue function by combining synthetic and living molecules in appropriate configurations and environments.[34] The scaffold, the cells, and the cell–scaffold interactions are the three major components of any tissue-engineered construct. Although many tissue scaffold materials, such as foams and nonwoven fabrics, have been developed and used,[35,36] many challenges must be overcome for the promise of tissue engineering to become a reality. These include: 1) low-cost fabrication of well-defined 3D scaffold configurations at both micro- and nanoscale; 2) incorporation of appropriate biocompatibility, bioactivity, and biodegradability in the scaffolding construct to manipulate cellular and subcellular functions; and 3) active control of transport phenomena and cell growth kinetics to mimic microvasculature functions. Micro-/nanofabrication technology of polymers has tremendous potential in this field because it can achieve topographical, spatial, chemical, and immunological control over cells and thus create more functional tissue engineering constructs.[37]

An ideal tissue scaffolding process should be able to produce well-controlled pore sizes and porosity, provide high reproducibility, and use no toxic solvents. This is because these physical factors are associated with nutrient supply and vascularization of the cells in the implant as well as the development of a fibrous tissue layer that may impede nutrient access to the cells. Current processing methods used for polymer

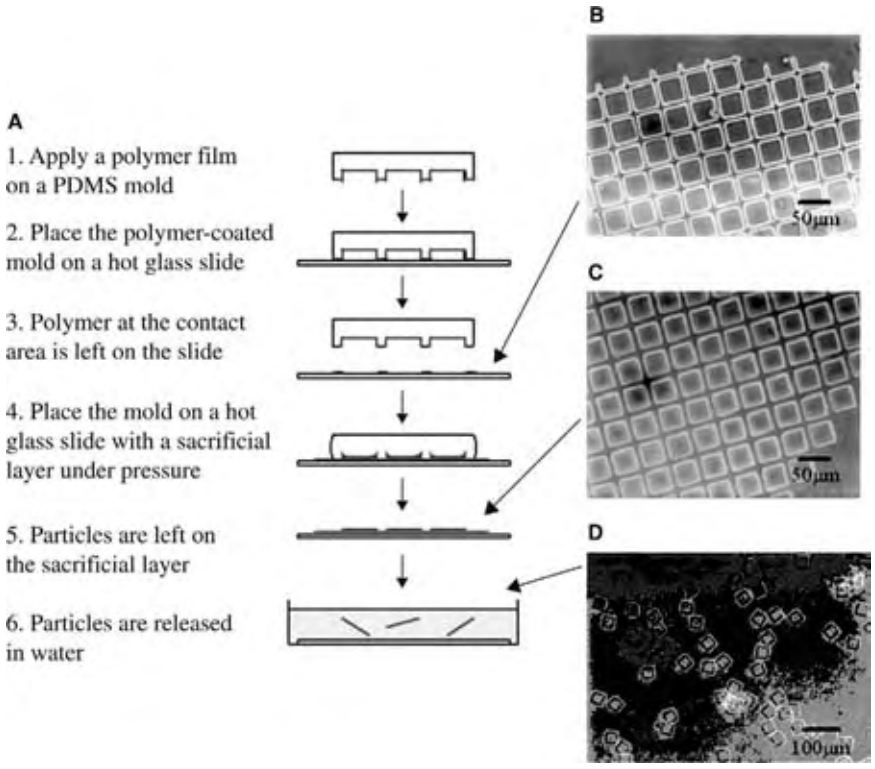

Fig. 2 Thin platelike microparticle fabricated by hot stamping. (A) The schematic of the procedure; (B) polymer at the contact area left on the glass slide; (C) polymeric microparticles left on the sacrificial layer after hot stamping; (D) and in water after release.

scaffolds include solvent casting, plastic foaming, fiber bonding, and membrane lamination.[35] However, precise, reproducible features in the micrometer and nanometer range are difficult to attain using these methods. By combining living cells and microfabricated 2D and 3D scaffolds with carefully controlled surface chemistry, investigators have begun to address fundamental issues such as cell migration, growth, differentiation, apoptosis, orientation, and adhesion, as well as tissue integration and vascularization.

The functioning of tissues such as retinal, cardiac, and vascular tissue is dependent on the controlled orientation of multiple cell types. A key issue in the engineering of these tissues is control of the spatial distribution of cells in vitro to recreate a lifelike environment. The current approach to seeding cells is to allow cells to be randomly distributed in the scaffold. Microfabrication techniques, on the other hand, can produce short- and long-range surface patterns to mediate cell distribution and adhesion, biological interaction, and immune responses. Porous scaffolds without integrated blood supply rely solely on diffusion for mass transfer. They are limited to millimeters in size, while normal tissues leverage convection from blood vessels to enable oxygenation of large tissues.[38] Incorporating microfluidic networks in 3D tissue scaffolds for cell culture and implantation can be achieved by microfabrication techniques.[47] This new approach can provide the functional equivalents of microvasculature and enable scale-up of tissue engineering. Many cell-based bioreactors can be designed in a similar manner.[39]

Scientific and commercial work to date in tissue engineering has been largely devoted to clinical needs and focused on physiological aspects. There is a lack of low-cost, solventless, and mass-producible processing methods to fabricate scaffolds with well-defined micro- and nanostructures. In our laboratory, a manufacturing protocol is currently being developed for 3D tissue scaffolds of various shapes. The scaffold can be easily fabricated by combining micropatterned biodegradable polymers and supercritical CO_2 foaming technology.

Depending on the type of bioMEMS application, the polymers used can range from low-cost commodity plastics for disposable biochips to biodegradable and biofunctional polymers for drug delivery and tissue engineering. The feature size in these microsystems can be in either the micrometer or the nanometer scale. For instance, 10–100 μm is the desired microchannel size in microfluidic biochips. Below that, detection is too difficult, and, above that, mixing, heat transfer, and mass transfer are too slow. Particles used in drug delivery and the cell size in tissue scaffolds are also in the micrometer range. On the other hand, nanosized features are essential for immunoisolation in cell-based gene therapy and cell culture in tissue engineering. The enabling processing methods need to cover a broad size range, be mass producible and affordable, and be

compatible with the polymers and biomolecules used in the process. Fluid transport in bioMEMS devices is crucial in many applications such as fast DNA sequencing, protein separation, drug delivery, and tissue generation.

Microfluidics

Microfluidics is the manipulation of fluids in channels, with at least two dimensions at the micrometer or submicrometer scale. This is a core technology in a number of miniaturized systems developed for chemical, biological, and medical applications. Both gases and liquids are used in micro-/nanofluidic applications,[40,41] and generally, low-Reynolds-number hydrodynamics is relevant to bioMEMS applications. Typical Reynolds numbers for biofluids flowing in microchannels with linear velocity up to 10 cm/s are less than 30.[42] Therefore, viscous forces dominate the response and the flow remains laminar.

Fluid motion in these small-scale systems can be driven by applied pressure difference, electric fields associated with charged Debye double layers (or electrical double layer—EDL)—common when ionic solutions are present, or capillary driving forces owing to wetting of surfaces by the fluid.[42] Pressure-driven flow is similar to the classic Poiseuille flow. Electrokinetic effects can result in either electro-osmotic flow (EOF) or electrophoretic responses. Electro-osmotic flow is a bulk flow driven by stresses induced in the thin EDL (i.e., 1–10 nm) near the channel walls, caused by an electric field imposed across the channel length. The velocity profile in the core of the channel is plug-like, even for a channel height as small as 24 nm.[43] Higher electrical permittivity of the fluid, imposed electric field strength, and zeta potential on the wall surface may all increase the flow rate.

Electrophoretic response, on the other hand, is the motion of charged molecules in a fluid caused by an electric field imposed across the channel length. Positively charged molecules move to the negative electrode, while negatively charged molecules move towards the positive electrode, leading to molecule separation. Electrophoresis is the most widely used separation method in the biotechnology field today. Typically, a buffer solution is chosen such that all biomolecules in the fluids, e.g., DNA/RNA fragments and proteins, are negatively charged. They all migrate from the sampling point to the detection point. Since DNA molecules have the same charge/mass ratio, separation is usually achieved by placing an immobilized gel or a mobile ''gel'' solution in the separation channel. Electro-osmotic flow may cause unwanted washout of the gel solution during electrophoresis, so some sort of channel coating may be necessary for EOF suppression if the channel wall has a high zeta potential (e.g., glass). On the other hand, undesirable electrophoretic separation may occur in EOF if the sample solution contains components with different charges. A high-ionic-strength-plugs method has been developed to facilitate sample transport. The use of solutions at different ionic strengths and therefore different electroosmotic mobility, however, creates a quite complex situation in microfluidics. Electrokinetic flows work very well in microchannels because of the large surface-to-volume ratio, which minimizes the Joule heating problem in this type of flow. Very high electric field strength (i.e., hundreds to thousands of volts per centimeter channel length) can be easily applied in microdevices to speed up the processing time from hours to minutes or even seconds. For nanosized channels, it has been found that very low electric power (e.g., several volts per micrometer channel length) can generate a volume flow rate that is practical for controlled drug delivery.[43]

Capillary separation is also highly favored in microfluidics. This method is simple and low-cost, but a gas–liquid interface must exist. It is mainly used for reagent loading and release in portable biochips and drug delivery systems. The velocity profile is similar to that in pressure-driven flow, but the flow is very sensitive to the surface tension of the fluid, solid surface energy and roughness, and channel shape.[44] Active control of surface tension forces to manipulate flows in microchannels can be achieved by forming gradients in interfacial tension on the channel surface[45] or by electrowetting.[46]

For most cases involving the flow of small-molecule liquids, such as buffer solutions, the standard continuum description of transport processes works very well, except that surface forces (surface tension, electrical effects, van der Waals interactions, and, in some cases, steric effects) play a more important role than usual. Although some discrepancies have been reported between pressure-driven flow measurements made in microchannels and calculations based on the Navier–Stokes equations, most have been found to be experimental errors.[42] This is because the pressure drop, as a function of flow rate, varies as the inverse fourth power of channel radius (or inverse third power of channel height), and a small change in the radius (or channel height) due to manufacturing imperfections or channel-wall contamination produces large changes in the flow. Since the volumetric flow rate varies linearly with channel radius (or height) for electrically driven flow,[43] EOF is a more reliable way than pressure-driven flow to verify microfluidic experiments with calculations. A recent study[43] shows that calculated flow rates from classical EOF analysis agree well with experimental data for channel heights in the range of 10–20 nm.

Retardation of flow of ionic liquids and solutions in microchannels, however, can be significant when the

channel walls have either the same static charge[47] (e.g., glass surface is negatively charged) in pressure-driven flow or opposite charges in EOF.[43] In the former case, the flow causes charges inside the EDL to accumulate downstream, while charges on the solid channel wall remain immobile. Such excess charge creates a potential drop in the channel direction, causing a ''backflow.'' For channel height in the range of 100 μm, this electroviscous effect (flow retardation is often counted as an increase in fluid viscosity) is small. But a retardation of 70% is observed when the glass channel diameter is in the range of several micrometers.[47] In the latter case, the backflow can be manipulated by surface micropatterning of opposite charges on the walls of the microchannel to achieve laminar chaotic mixing[48] or controllable membrane permeation.

In many bioMEMS applications, the sample fluid contains molecules and particles of various sizes. Small organic molecules are a few angstroms in size, typical protein molecules are about 2–5 nm, and large DNA molecules and cells are in the range of 1–10 μm. In some cases, the radii of near-spherical fluid droplets or gas bubbles are comparable to that of the channel, but in others, their lengths may be larger.[42] Non-Newtonian fluid and multiphase flow mechanics must be applied. In microchannels, the shear rate can be very high, e.g., $10^7\,\mathrm{sec}^{-1}$, even though the Reynolds number is low. Rheological characterization of polymeric fluids and biofluids in such a flow field has recently been studied in our laboratory.[48] It was found that the standard rheological analysis used at the macroscale also works at the microscale. The high-shear Newtonian plateau can be easily observed. For solutions containing large polymer (or DNA) molecules, polymer degradation and wall slip are substantial when the flow rate is high. Rheology in microchannels needs to be studied further because many biofluids are highly non-Newtonian. One advantage of microfluidics is that a single biomolecule such as DNA can be isolated and analyzed on a biochip containing small channels or wells.[49,50] Since the molecule size is comparable to the channel (well) dimension, understanding and manipulating both the macroscopic and microscopic transport phenomena of the confined molecule undergoing flow is an active area of research.[42]

CONCLUSIONS

The miniaturization of biomedical and biochemical devices for bioMEMSs has gained a great deal of attention in recent years. Products include biochips/biosensors, drug delivery devices, tissue scaffolds, and bioreactors. In the past, MEMS devices have been fabricated almost exclusively in silicon, glass, or quartz because of the comparable technology available in the microelectronics industry. For applications in the biochemistry and biomedical field, polymeric materials are desirable because of their lower cost, good processability, and biocompatibility. Polymer microfabrication techniques, however, are still not well developed.

Ee Lui Ang
Huimin Zhao
Department of Chemical and Biomolecular Engineering, University of Illinois, Urbana, Illinois, U.S.A.

INTRODUCTION

Biomolecular engineering is an emerging field of academic research and industrial practice having the goal of engineering value-added biomolecules and biomolecular processes for applications in medical, chemical, agricultural, and food industries.[1] This new subject is very broad and highly interdisciplinary, including, but is not limited to, protein engineering, metabolic engineering, bioinformatics, bioprocessing, gene therapy, drug design, discovery and delivery, biomaterials, and nano-biotechnology. In the past decades, biomolecules such as protein pharmaceuticals, DNA vaccines, monoclonal antibodies, and industrial enzymes have been increasingly commercialized. In this entry, the key concepts and technologies in biomolecular engineering and their applications in engineering proteins, pathways, and nucleic acids are introduced.

KEY CONCEPTS AND TECHNOLOGIES EMPLOYED IN BIOMOLECULAR ENGINEERING

Protein Engineering

Protein engineering refers to the ability to alter protein structure to achieve a desired protein function. Two main protein engineering approaches, rational design and directed evolution, have been developed in the past two decades (Fig. 1). The former involves alterations of selected residues in a protein via site-specific mutagenesis to achieve predicted changes in function. In comparison, directed evolution mimics the process of natural evolution in the test tube, involving repeated cycles of creating molecular diversity by random mutagenesis/gene recombination, followed by screening/selecting the functionally improved variants.

Metabolic Pathway Engineering

Metabolic pathway engineering involves the directed improvement of product formation or cellular properties through the modification of specific biochemical reaction(s) or through the introduction of new one(s) by recombinant DNA technology.[2] Specifically, metabolic engineering includes identification of metabolic pathways, elucidation of regulatory mechanisms, metabolic flux analysis, metabolic control analysis (MCA), identification of inter- or intra-cellular transport mechanisms, and discovery and manipulation of biosynthetic pathways. This area is particularly important to biotechnology because it offers ways for improving existing bioprocesses, designing new bioprocesses, as well as producing novel chemicals and pharmaceuticals.

Many molecular biology and analytical chemistry tools have been developed for metabolic engineering.[3] For example, various vectors have been designed for the optimal expression of heterologous genes in industrial hosts. Several gene-cloning techniques have been developed to isolate novel genes from cultivable or uncultivable organisms, whereas RNA-antisense techniques have been used to silence gene expressions. In addition, directed evolution methods have been used to construct genes, pathways, or whole genomes with altered functions. As important as these genetic engineering tools, a number of powerful analytical techniques have also been developed for metabolic pathway analysis and analyses of cellular functions, such as gas chromatography and mass spectrometry (GC–MS), nuclear magnetic resonance (NMR), two-dimensional gel electrophoresis, DNA chips, and protein chips.

Because of the complexity of metabolic networks, rationally designed metabolic pathways often have undesired metabolic consequences on unrelated cellular properties. To address this limitation, a new metabolic engineering strategy of particular interest, ''inverse metabolic engineering'' (IME), was developed[4] (Fig. 2), which integrates directed evolution principles with the ''direct'' classical metabolic engineering. The strategy begins with the construction and identification of a desired phenotype; then the genetic basis or environmental factor for the desired phenotypic characteristic is determined; finally, this phenotype is endowed on another strain or organism by genetic manipulation. The essential and challenging step of IME is to identify the genetic basis of the desired phenotype,[5] which is illustrated later.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120019077

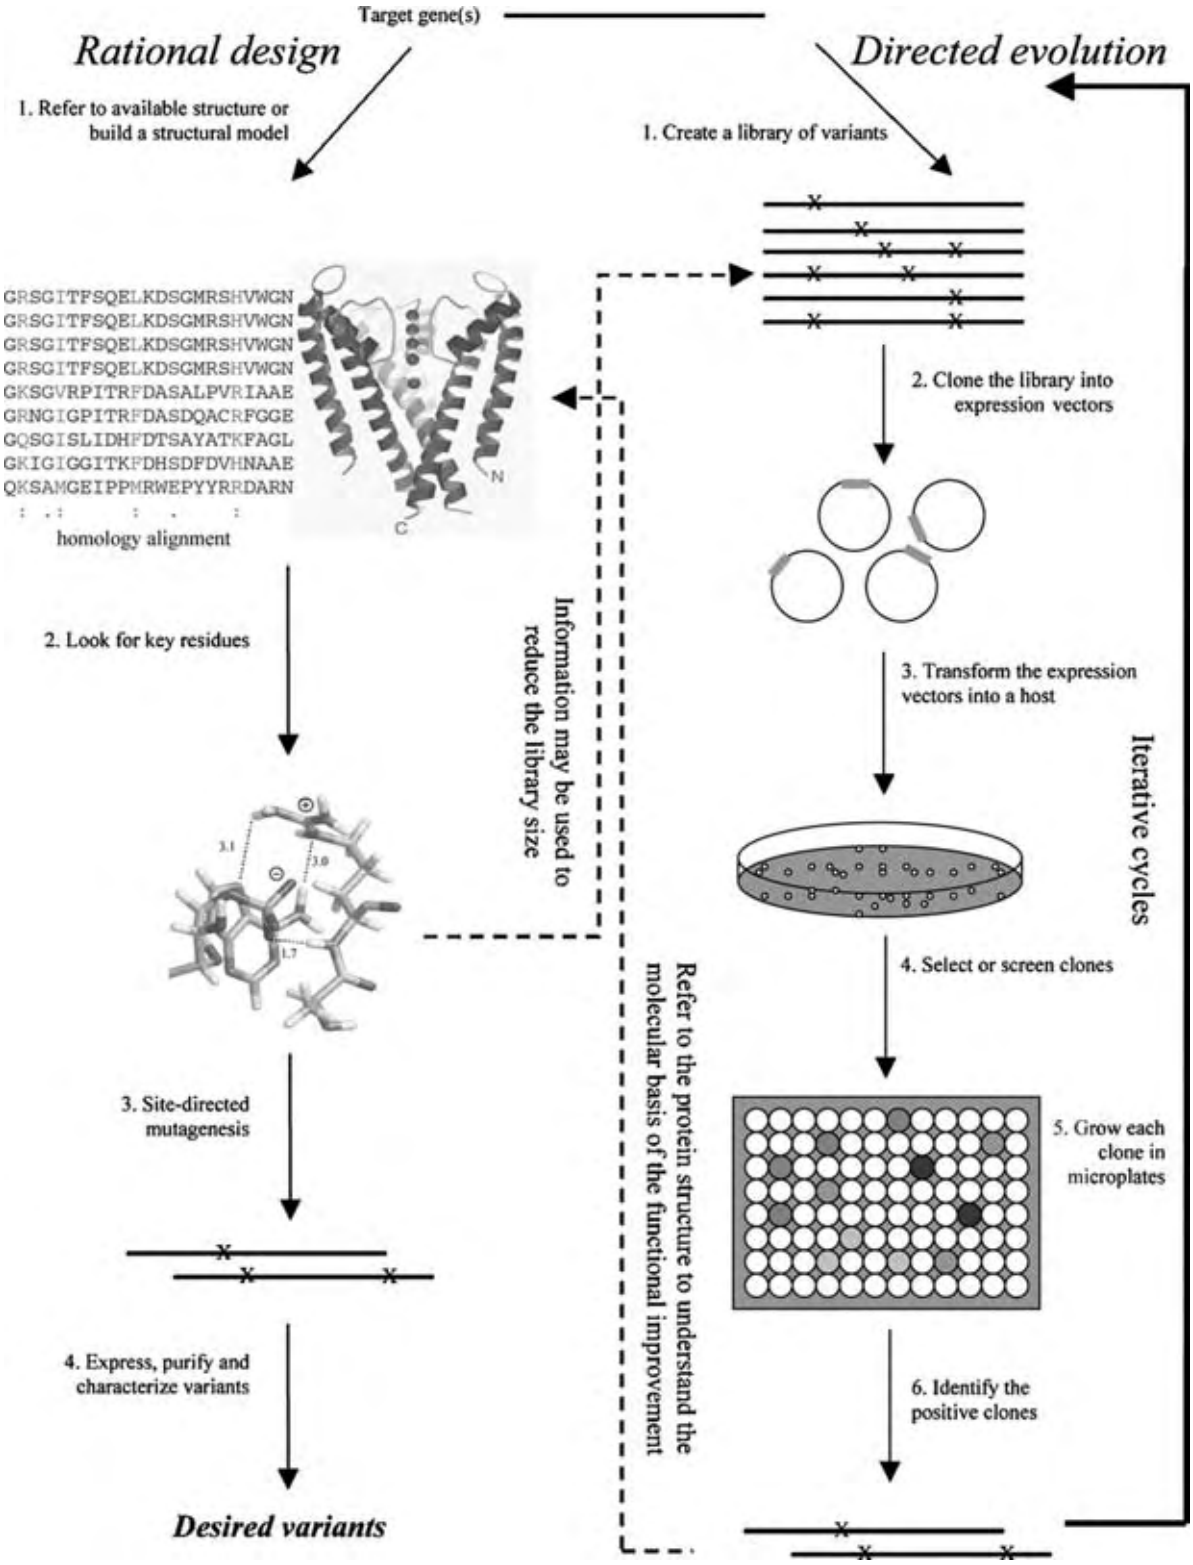

Fig. 1 Comparison between rational design and directed evolution. *(View this art in color at www.dekker.com.)*

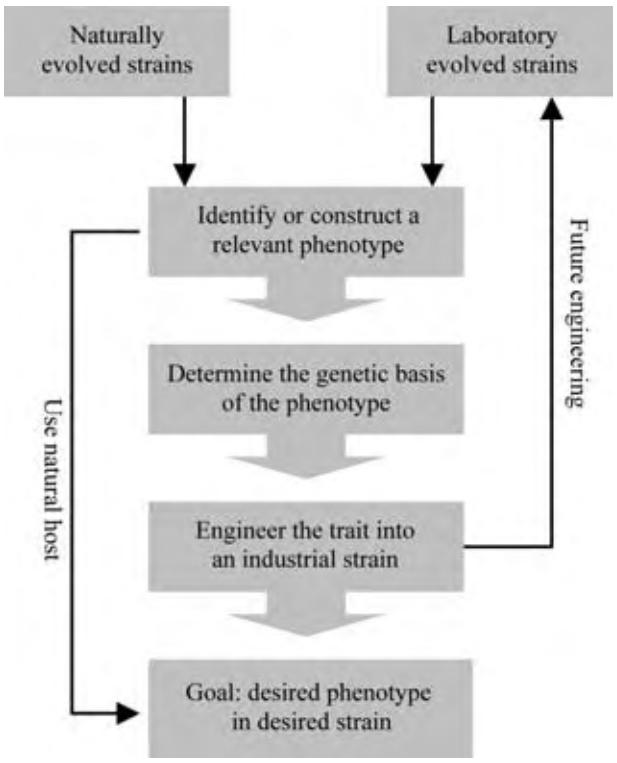

Fig. 2 The scheme of the inverse metabolic engineering (IME) approach. (From Ref.[5].)

Another two key concepts in metabolic engineering are metabolic pathway analysis and metabolic pathway modeling. The former is used for assessing inherent network properties in the complete biochemical reaction networks. It involves identification of the metabolic network structure (or pathway topology), quantification of the fluxes through the branches of the metabolic network, and identification of the control structures within the metabolic network.[3]

To identify metabolic network structure of common organisms, it is often helpful to do an extensive literature review. Also, a few pathway databases, such as BioCyc Knowledge Library (www.biocyc.org), may be used to identify specific metabolic pathways. However, in some cases, it is not easy to identify the complete metabolic network. This will cause a serious problem as some parts of the pathways that carry significant metabolic fluxes will possibly be ignored, resulting in only partial or even false estimation and analysis of the network structure. In these cases, enzyme assays and isotope-labeling techniques combined with either NMR or GC–MS are valuable tools for confirming the presence of specific enzymes and pathways. Once the whole metabolic network structure has been identified, quantification of the flux distribution through branches can be determined by solving a series of algebraic mass balance equations in terms of substrates, products, biomass constituents, and intracellular metabolites. For example, Fig. 3 shows how the carbon fluxes are distributed through the individual branches of metabolic pathways of *Saccharomyces cerevisiae* under anaerobic growth. It offers insights into other important cell physiological characteristics that can be used for controlling and directing metabolic fluxes, identifying alternative pathways, and calculating the maximum theoretical yields of the products.[6] Once the fluxes through the different branches are quantified, controlling the fluxes can be attempted. It is necessary and important to understand how the enzymes at the branch points are regulated. Various types of regulatory mechanisms have been identified, such as feedback inhibition, cooperativity, modification of covalent enzymes, and control of enzyme synthesis.[6] Determining the metabolite concentrations is also important for understanding how metabolic fluxes are controlled. In this case, GC–MS and LC–MS–MS are good choices for measuring a large number of metabolites.[3] Furthermore, to quantify the flux control, the concept of metabolic control analysis is commonly used with flux control coefficients (FCC), which is defined as the relative change in the steady-state flux, resulting from an infinitesimal change in the activity of an enzyme of the pathway, divided by the relative change of enzymatic activity.[6]

For pathway modeling, the typical aims include exploration of the possible behavior of a system, interpretation and evaluation of measured data, systematic analysis of a metabolic network structure and its qualitative behavior, and designing/predicting/optimizing the outcome of future experiments. The different modeling approaches currently used, including structure model, stoichiometric model, carbon flux model, stationary and nonstationary mechanistic model, and gene regulation model, are discussed and evaluated by Wiechert.[7]

Nucleic Acid Engineering

Previously, nucleic acids were considered as the carriers of genetic information in cells, with very few other functions. However, with the recent discovery of ribozymes (catalytic RNA), aptamers (binding RNA/DNA), and DNAzymes (catalytic DNA), nucleic acids have also been increasingly explored for diagnostic and therapeutic applications. As nucleic acids carry both structural (genotype) and functional (phenotype) information in a single molecule, they are particularly amenable to powerful in vitro selection methods such as SELEX (Systematic Evolution of Ligands by Exponential Enrichments) (Fig. 4).[8] The principle behind these selection methods is the same as that of directed protein evolution, where the DNA or RNA molecules are put through iterative rounds of diversification and selection.

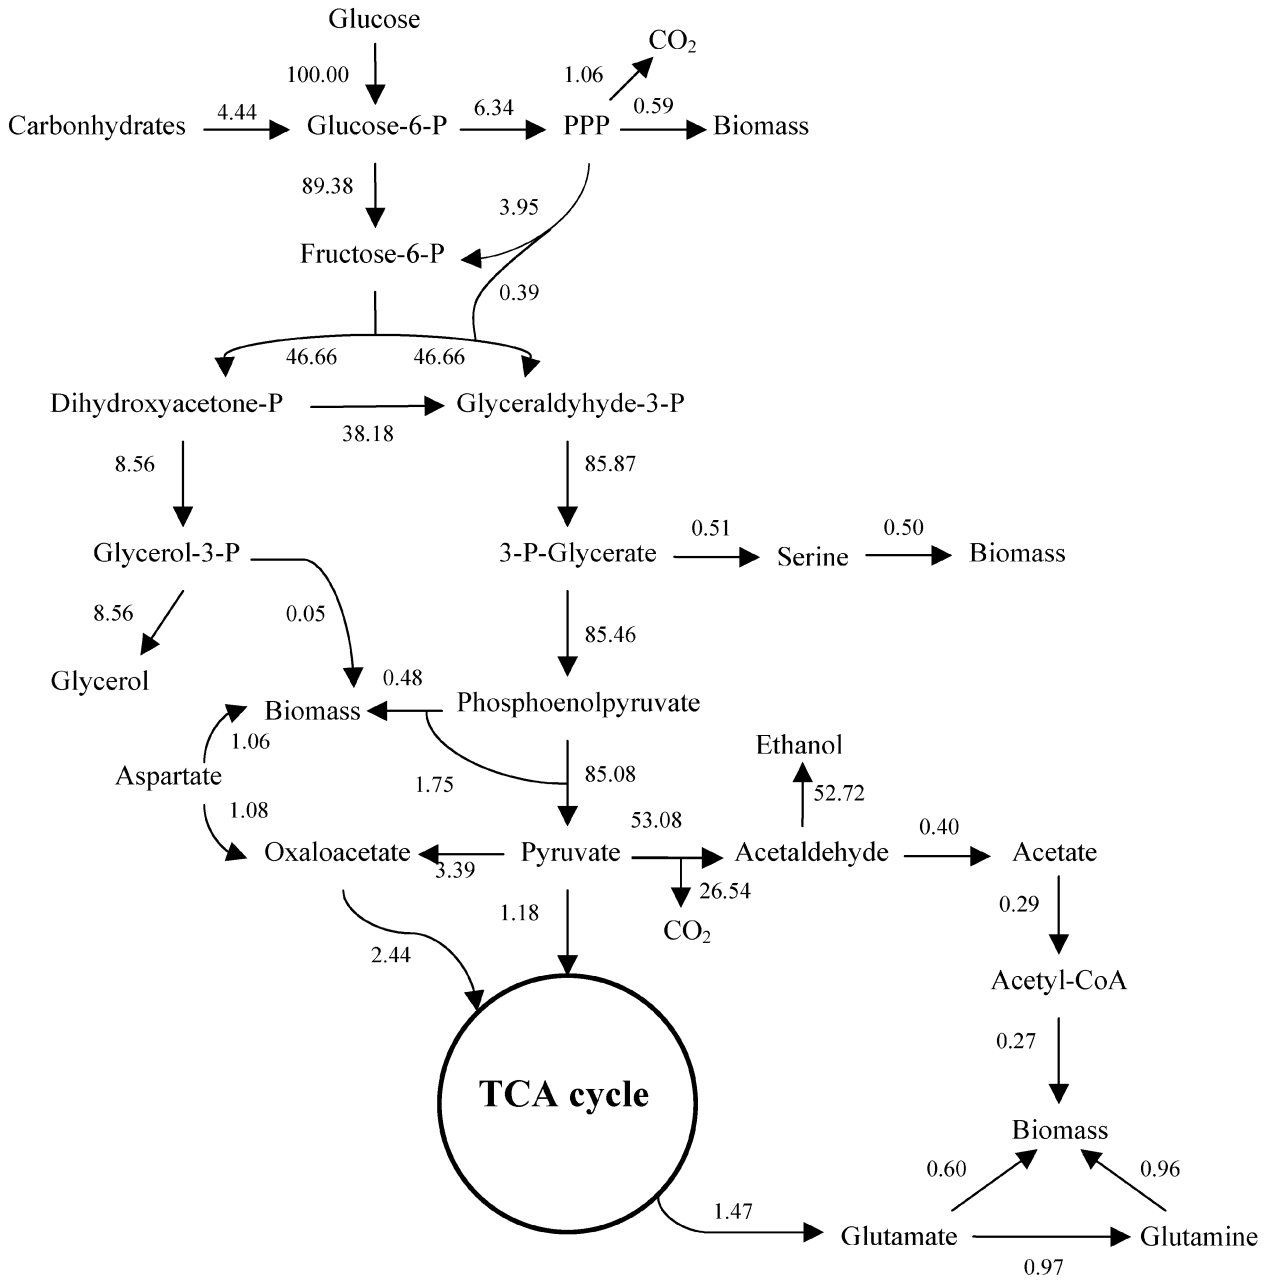

Fig. 3 An example of metabolic flux analysis showing fluxes through the different metabolic pathways of *S. cerevisiae* under anaerobic growth. (Adapted from Ref.[6].)

Although the different classes of therapeutic nucleic acids work via different mechanisms to treat diseases, the development of all forms of nucleic acid molecules into practical therapeutic agents faces a common obstacle—the omnipresence of nucleases in biological fluids. Nucleases degrade the DNA or RNA agents in the body, shortening the life span and consequently the efficiency of the nucleic acid therapeutic agents.[9] As a result, larger doses are required to achieve desired results, making the treatment very expensive. There are several methods to overcome this limitation, first of which is modification of bases. By replacing the 2′-OH-group in RNA with a host of different bases, such as 2′-NH_2– and 2′-F-pyrimidines, the stability of aptamers that were used as RNA-based therapeutic agents can be greatly increased.[10] However, 2′-modified aptamers must be compatible with the overall SELEX protocol. Therefore, any modified nucleotides used must be recognizable by the various polymerases used in the amplification process. Alternatively, the use of "Transcription Free SELEX" bypasses the need for polymerase compatibility by allowing random RNA

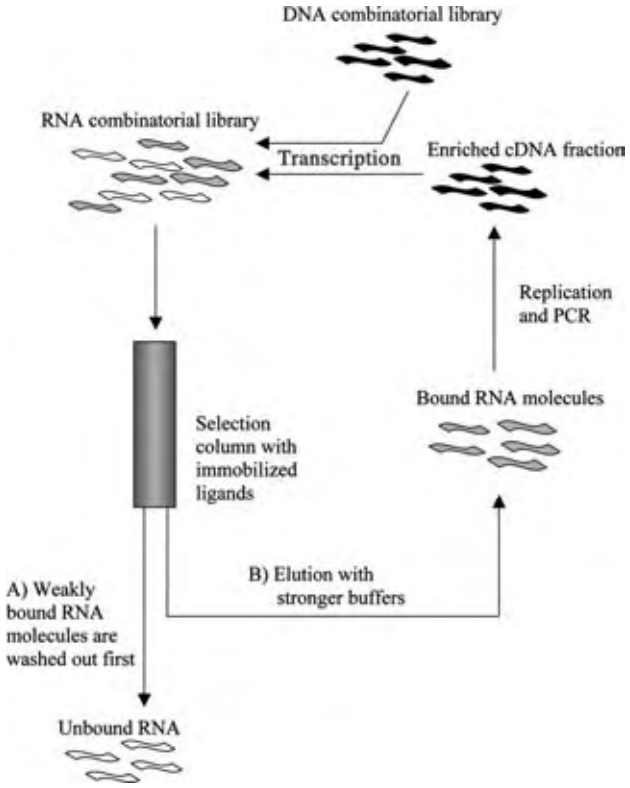

Fig. 4 The scheme of the SELEX method.

nucleotide fragments to bind to random DNA templates. Standard chemical reactions such as carbodiimide[11] or cyanogen bromide condensations[12] can then be used to ligate these fragments, and the RNA aptamers can then be recovered by melting the duplex.[13]

The modification of bases has also been applied to another type of RNA therapeutic agent, the antisense oligonucleotides. Currently, the modifications can be classified into various generations. In the first generation, modifications were done on the backbone of the oligonucleotides, a common example is the replacement of one nonbridging oxygen atom with sulfur.[14,15] These were known as phosphorothioate (PS) oligonucleotides. One successful example is Vitravene^{TM}, which is currently the only FDA-approved antisense drug in the market. The second generation contains sugar modifications, with the substitution of the 2′-OH groups being the most common. Oligonucleotides with 2′-O-alkyl derivatives were found to be more resistant to DNA- or RNA-cleaving enzymes. Currently, 2′-O-methyl and 2′-O-alkyl have already been incorporated into a number of oligonucleotides in clinical trials.[16] The third generation of antisense RNA consists of zwitterionic oligonucleotides.[17] It was found that a modification of 2′-O-aminopropyl (AP)-RNA displayed a much higher resistance to snake venom phosphodiester (SVPD) compared with a 2′-O-butyl-modified RNA.[18] AP-RNAs were able to competitively inhibit the degradation of single-stranded DNA by *Escherichia coli* Klenow fragment (KF) 3′-5′ exonuclease and SVPD. Crystal structure studies of AP-RNA revealed that the positively charged 2′-O-substituent is able to interfere with the metal-ion binding site B of the KF exonuclease, slowing down the degradation process.

Another method of improving nucleic acid stability is the use of mirror image molecules. Substrate recognition by natural nucleases is inherently stereospecific because these enzymes consist of only L-amino acids. Thus, only (D-)oligonucleotides can be recognized and degraded by the nucleases. To increase the stability of aptamers in biological fluids, nuclease resistant aptamers can be generated by using non-natural L-nucleotide aptamers, which are also known as spiegelmers (''spiegel'' meaning mirror in German).[19] However, because of the very reason that spiegelmers can escape nuclease recognition, no natural enzymes are able to recognize and amplify such nucleic acids. This greatly limits the screening of spiegelmers for potential drug agents as they cannot be directly screened using SELEX methods. To overcome this problem, unmodified D-RNA or D-DNA libraries were screened against the mirror image of the natural drug target instead.[19] Following the rules of symmetry, the mirror image of the selected D-aptamers will in turn bind to the natural drug targets.

Bioinformatics

Bioinformatics is a rapidly expanding field, involving the application of computer technology to the management of biological information. Here, only two of the key bioinformatics components related to biomolecular engineering, database and computer modeling, are discussed.

The successful sequencing of the genomes from more than 100 organisms, including humans, has led to the increasing use of genomic databases such as GenBank, European Molecular Biology Laboratory Nucleotide Sequence Database (EMBL), and DNA Data Bank of Japan (DDBJ). Each of these three international databases collects and archives the sequencing data reported worldwide on a daily basis.[20] One extremely powerful tool for searching these nucleotide and protein databases is the Basic Local Alignment Search Tool (BLAST),[21] which compares a target DNA or protein sequence to all the existing sequences in the databases to find known sequences with high sequence similarities, and thereby obtain insights into the structure and function of the DNA or protein of interest. This tool is freely available to the public on the

National Center for Biotechnology Information (NCBI) website (www.ncbi.nlm.nih.gov/BLAST). It should be noted that many powerful tools for web-based database searching and sequence analysis have been developed, such as the San Diego Supercomputer Center Biology Workbench (SDSC Biology Workbench, workbench.sdsc.edu). In the SDSC Biology Workbench, database searching is combined with access to a wide variety of sequence analysis and modeling tools, which makes it very convenient for researchers to analyze nucleic acids and proteins.

The availability of a protein crystal structure is important for understanding the molecular basis of protein functions as well as for engineering new or improved protein functions. However, the protein structures are typically solved by x-ray crystallography and nuclear magnetic resonance (NMR), which are very time-consuming and laborious processes. As a result, the number of solved protein structures is far fewer than that of known proteins. Within this context, the use of computer-modeling algorithms and programs to rapidly create a structural model of the target protein in silico is a very attractive alternative to experimental structure-determination methods. In general, there are three basic methods for structure prediction: ab initio, homology (comparative) modeling, and fold recognition (threading).

Ab initio methods rely on the fact that the folded protein is in a state of lowest free energy; hence, the predicted structures are created through energy minimization based solely on possible interactions between the residues. As ab initio methods do not refer to existing protein structures, they are typically computation intensive. However, theoretically these methods could be superior, as, unlike homology modeling and fold recognition, they are not biased by existing structural information. Many different types of empirical force fields and levels of structure description are used in ab initio methods. Homology modeling attempts to predict protein structure based on the similarity between the sequence of a protein and the sequences of other proteins of known structures, whereas fold recognition defines a database of known structures and then fits (threads) the sequence to that database, evaluating the score that assesses the suitability of each possible fit to a given fold. For high sequence identities ($>30\%$), homology modeling usually gives a reasonably accurate model. In cases of low sequence identities ($<30\%$), threading methods often yield more accurate models than does homology modeling,[22] especially considering that there are some cases where folds are the same, yet sequences are very different (low identity).

As mentioned earlier, many bioinformatics tools were developed by individual research groups all around the world and are freely available on the Internet. In addition, there are also a few commercial software programs, such as Insight II (Accelrys Inc., San Diego, California) and SYBYL®/Base (Tripos, Inc., St. Louis, Missouri). These programs integrate force fields, energy minimization, homology modeling, molecular dynamics simulation, and molecular visualization into a single platform, making them very powerful tools for protein analysis, modeling, and design.

EXAMPLES

Protein Engineering

There are many examples of protein engineering that use rational design and directed evolution.

Metabolic Pathway Engineering

Metabolic pathway engineering has numerous applications in food, agriculture, chemical, and pharmaceutical industries. Examples include, but are not limited to, increasing the yield of antibiotics, biosynthetic precursors, or polymers, expanding the metabolic capacity to degrade harmful compounds, or producing novel compounds that cannot be found in nature.

Biosynthesis

To establish metabolic pathways in a production host that are able to channel carbon flux to a desired product at a high yield requires careful consideration of the entire metabolic microenvironment in the host. These efforts normally include four key elements: 1) direct and optimize the primary metabolic pathway flux to the target product, including removal of rate-limiting steps, and transcriptional and allosteric regulation; 2) genetically block competing branch pathways; 3) modify secondary metabolic pathways to enhance energy metabolism and availability of required enzymatic cofactors; and 4) remove detrimental side-products.[23] For example, the central glucose metabolic pathway of *E. coli* was engineered to achieve high recombinant protein production. The acetate accumulated at the end of the central glycolysis pathway affected both the recombinant protein production and the cell density detrimentally.[24] Strategies investigated to reduce acetate accumulation included modification of glucose uptake rate by a glucose analog methyl α-glucoside,[25] redirection of carbon flux toward a less inhibitory byproduct, acetoin, by introducing acetolactate synthase gene of *Bacillus subtilis* into *E. coli* to convert pyruvate to acetoin instead of acetate,[26] and elimination of critical enzymes, including acetate kinase and phosphotransacetylase that are involved directly in

the formation of acetate.[27] Another example is synthesis of hydrocortisone, an important starting material for steroidal drug synthesis, from glucose in yeast.[28] The whole process involved the natural yeast biosynthetic pathways, a yeast pathway rerouted by one plant enzyme and other five enzyme steps catalyzed by eight mammalian proteins. Experimentally, recombinant *S. cerevisiae* was engineered to express 13 assembled genes, while several unwanted side reactions brought about by endogenous yeast genes were disrupted, efficiently directing endogenous carbon flux toward the target product, hydrocortisone.

Biodegradation

Some natural organisms can degrade harmful organic compounds, referred to as xenobiotics, such as aromatics, halogenated aliphatics, and pesticides. However, these naturally occurring degradation processes are extremely slow and inefficient. Thus, speeding up these processes by metabolic engineering has become an attractive strategy. Most work in this field has focused on biodegradation of aromatic hydrocarbons, among which the TOL pathway of *Pseudomonas putida* was studied extensively.[29] The TOL pathway is a plasmid-encoded pathway and can utilize toluene, *m*-, and *p*-xylene as sole sources of carbon and energy. However, it cannot use benzene, which is often present with toluene and xylene as a mixture. Heterologous expression of a toluene dioxygenase in a *P. putida* strain carrying the TOL pathway resulted in a recombinant micro-organism that can degrade all these four aromatic compounds at a high rate.[30]

Inverse metabolic engineering

The strategy of IME starts from variant construction, which can be classified into two categories: ''exogenous'' mutagenesis and ''endogenous'' mutagenesis. The former, which is usually plasmid based, involves directed evolution of proteins, whereas the latter mainly involves evolutionary engineering of host chromosome(s). An approach to create more robust strains by random mutagenesis of the *E. coli* chromosome was successfully carried out by transforming an exogenous plasmid pmut containing the *mutD* gene into the host.[31] The *mutD* gene encodes the ε-subunit of DNA polymerase III, which is responsible for proofreading of DNA replication. *mutD5*, which carries two amino acid substitutions, is non-functional, but still competes with the functional MutD protein produced from the chromosomal copy *mutD* gene, resulting in an increase of the mutation frequency of *E. coli*. In this way, a number of *E. coli* cells with a broad spectrum of base substitutions and even frameshift mutations were obtained. Among these, it was found that three bacterial strains can tolerate dimethylformamide up to 10–20 g/L. Another approach to create novel traits in microbes is genome shuffling. In this strategy, classical strain-improvement method is used to create a population (pool) of microbes with small functional improvements that are then shuffled by recursive pool-wise protoplast fusion.[32] For example, it was reported that the acid tolerance of *Lactobacillus* was improved by genome shuffling.[33] The lower pH is desirable because, at low pH, the fermentation product of *Lactobacillus*, lactic acid, is mostly in the free-acid form and can be purified much more easily than its lactate form (which is the predominant form at higher pH). The initial genetic diversity was first created in a fermenter by slowly decreasing the fermentation pH from 6.0 to 4.1 over a period of 1200 hr, resulting in a stable population of *Lactobacilli* variants growing at pH 4.1, a pH that severely inhibits growth of wild type strain. Then genome shuffling was carried out within the selected population by means of pool-wise recursive protoplast fusion, and finally a population of microbes that can grow at pH 3.8 was obtained. The yield of lactic acid of these improved microbes was threefold higher than that of the wild type microbes at pH 4.0.

Identifying the genetic basis for the desirable phenotype remains one of the central challenges in IME. Traditional approaches include DNA sequencing of the inserts after identifying desirable clones from the plasmid-based library and evaluation of gene disruption libraries to identify the genes essential for a desired phenotype.[5] However, these approaches are quite time-consuming and expensive, because it is not easy to ensure that all the relevant genes have been analyzed or the same insert will not be repeatedly sequenced. Thus, new approaches such as DNA microarray combined with molecular bar codes[34] and insertional mutagenesis[35] were developed to address these limitations. For both approaches, a pool of cell variants was generated, with its specific gene interrupted by DNA fragments (molecular bar codes or insertional elements) that can facilitate later identification and quantification of each interrupted gene by DNA microarray. Cell variants, growing in different selective conditions competitively, were combined. Under a selective pressure, the genes involved in the biosynthesis of nutrients not provided in the media would be significantly enriched,[35] while the sequence tags of the interrupted genes would diminish in the culture if the deleted genes were important for the growth.[34] Compared with the wild type or unselected library profile, the relevant genes for a specific phenotype can be identified and quantified through DNA microarray.

Nucleic Acid Engineering

Ribozymes

Ribozymes are RNA molecules with catalytic activities. These molecules were discovered by Cech et al. in 1981,[36] and have been found to catalyze a variety of reactions in the cell such as RNA splicing, RNA processing, the replication of RNA genomes, and peptide bond formation during translation.[37] The main function of naturally occurring ribozymes is the sequence-specific cleavage of RNA molecules. Ribozymes can function either in the *cis* manner, in which they catalyze the splicing of their own RNA sequence, or in the *trans* manner, in which they catalyze the cleavage of other RNA molecules.

One of the most studied *trans*-acting ribozymes is the hammerhead ribozyme. It consists of three base-paired helices surrounding a ''core'' sequence (Fig. 5). Stems I and III bind to complementary sequences on the target RNA, and the central region catalyzes the cleavage of the RNA at the 3′ end of a UH sequence (where H = U, A, or C). Thus the ribozyme can theoretically be designed to target any RNA molecule containing the UH sequence. Hammerhead ribozymes possess great therapeutic potential and have been targeted at numerous genes, ranging from viral disease genes, such as hepatitis B and HIV-1, to cancer related genes, such as multidrug resistance (MDR-1).[37] The hammerhead ribozyme can be improved in a variety of ways such as in vitro selection to isolate ribozymes with higher activity and chemical modification of the nucleotide bases to improve nuclease resistance. These engineering methods have been covered in the review by Usman et al.[38] In a recent study, a hammerhead ribozyme (RzA) that cleaves the hepatitis B virus (HBV) poly A signal was connected to the viral encoded RNA involved in the packaging of bacterial virus Φ23 DNA into procapsids (pRNA).[39] The chimeric ribozyme (pRNA-RzA) was able to cleave the substrate HBV-polyA with nearly 100% efficiency. Furthermore, *e*-antigen assays and northern blot analysis showed that the chimeric ribozyme displayed better performance in inhibiting the HBV-polyA than the ribozyme alone in cell cultures. These findings suggest that pRNA can chaperone and escort the hammerhead ribozyme to function in the cell, enhancing the cleavage efficiency and inhibition effect of the ribozyme on HBV.

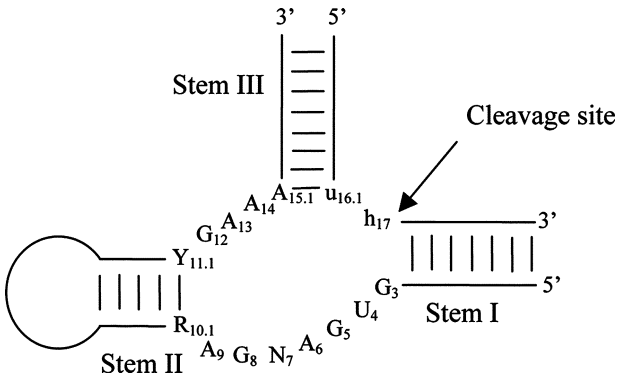

Fig. 5 The hammerhead ribozyme, showing the three non-conserved stems and the cleavage site. Ribozyme nucleotides are in uppercase letters, while substrate nucleotides are in lowercase. Y represents C or U; R represents A or G; N represents A, C, U, or G; h represents A, C, or U. (From Ref.[48].)

Another type of ribozyme is the Group I intron, which carries out a self-splicing reaction via a two-step *trans*-esterification reaction. As such, *trans*-splicing Group I ribozymes can be used as a form of treatment for genetic disorders as they can repair RNA transcripts from mutated genes. The Group I ribozyme recognizes the target mRNA by base pairing to an accessible region of the transcript upstream of a non-sense or mis-sense mutation via an internal guide sequence (IGS). After base pairing, the ribozyme cleaves off the downstream region and splices in a corrected transcript to restore the correct genetic information (Fig. 6).[40] The Group I ribozyme has been adopted to mediate the repair transcripts of mutated p53 gene, a tumor suppressor gene that is mutated in many cancers.[41] Using in vitro selection, two ribozymes, Rib41 and Rib65, which were able to cleave the majority of p53 transcripts and yield products of the correct size, were isolated from a ribozyme library containing randomized IGS, 5′-GNNNNN-3′ (where N represents any of the four nucleotides). These ribozymes were able to repair the defective p53 RNA transcripts with high fidelity and specificity. In addition, the corrected transcripts were found to be functionally translated, resulting in a 23-fold induction of a p53 responsive promoter and a threefold reduction in the MDR-1 gene promoter.

DNA enzymes

DNA has long been regarded as a passive molecule that is ideal for carrying genetic information but is structurally monotonous and thus functionally impoverished. However, this notion was changed with the discovery of catalytic RNA.[42] Since then, DNA enzymes, which are cation-dependent enzymatic molecules composed entirely of DNA, have been developed.[43,44]

In the seminal work by Breaker and Joyce,[43] a mixture of random N_{50} DNA oligomers were tethered to a matrix by a RNA nucleotide-containing linker.

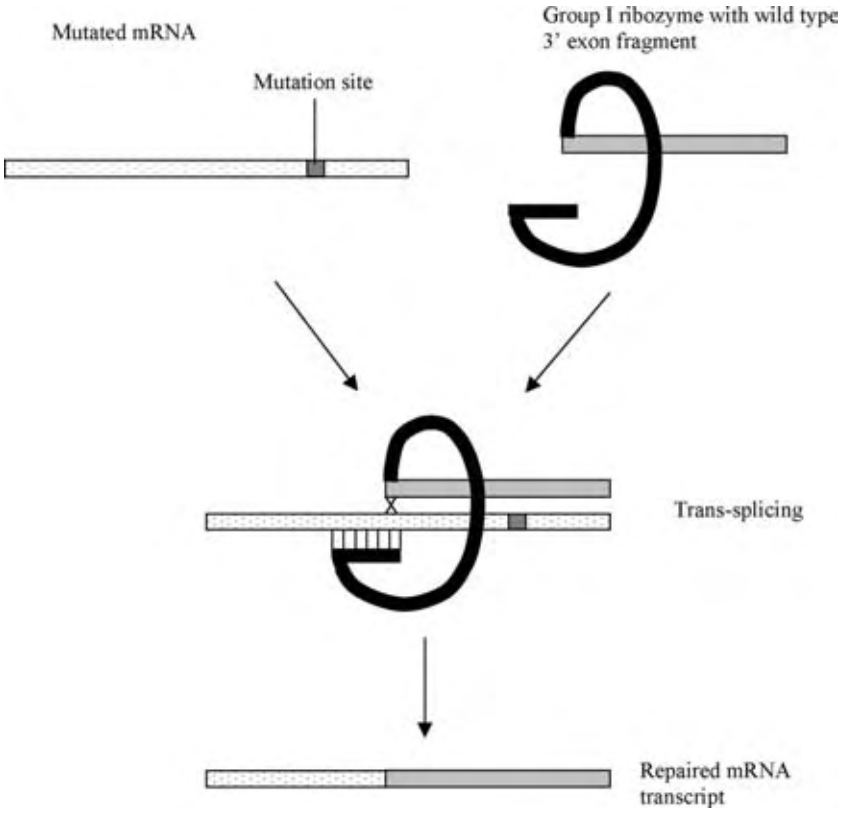

Fig. 6 The scheme of mRNA repair by Group I ribozyme.

When washed with lead solution, oligomers capable of utilizing lead ions to cleave the tethering RNA were eluted together with the solution. Hence the DNA enzymes were able to ''select'' themselves. It was also found that these enzymes can be engineered to cleave RNA substrates specifically and efficiently. DNA enzymes with 10–23 motifs or 8–17 motifs are prominent examples of such biomolecules. Both the DNA enzymes consist of a nucleotide catalytic core flanked by two substrate-binding arms of seven to eight bases each.[44] By changing the substrate-binding domain sequence, the DNA enzyme can be designed to target the AU nucleotides of different mRNA substrates with high specificity.

One potential target for DNA enzyme therapy is angiogenesis of solid tumors. Although angiogenesis is an important step in tumor development, current understanding of key transcription factors regulating it is limited.[45] However, it is known that one gene involved in angiogenesis is the early growth response (Egr-1) gene. A 10–23 motif DNA enzyme designed to target a specific motif in the 5′-untranslated region of Egr-1 mRNA was able to inhibit Egr-1 protein expression, microvascular endothelial cell replication and migration, and microtubule network formation on basement membrane matrices.[45] In addition, the Egr-1 DNA enzymes suppressed tumor growth by fivefold without influencing body weight, wound healing, blood coagulation, or other hematogical parameters of mice. This study not only shed light on the understanding of key transcription factors regulating angiogenesis but also showed the huge potential of DNA enzyme as therapeutic drug in cancer treatments.

Aptamers

Aptamers are ligands of double-stranded DNA or single-stranded RNA that can be generated against amino acids, drugs, proteins, and other molecules. They have potential applications in analytical devices, such as biosensors, and as therapeutic agents. When combined with in vitro selection techniques,[8,46] aptamers can become powerful screening tools for rapidly identifying targets for new pharmaceuticals.

A spiegelmer, NOX 1255, with a high affinity (K_D = 20 nM) for the peptide hormone, gonadotropin-releasing hormone (GnRH), was isolated by using the mirror image selection method.[47] The stability of this molecule was further increased by adding a 40 kDa polyethylene glycol moiety onto its 5′ end (NOX 1257). The spiegelmer was also found to be highly specific as it did not show any inhibition by buserelin, a peptide analog of GnRH. Furthermore, the anti-GnRH spiegelmer

exhibited a very low immunogenic potential in in vivo experiments with rabbits, suggesting that spiegelmers are not recognized by the immune system and can be administered repeatedly over long periods without adverse effects. This study demonstrates the potential of spiegelmers as a new pharmaceutical approach against GnRH and other targets.

Selected spiegelmers must be synthesized chemically, as no enzyme is able to synthesize L-DNA or L-RNA. However, with the current technology the efficient chemical synthesis of oligoribonucleotides is limited to 60 nt. Typical spiegelmers identified through the SELEX method are 60–90 nt long consisting of a 30–40 nt long randomized region and fixed primer sites of about 15–25 nt on each end. Truncation of these flanking primer regions from selected spiegelmers is required before further testing in biological systems. However, the flanking primers may affect the binding ability of the spiegelmer to its target and spiegelmers may not work well if they are truncated. To reduce this uncertainty, Vater et al. developed a strategy known as Tailored-SELEX to minimize the number of fixed primer regions in a spiegelmer.[9] Using this strategy, a rat α-CGRP binding spiegelmer with a calculated affinity of $K_D = 2.5\,nM$ at 37°C, which is close to the binding constant of the neuropeptide to its receptor ($EC_{50} = 1\,nM$), was isolated.

CONCLUSIONS

With the advances in high-throughput screening method for discovering target biomolecules and the accumulation of data in functional genomics and proteomics, the rate of designing and discovering valuable biomolecules will rapidly grow. Many enzymes and proteins have been engineered for process improvement and generation of high-value products at a low cost. A few biomolecular techniques have been utilized in disease diagnosis, and some engineered biomolecules have entered clinical trials for therapeutic uses. When the enabling technologies such as protein engineering, metabolic engineering, microarray, mass spectrometry, and bioinformatics grow more mature, and when our understanding of cells becomes more thorough, biomolecular engineering will no doubt become one of the most important research areas in both academia and industry.

ACKNOWLEDGMENT

We thank the Office of Naval Research and National Science Foundation for supporting our work in biomolecular engineering.

Bioprocess and Chemical Process Intensification

G. Akay
Process Intensification and Miniaturization Centre, School of Chemical Engineering and Advanced Materials and Institute for Nanoscale Science and Technology, University of Newcastle, Newcastle Upon Tyne, U.K.

INTRODUCTION

Process intensification (PI), motivated by plant cost reduction, emerged as a design strategy in which the processing volume is reduced (and ultimately miniaturized) while enhancing the processing field strength. Process intensification can be based on purely physical considerations. However, when there is a synergy between miniaturized processing volume and intensified processing field, PI can be considered to be inherently intensive or phenomenon based. It is therefore often necessary to consider PI with process miniaturization. Literature on PI and PI miniaturization (PIM) is reviewed within a unifying framework that allows the identification of intensification field(s) and the underlying phenomenon responsible for PI. The scope and limitations of intensified processes are examined, and through the survey of patent literature, PIM-based technology transfers are revealed. Although some of the technology transfer involves the replacement of existing unit operations with more efficient intensified processes, there are examples where PI, miniaturization, and integration are combined to address the ultimate aim of these design objectives. Despite the possibility of achieving bioprocess intensification (BI) that approaches 100-fold or more, compared with the existing technology, such intensifications are not based on that of processing field but on miniaturization in which the biocatalyst–support interactions are important. Therefore, microbioreactors coupled with highly selective biocatalysts can achieve intensification over 100-fold, making biotransformations more cost-effective compared with chemical PI. In addition to microreactor fabrication, PIM also requires the development of catalysts with not only enhanced surface area and selectivity but also accessibility of the active sites. Active site accessibility can be achieved through the development of nanostructured microporous catalysts and catalyst support with arterial channels. Such systems will enhance the scope and acceptance of PIM as they provide a clear path for sustainable technology.

When first introduced during the 1970s, PI represented a novel design strategy that aimed at reduction in the processing volume by at least an order of magnitude, compared with the existing technology, but without any reduction in process output. This restricted view of PI was relativistic and represented a design objective driven primarily by cost savings, because a significant part of the plant cost is associated with piping, support structures, and civil engineering items.[1–3] On the other hand, process miniaturization (PM) in the chemical industry has existed and continues to make excellent progress in the form of analytical equipment and sensors. Therefore, for a given production objective (or processing rate), PI and PM represent top-down and bottom-up approaches in process design, respectively. These two design approaches can be integrated with the sole aim of plant size reduction to provide major savings on capital and operating costs.

However, the integration of PIM also creates synergy in the development of intensified processes, novel product forms, and size dependent phenomena, which in turn provides novel intensified processes. Process intensification-miniaturization is seen as an important element of sustainable development because it can deliver: 1) at least a 10-fold decrease in process equipment volume; 2) elimination of parasitic steps and unwanted by-products, thus eliminating some downstream processing operations; 3) inherent safety because of reduced reactor volume; 4) novel product forms; 5) energy, capital, and operating cost reduction, and an environment friendly process; 6) plant mobility, responsiveness, and security; and 7) a platform for other technologies.

DRIVING FORCES FOR PI

Process intensification is achieved by the superimposition of two or more processing fields (such as various types of flow, centrifugal, sonic, and electric fields), by operating at ultrahigh processing conditions (such as deformation rate and pressure), a combination of the two, or by providing selectivity or extended interfacial area or a capacity for transfer processes. In heat and mass transfer operations, drastic reduction in diffusion/conduction path results in equally impressive transfer rates. As the processing volume (such as reactor

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120022532

size) is reduced by several orders of magnitude, the processing equipment ultimately becomes miniaturized.

The summary of PI driving forces, type of intensification/associated phenomenon, and their applications are shown in Table 1.

TYPES OF PI: PHYSICAL AND PHENOMENON-BASED INTENSIFICATIONS

Operations at high/ultrahigh process field strengths (driving force) such as pressure, temperature, or reduction in conduction/diffusion path often increase transport processes, and such processes can then be deemed to be intensified. Process integration can also have the same effect, often providing energy efficiency and reduced reactor volume. We can call this physical PI, which is limited by the availability of manufacturing technology to carry out such processes.

Miniaturized systems where the transport processes occur across a length scale of 100–0.1 μm (or less) not only provide a reduced diffusion/conduction path length, but can also offer process selectivity. When the enhanced transfer rates are solely caused by reduction in length scale or enhanced surface area, the intensification is still physical. However, when there is an underlying phenomenon associated with a small processing volume, then this phenomenon can be used to obtain PI. In a large number of physical, chemical, and biological processes stage-wise operations are common. When such processes are repeated several thousand times in microscopic volumes, process selectivity at each stage results in PI. There are four main reasons for PI in miniaturized systems: 1) reduced diffusion/conduction path, which can be viewed as a physical means of PI; 2) interaction between the walls of the microscopic processing volume and the fluid microstructure; 3) the ability to control the transport (momentum, heat, and mass) conditions within a small processing volume, which in turn can enhance the selectivity/efficiency of the target reaction/process; and 4) behavior of matter and microorganisms within the microenvironment.

Clearly, the above argument indicates the multidisciplinary nature of PI, which involves materials science and engineering and a detailed understanding of the molecular mechanisms of chemical processes and bioprocesses. Chemical PI and BI based on selectivity are therefore associated with an underlying phenomenon, the macroscopic manifestations of which result in

Table 1 Summary of driving forces in process intensification

Driving force	Type of intensification	Applications
Body forces	Heat and mass transfer	Rotating packed beds Spinning disks
Flow field/fluid microstructure interactions (TSVs $\Leftrightarrow$ DSVs)[a]	Flow induced phase inversion (FIPI) Flow induced phase change	Agglomeration, Microencapsulation Emulsification Structuring
High/ultrahigh pressure	Mass transfer and chemical reaction	Food processing Chemical reaction

(From Ref.[1].)

intensification. Such an intensification technique is termed as inherently intensive PI or phenomenon-based PI in which the small processing volume is a prerequisite to an intensified process viability and efficiency. The interaction between the process driving force, processing volume, and type of intensification is shown in Fig. 1.

BIOPROCESS INTENSIFICATION

Process intensification in biotechnology has certain inherent restrictions in terms of "intensification fields," or PI-driving forces, such as temperature, pressure, concentration of reactants/products, mechanical stresses and deformation rates, and the electric field.[4–8] The above-mentioned PI fields/driving forces are commonly used in chemical PI, often in combination. Chemical PI increases with increasing field strength and therefore the PI is only limited by the limits of the reactor engineering. However, in most cases, the above-referred intensification fields cannot be used in BI. Because of these restrictions on the type of PI-driving forces, BI can therefore be achieved, in the first instance, through the reduction of the diffusion path for the reactants and products, and through the creation of the most suitable environment for the biocatalysts and micro-organisms, which can enhance selectivity, resulting in phenomenon-based intensification. It is likely that the optimization of the strength and type of the intensification field will be required in BI.

PHYSICAL PI

Physical PI based on the intensification of the processing field and subsequent reduction in processing volume as a result of enhanced momentum, heat, and mass transfer is mostly encountered in multiphase systems. In such systems, the primary aim is to create a large surface area between the phases and to achieve a high-interface renewal rate and product removal rate. Some of these processes are commonly provided using stirred-tank reactors in which the volume is very large and the process driving force (shear or extension rate) is low, nonselective with a broad distribution.

It is well known that mixing can be conducted using flow instabilities, especially when the instability is time dependent, such as those encountered in capillary entrance flows of viscoelastic fluids, so that the instability in the form of vortices causes mixing and the primary flow discharges the mixed "batch" from the mixing unit. Flow instabilities in thin liquid films also have the same effect, and in all cases, a small mixing volume is utilized at a very high rate, because such instabilities require a high flow rate (which can be quantified by the Reynolds number) for a given flow geometry. There are a number of "intensified" reactors available that can be further modified to include other processing fields (such as ultrasound and electric field) superimposed on the flow field. Process intensifications based on the generation of flow instabilities are summarized below.

Spinning Disk Reactors

Spinning disk reactors (SDRs) have been developed for the intensification of processes involving low-viscosity liquid-phase reactions, including polymerization, crystallization, and catalytic organic reactions.[9–12] Thin films with intense surface ripples are generated under the effect of high acceleration fields created by rotation of the disk surface. Film thicknesses of the order of 50–200 μm are typical. Vigorous mixing characteristics and enhanced heat and mass transfer rates, obtained in

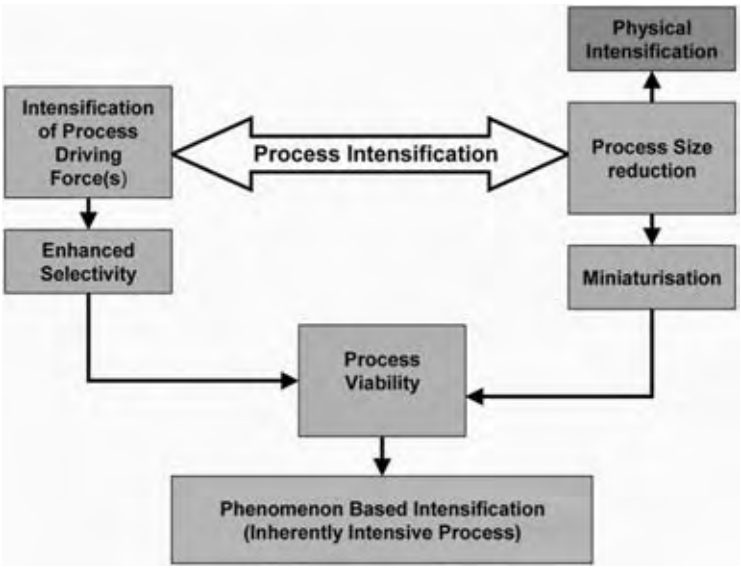

Fig. 1 Relationship between PI fields, physical PI, process miniaturization, selectivity, process viability, and phenomenon-based intensification. *(View this art in color at www.dekker.com.)*

the thin films, make the SDR an ideal reactor for operations involving fast reactions, which require rapid mixing/mass transfer and highly exothermic reactions that require an efficient heat removal system. The thin films also offer the potential of uniform penetration of ultraviolet (UV) radiation for the efficient processing of UV-initiated polymerizations.

The thin film characteristics of the SDR have been exploited for polymerization reactions proceeding by three mechanisms: free-radical polymerizations initiated by a chemical initiator and by UV-irradiation and condensation polymerizations.[9,10,11] Generally, faster rates of polymerization were observed in the SDR than in a batch reactor or a thin static film system with the SDR also producing a polymer with controlled molecular weight. For instance, the photopolymerization of *n*-butyl acrylate in the SDR showed that a high conversion (>90%), high molecular weight polymer with narrow MWD (M_n up to 35,000, M_w up to 70,000, and polydispersity index of 1.8–2.4) was obtained from the SDR under exposure to modest UV light intensities of 25 mW/cm^2, at residence times of about 2 sec.[10] In contrast, only 30% conversion could be achieved in a thin static film, after a longer exposure time of 10 sec at the same UV intensity, with a lower molecular weight polymer being formed. These results demonstrate that the high-intensity mixing taking place with the thin SDR film allows the polymerization to proceed faster than under static thin film conditions and that a better-quality polymer can also be obtained from processing in the SDR.

The vigorous mixing regime in the thin films of the SDR has also been exploited for crystallization processes.[12] Homogeneous nucleation in the thin films results in a narrow crystal size distribution for crystals formed in the SDR. Uniformly shaped barium sulfate crystals of 0.5–1 μm have been produced with a reasonably low power dissipation of 115 W/kg.[12]

Oscillatory Flow Reactors

Oscillatory flows are known to increase the transfer processes.[13] In oscillatory flow reactors (OFRs), there is a controlled stage-wise mixing present, which is achieved using tubes fitted with low-constriction orifice plate baffles and oscillatory motion (range: 0.5–10 Hz) superimposed upon the net flow of the process fluid.[14,15] The combination of the baffles and the oscillatory motion creates a flow pattern conducive to efficient heat and mass transfer while maintaining plug flow. Unlike conventional tubular reactors where a minimum Reynolds number must be maintained, the degree of mixing is independent of the net flow, allowing long residence times to be achieved in a reactor of greatly reduced length-to-diameter ratio.

An OFR can therefore be much more compact than conventional plug flow reactor designs, allowing reactor designs for longer residence times to be of practical dimensions. The main niche application envisaged is to allow the conversion of long residence time batch processes to continuous processing, when other continuous reactor designs are too expensive or impractical. This is not the only application of this technology: it can be used in a range of unit operations, including heat and mass transfer, multiphase mixing, particle suspension, bioreactions, and fermentations. Some selected examples are given below.

Mass transfer rates have been shown to be increased in yeast cultures because of increased breakup of bubbles and increased gas holdup resulting in enhanced aeration. Three-phase heterogeneous photocatalytic OFR that suspends catalyst-coated particles while they are contacted with air and exposed to UV radiation from an axially located lamp represents a good example of the utilization of several processing fields to enhance reaction rates. In this reactor, particle disengagement occurs in a baffle-free zone at the top of the column. Conversion of a batch saponification reaction to continuous processing in an OFR has been shown to result in a 100-fold reduction in reactor size, as well as greater operational control and flexibility. The mixing in OFRs is very uniform, as the radial and axial velocities are of the same magnitude. This has been shown to be an advantage when handling shear-sensitive materials, such as certain pharmaceutical crystals and in flocculators. The scale-up and design of OFRs are well understood. Indeed, the understanding of the OFR's scale-up is believed to be one of its advantages. A full review of the history and further details of the theory and applications of OFR technology are available.[15]

Controlled Deformation Static or Dynamic Mixers/Reactors

The above-described mixers are essentially low-viscosity devices. In many operations where the viscosity is high, when dealing with concentrated multiphase gas–liquid–solid binary or tertiary systems, or when liquid-to-solid phase transformation occurs during mixing, novel equipment designs are needed to intensify the heat/mass transfer processes. The multiphase fluids also represent an important class of materials that have microstructure developed during processing and subsequently ''frozen-in,'' ready for use as a product. To deliver certain desired functions, the control of microstructure in the product is important. This microstructure is developed in most cases by the interaction between the fluid flow and the fluid microstructure; hence, uniformity of the flow field is important.

Typical products with microstructure are detergents, emulsions, suspensions, paints, food emulsions, margarines, low-fat spreads, ice cream, cosmetics, personal care products, microcapsules, and agglomerated powders. The classical processing of these materials aims for low-viscosity operations, which usually result in either dilute systems or high operation temperature. Intensified processes involving microstructured products (also known as intensive structuring) deliberately use low temperature/high concentration (which results in high viscosity—non-Newtonian flow behavior), small processing volume (provides uniform deformation fields), and high/ultrahigh deformation rates under laminar flow conditions so that high/ultrahigh stresses can be generated and sustained to achieve a small microstructure at a fast production rate. These requirements therefore qualify this processing strategy as intensive processing.

All flows can be decomposed into shear and extensional components. The effectiveness of the flow field is dependent on the deformation rate, the relative values of shear and extension, and the microstructure of the fluid.[16,17] Extensional flows are more effective in microstructure development, such as droplet breakup and mechanochemical reactions. However, such flows are difficult to generate and to maintain and therefore, in practical applications, capillary entrance/exit flows provide a suitable means of achieving extensional flows where the shear component of the flow field changes with the capillary entry–exit angle.[16,17] Indeed, OFRs also generate extensional flows, which result in efficient droplet breakup in emulsification. Mixers in which the deformation rate and the relative values of shear/extension rates can be controlled are known as controlled deformation mixers.[18–20] The multiple expansion–contraction static mixer (MECS mixer), which is just a series of short capillaries separated by flow dividers, is an example of a controlled deformation static mixer and provides all of the above requirements because ultrahigh shear/extension rates approaching $10^6\,\mathrm{sec}^{-1}$ can be generated and maximum shear/extension rate ratio can be controlled.[6,17,21] Although MECS mixers are very useful in the processing of liquid/liquid systems (emulsions), they are not suitable for solid/liquid systems, in which case the controlled deformation dynamic mixer (CDDM) can be used.[19,20,22–25] Such mixers are suitable for highly viscous fluids and can also have pumping action and heat transfer facilities.

Controlled deformation dynamic mixers can be regarded as stage-wise reactors in which each stage is connected to the neighboring stages in parallel and in series. The fluid motion is three-dimensional; when the fluid leaves a stage in series, it undergoes extensional deformation while parallel-stage transfer provides mixing. Such devices have two elements, a rotor and a stator, both of which have cavities machined on them. The rotor and stator cavities can match, thus providing a suitable geometry for extensional flow at the exit/entrance to a cavity. Shear deformation is dominant within the cavities, and shear and extensional flows are superimposed in the regions where there is minimum rotor/stator clearance.

There are two such devices available. They are either in the form of two concentric cylinders (inner cylinder is the rotor) or as two (or four) disks as shown in Fig. 2.[19,20,22–25] The cavity arrangement in a disk CDDM is shown in Fig. 3. The rotor (Fig. 3A) and stator (Fig. 3B) disks can be further modified to have microporous disks for simultaneous reaction and separation or an electric field can be applied across the disk clearance.[22] Furthermore, the disks can have

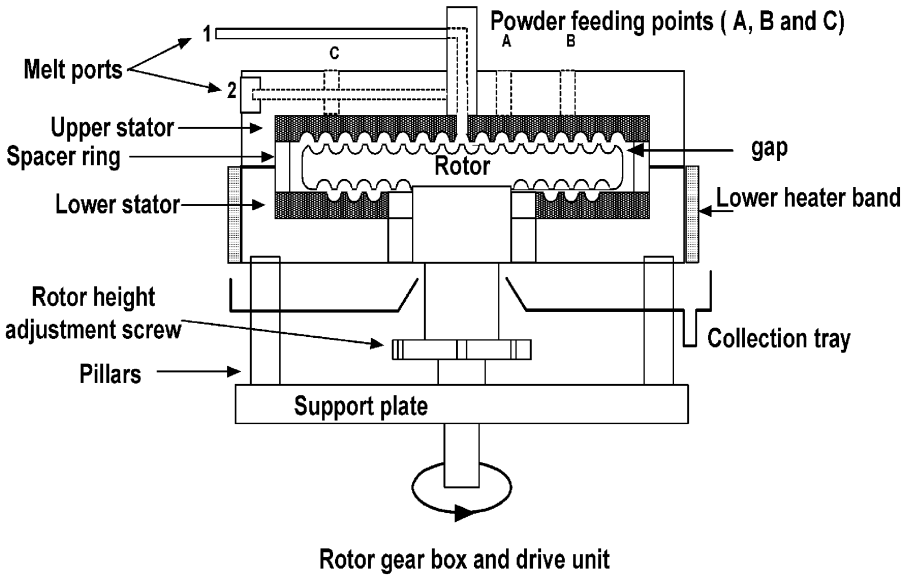

Fig. 2 Diagrammatic view of a CDDM in rotor–stator disk configuration. (From Ref.[22].)

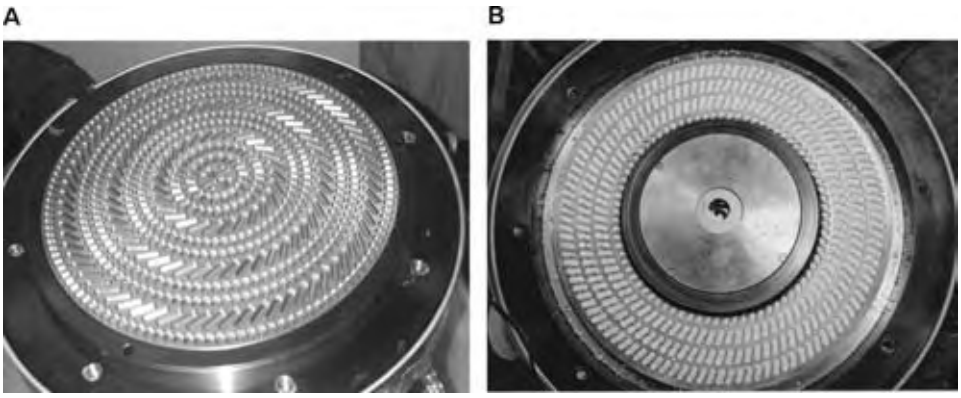

Fig. 3 Cavity arrangement in the upper rotor and lower stator disks of a CDDM in rotor–stator disk configuration. Elongated cavities are more efficient in pumping/conveying and smaller-aspect ratio cavities are for mixing. (A) Upper rotor. (B) Lower stator. (From Ref.[23].) *(View this art in color at www.dekker.com.)*

a temperature profile imposed on them. Controlled deformation (static and dynamic) mixers have been used in the intensive structuring of concentrated detergent formulations, agglomeration and microencapsulation of fine powders, and intensive separation of stable water-in-crude-oil emulsions.[19,20,22,26–31]

PHENOMENON-BASED PI

Miniaturization or reduced processing volume can result in physical PI by virtue of increasing surface area per unit volume. Miniaturized heat exchangers/reactors can be fabricated using microchannels, but such fabrication techniques are expensive and are limited by the availability of the fabrication technique for industrial scale applications. On the other hand, if the small processing volume results in enhanced selectivity, then the subsequent process has a greater degree of intensification. Therefore, in phenomenon-based PI, for a given reaction, both the reactor size/material and the nature/strength of the processing field must be considered carefully to achieve an even more impressive degree of intensification. Here, we review some of the phenomena that have been used in PI and already utilized in industry.

Flow Induced Phase Inversion Phenomenon and PI in Particle Technology

Flow induced phase inversion (FIPI) has been observed by the author and applied to intensive materials structuring such as agglomeration, microencapsulation, detergent processing, emulsification, and latex production from polymer melt emulsification.[16–18,21,29,32–35] A diagrammatic illustration of FIPI is shown in Fig. 4. When material A is mixed with material B, in the absence of any significant deformation, the type of dispersion obtained [(A-in-B) or (B-in-A)] is dictated by the thermodynamic state variables (TSVs) (concentration, viscosity of components, surface activity, temperature, and pressure). If the prevailing TSVs favor the formation of (A-in-B) dispersion, phase inversion to (B-in-A) dispersion can be achieved by changing the TSVs (thermodynamically driven process). Alternatively, the dispersion can be subjected to a well-prescribed deformation, characterized by its rate and type of deformation state variables (DSVs) to invert the dispersion under constant thermodynamic conditions; this phenomenon is known as FIPI. It is found that FIPI is not catastrophic and the dispersion goes through an unstable, cocontinuous state denoted as [AB], followed by a relatively stable

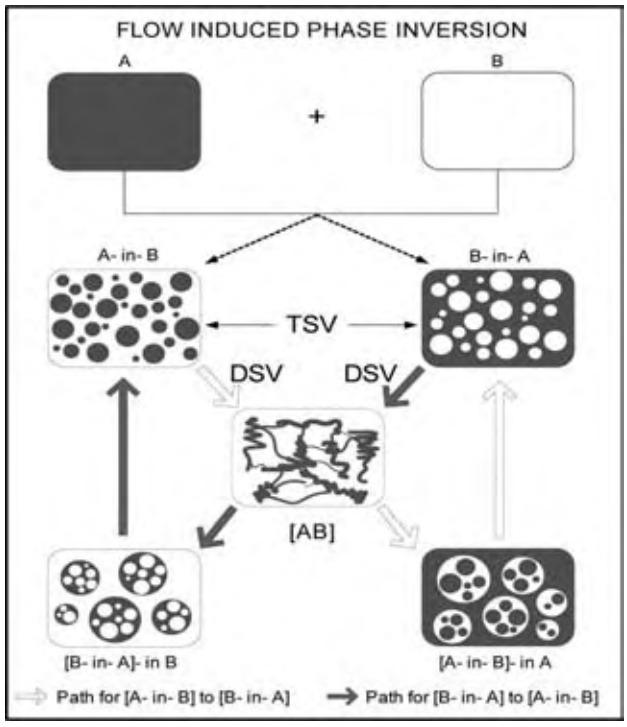

Fig. 4 Isothermal FIPI paths for the inversion of (A-in-B) or (B-in-A) emulsions through a cocontinuous unstable emulsion phase (AB). TSV, thermodynamic state variable; DSV, deformation state variable. *(View this art in color at www.dekker.com.)*

multidispersion state, denoted as [(A-in-B)-in-A], before complete phase inversion to (B-in-A). Therefore, the interchangeability of TSVs with DSVs forms the basis of FIPI processes.

The importance of FIPI is twofold. It can be used to promote phase inversion without changing the thermodynamics of the system to obtain a higher entropy state, or it is possible to delay phase inversion while reducing the system entropy.[36] The characteristics of the microstructure formed (such as emulsion droplet size) are dependent on the type of microstructure and deformation (shear, extension, or combined), as well as the deformation rate. To maximize the fluid microstructure/flow field interactions, the flow field must be uniform, which requires the application of the flow field over a small processing volume, which can be achieved by using MECS mixers or CDDMs.

Isothermal FIPI Emulsification

Isothermal emulsification of viscous oils to obtain concentrated oil-in-water emulsions is carried out by inverting a water-in-oil emulsion under flow conditions using an MECS mixer.[16,17,21] Initial water-in-oil emulsion is prepared using a batch mixer (typical shear rate of $100\,\text{sec}^{-1}$), which is subsequently inverted to oil-in-water emulsion at extension rates approaching $10^6\,\text{sec}^{-1}$. It is found that the FIPI starts at a critical extension rate and the extension rate has to be increased to achieve full inversion resulting in submicrometer size emulsion droplets with a very narrow size distribution (size span < 1).[17]

In a novel process, FIPI was also applied to the emulsification of polymer melts in water, thus providing an alternative method to emulsion polymerization for the production of latexes.[18,21,32–34] In fact, some thermoplastic melts (such as polyethylene) cannot be obtained through the emulsion polymerization route; hence, the present technique is an example of PI providing a novel product form. To achieve the emulsification of thermoplastics, it is necessary to operate near or above 100°C and at elevated pressures, which necessitates the use of polymer processing equipment fitted with a MECS mixer at the outlet. It was found that molecular surfactants could not be used to obtain the initial (water-in-polymer melt) emulsion. Instead, hydrophobically modified water-soluble polymers were used as the surface active material. After the phase inversion in the MECS mixer, the resulting emulsion was diluted to the level required. This also freezes the molten latexes. The important attributes of FIPI emulsification include a low level of surfactant use, low temperature processing, production of submicrometer particles with a narrow size distribution, and production of novel products.

Nonisothermal FIPI and Intensive Granulation Technology

Although the underlying manifestation of FIPI is the same, detailed molecular or microscopic mechanisms are different from one multiphase system to another. When FIPI is applied to granulation (i.e., agglomeration and microencapsulation of fine particles in the absence or presence of liquids) using polymers as binders, the dominant mechanism for phase inversion is based on the behavior of macromolecules in flow fields, which includes stress-induced crystallization, diffusion, macromolecular chain scission, macromolecular confirmation, deposition, and reaction. Therefore, high/ultrahigh stresses must be generated and sustained to achieve these phenomena. A combination of these phenomena results in FIPI in polymer melt/solid particle dispersions, which is further enhanced by operations at low temperatures as a result of high viscosity (i.e., high stress generation) and differential crystallization, because of the distribution of the molecular weight of polymeric binders.

Intensive granulation technology

Agglomeration and encapsulation of fine particles are encountered in several industrial sectors such as pharmaceuticals, detergents, fertilizers, and animal feedstocks. The volume throughput in these processes can vary enormously. Batch processing is suitable for pharmaceutical applications where the volume of production is quite low and product values are very high, while a continuous process is essential in other sectors where the volume throughput is very high.

Currently available agglomeration techniques are either based on the provision of a suitable processing environment for primary particle collisions (growth agglomeration) or on the compression of particles to form densified particles (pressure agglomeration) in the presence or absence of a binder. These techniques are well known and periodic reviews are available. The growth agglomeration technique is often conducted in batch mixers or fluidized beds in which particle breakup and agglomeration occur simultaneously. The residence times are relatively long and the variety of possible primary particles for agglomeration and binders is restricted. In pressure agglomeration, pressurization is confined to a small volume and there are restrictions on the raw materials.

The so-called multinucleus-type capsules/microcapsules are essentially agglomerated particles with prescribed released characteristics, which can be controlled by the concentration and solubility of the binder. In agglomeration, the amount of binder is kept to a minimum, as long as the agglomerates are

sufficiently strong. Therefore, in principle, multinucleus microcapsules can be manufactured through an agglomeration process, where the binder concentration should be controlled. However, currently available agglomeration processes do not have this flexibility and therefore such capsules/microcapsules are produced through specific techniques.

A novel agglomeration/encapsulation (granulation) technique based on isothermal FIPI has been disclosed recently and applied to several industrial processes. In an isothermal FIPI granulation, a concentrated suspension of powder in liquid is caused to crumble (phase invert) through the further addition of a powder (a ''crumbling agent''), i.e., a phase inversion from a solid phase suspended in liquid (a paste) to a liquid phase suspended in solid (an agglomerated granular material). The process requires a degree of mechanical energy input to disperse the two phases and, therefore, it must be carried out in some kind of mixing environment. Also, the critical deformation rate at which FIPI starts is dependent on the thermodynamic state of the structured fluid as well as the type of flow field, i.e., shear, extensional, or combined flows. This mixing flexibility allows FIPI in either a batch or a continuous mode of operation. The FIPI granulation technique combines both growth and pressure agglomeration processes. For a typical isothermal FIPI agglomeration/microencapsulation process, phase inversion takes place at a critical dispersed phase concentration (crumbling concentration), when the primary particle size and mixing conditions are kept constant.

The use of temperature and deformation as processing parameters can therefore promote phase inversion in solid particle/polymer systems and can be utilized in PI in particle technology. The reduction in temperature in polymer melt/particle mixture (paste) results in a reduction of the continuous phase volume because of the crystallization and stress induced deposition of the higher molecular weight fractions of the polymer. Furthermore, at lower temperatures, because of the reduced polymer chain mobility and interactions with the large numbers of small primary particles, which make a three-dimensional cage, the effective mobile-phase volume decreases further with increasing primary particle concentration. Consequently, the continuous phase can no longer sustain the increased phase volume of the dispersed phase and phase inversion takes place in the form of the melt fracture. This phenomenon now forms the basis of the present granulation technique.

Intensive granulator

The complete granulation process is carried out in a system that consists of an extruder and a CDDM in the form of rotor–stator disks with heat transfer facilities. A diagrammatic illustration of the granulator is shown in Fig. 2. It consists of two back-to-back rotors (referred to as upper and lower rotors) made from a single circular block and two stators (also referred to as upper and lower stators) facing the rotors. As shown in Fig. 3, the rotors and stators contain cavities on their surfaces, which are designed to pump/convey and/or achieve mixing. The cavities on the rotor and stator are offset by half a cavity length so that the rotor and stator cavities never exactly match with each other. The separation (gap) between the upper or lower rotor and the corresponding stators can be varied independently.

The filled polymer melt from the extruder output flows into the gap between the upper stator and rotor. The rotor block (incorporating the upper and lower rotors) spins sandwiched between the upper stator and lower stator of the granulator. The upper rotor temperature is equal to the temperature when solidification of the binder starts, while the upper stator temperature is maintained at the temperature when the solidification is complete. Granulation takes place inside the gap between the upper stator and rotor. Once the granules are formed, they travel through the gap between the lower stator and the rotor and finally emerge and drop onto the collection tray. The upper stator also contains three auger powder feeders located symmetrically at various distances from the center. Additional powder can be added into the filled polymer melt after phase inversion. The addition of the extra powder is useful to increase the particle content of the agglomerates and to form a shell-and-core-type microcapsule.

Samples from various regions were recovered and analyzed. It was found that granulation takes place over four steps. These steps are associated with the following zones: 1) melt flow zone; 2) granule nucleation zone; 3) crumbling (melt fracture and fragmentation) zone; and 4) granule transport zone. The granulation occurs over a short distance, within a distance of 2–5 mm. The location of the crumbling (phase inversion) is important as it dictates the size of the granulator. This location is dependent on the effectiveness of heat transfer, the temperature of the polymer melt from the extruder, the polymer concentration, and the clearance between the rotor and the stator.

Fig. 5 illustrates the granule particle size distribution as a function of gap size between rotor and stator.[25] As can be seen, the average particle size $D(50)$ is approximately equal to the gap size, and the particle size span (ca. 0.5) is very low and independent of gap size. Typically, the concentration of the binder is 25 wt%. In all of the known agglomeration and microencapsulation techniques, the concentration of

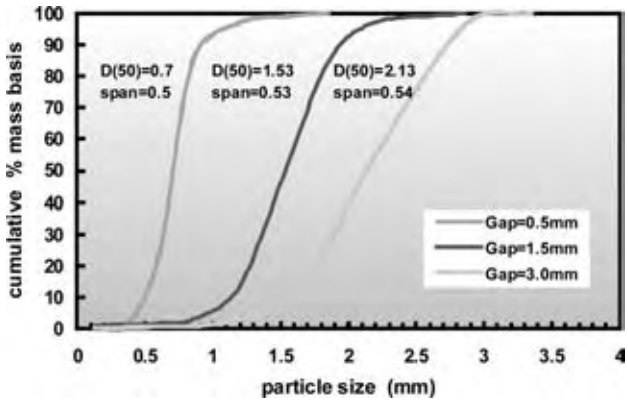

Fig. 5 Granule size distribution as a function of gap (clearance) between the rotor and stator disks. Average granule size $D(50)$ in mm and particle size span are also indicated. (From Ref.[24].) *(View this art in color at www.dekker.com.)*

the active material (filler) is dependent on the granule size, larger granules having a higher binder concentration. Because of the fact that the granulation is induced from a molten state where the filler concentration is uniform, it is therefore not surprising that the granules have a constant active (filler) concentration.

CHEMICAL PI USING NANOSTRUCTURED MICROPOROUS MATERIALS AND CATALYSTS

B

Preparation of Novel Porous Materials for PI

Functionalized microporous polymers (with a superimposed nanostructure in the form of nanopores within the walls of the micropores) have been prepared through a high internal phase emulsion (HIPE) polymerization route.[35,37–40] These polymers (known as PolyHIPE Polymers, PHP) were subsequently metallized by solution deposition followed by heat treatment.[39,41]

Microporous polymers have been used in the intensification of several processes encountered in nuclear, petroleum, bioconversion, tissue engineering, chemical, and environmental technologies.[22,31,39–45] The advantages of PHP and its metallic form are associated with the accessibility of their pores, controllability of the pore and interconnect structures, versatility of fabrication, and chemical modification of their walls. The structure of these materials is shown in Figs. 6A–C. These polymers can be manufactured over a wide range of pore size (D) ($0.5\,\mu m < D < 5000\,\mu m$) and interconnect size (D) ($0 < d/D < 0.5$).

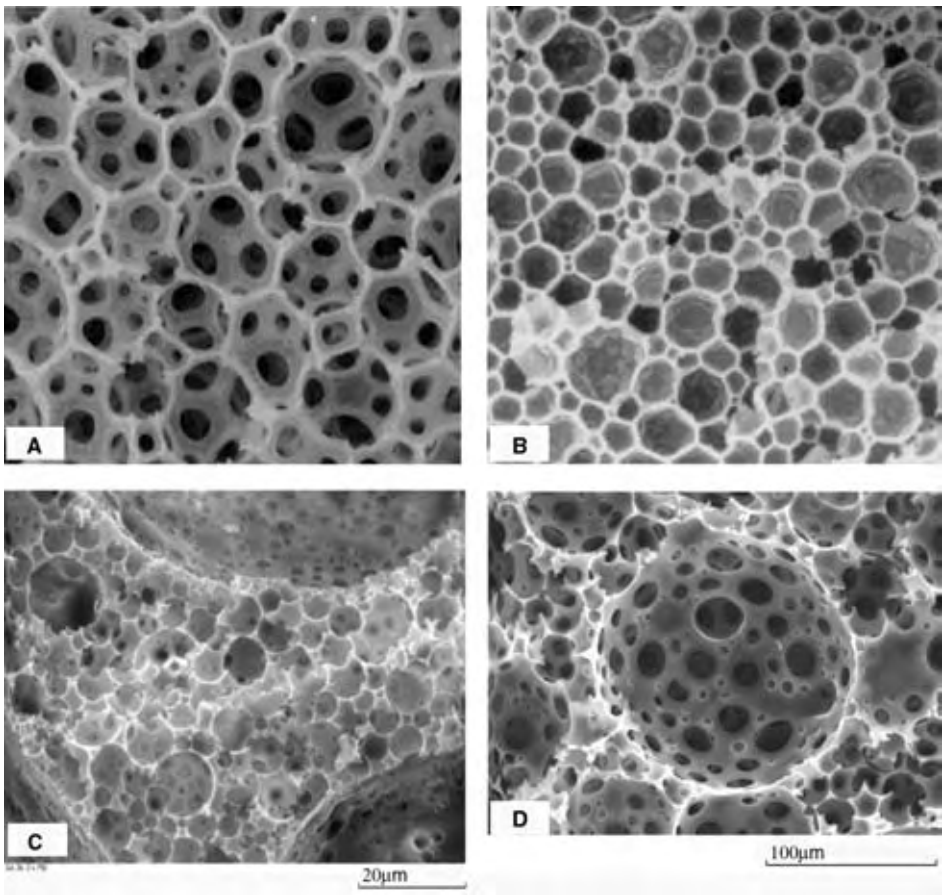

Fig. 6 Basic PHP structures: (A) primary pores with large interconnecting holes; (B) primary pores with nanosized interconnecting holes; (C) large coalescence pores (three such pores are partially shown) dispersed into the primary pores in the process of coalescence; and (D) detail of the coalescence pores. Note that these pore structures can be prepared over a wide size range.

Pores with size above ~200 μm are obtained through a coalescence polymerization route.[35,39]

Nanostructured microporous catalysts or catalyst supports offer intensified catalysis as they provide enhanced surface area accessible to the reactants and products. In nonstructured catalysts, although the surface area may be large, they are often inaccessible as a result of surface fouling and diffusion resistance can slow down the rate of reaction. In a recent development, microporous materials were used as templates for the solution deposition of metals, which were subsequently heat treated to obtain porous metallic structures, where the size of the pores ranged from 10 μm to 10 nm.[39,41] The relative phase volume of these two regions can be controlled and the overall porosity can be in excess of 50%. Fig. 7 illustrates the size scale of structures ranging from 10 μm to 10 nm.

These attributes are used in devising intensified processes as well as in the discovery of several size dependent phenomena, especially in biology, which are subsequently utilized in BI. Currently, PHPs (both hydrophobic and hydrophilic versions) are used in the intensification of stable water-in-oil emulsion separation (demulsification), gas–liquid separation, as applied to tar and water removal from biogas produced through the gasification of biomass, BI, tissue engineering, and metal ion/toxin removal from contaminated water.[8,22,31,35,39,40,42–45] The accessibility of the pores increases both the rate and the capacity of metal ion removal. In currently available ion-exchange resins, only the outermost part of the resin beads is utilized, because as soon as the resin surface is saturated or fouled, metal ion removal rate and capacity are drastically reduced.

Intensification of Stable Water-in-Oil Emulsion Separation

The breakdown of the stable emulsions and subsequent separation to oil and water (demulsification) are important in nuclear, petroleum, and environmental technologies. The emulsion stability is primarily induced by the use of surfactants and is enhanced by reduced size and narrow size distribution of the emulsion droplets. Disruption to low interfacial activity (hence instability) can be achieved by using demulsification agents, which are, however, costly and environmentally undesirable, as they are irrecoverable. Demulsification can also be achieved by electric and/or centrifugal fields, or by chemical treatment of the emulsion.

During the reprocessing of depleted uranium, a highly stable and viscous water-in-oil emulsion is

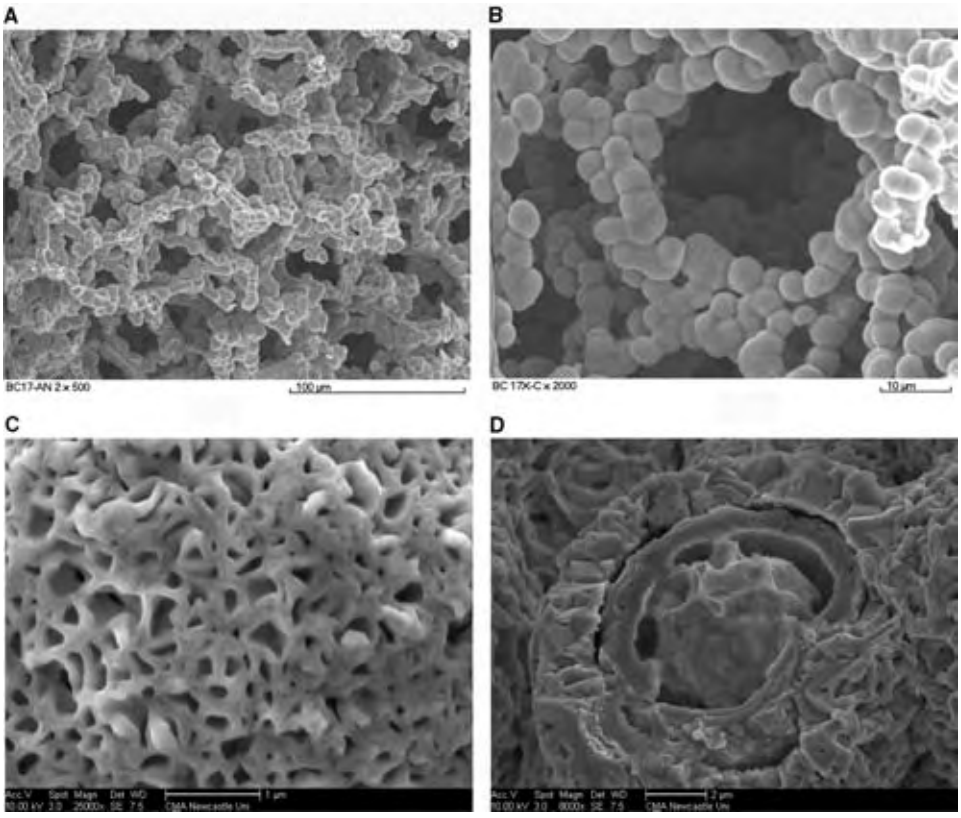

Fig. 7 Nanostructured microporous nickel with accessible pores showing the hierarchy of the pore sizes: (A) micropores created by fused metal grains; (B) structure of the metal grains before heat treatment; (C) surface pore structure of the grains; and (D) inner structure of metal grains showing the existence of a porous inner core.

formed called interfacial crud (or crud). This emulsion deposits in the process lines, thus reducing the heat/mass transfer rates, making it necessary to periodically remove crud by solvent washing.

The removal of water from crude oil and the subsequent treatment of the water produced is a very important process as the crude oil may contain up to 90% water, although it is still economically viable to separate crude from water. In offshore applications, if the separation is achieved at the seabed, massive savings in pumping and heating costs can be achieved. Such a separation process must be intensive, because of the volume of crude oil produced and the hostile environment, or limited space such as the seabed or offshore oil platform. However, such a separation technology at the source would be sustainable utilizing the potential energy of the crude oil from the well, i.e., high temperature and pressure, both of which increase the demulsification rate. Furthermore, the produced water must also be treated, if it is to be discharged into the sea.

Recently, we have shown that sulfonated PHP can act as a demulsifier for highly stable emulsions like crud and water-in-crude oil emulsions.[31,44] The mechanism of demulsification is that sulfonated PHP removes selectively surface active species in the emulsion, causing destabilization. At the same time, it also adsorbs metal ions, thus achieving two functions at the same time. As a result, these materials are called demulsifier adsorbers. In highly stable emulsions where neither electric field nor demulsifier adsorbers are effective, the combination of these two methods appears to create synergy for separation.

The intensification of crude oil-in-water emulsions was tested using BP Amoco crude (Harding Field, North Sea) with specific gravity of $0.8\,g/cm^3$ and viscosity of 150 mPa sec at 25°C. The aqueous phase is a model seawater containing 28.1 g/L NaCl, 0.6 g/L $CaCl_2$, 5 g/L $MgCl_2$ in double-distilled water. The emulsion viscosity at 25°C and shear rate of $1000\,sec^{-1}$ is 1030 mPa sec. These emulsions show no sign of separation after 4 weeks of standing. The tests were carried out using a flow-through electric field separator described in Refs.[44,46]. This cell contains a circular channel of 1 cm diameter with two electrodes separated by 10 cm in which the anode is electrically insulated and the counter electrode is earthed. Freshly prepared emulsion containing 0.5 g demulsifier per kilogram of 50/50 emulsion was fed from the center of the circular channel and oil-rich and water-rich phases were collected from the top (anode) and the bottom (cathode) and allowed to separate. The overall degree of separation was measured within 10 min of collection of the sample.

The effect of PHP demulsifier adsorber is illustrated in Figs. 8 and 9. Fig. 8 shows the variation of percentage separation as a function of flow rate under a constant electric field, while Fig. 9 shows the variation of separation as a function of the electric field at a constant flow rate. Both figures clearly show the synergy present between the two types of intensification in oil–water emulsion separation. A continuous intensified separator based on the rotating disk in rotor–stator arrangement with electric field has been disclosed recently.[22]

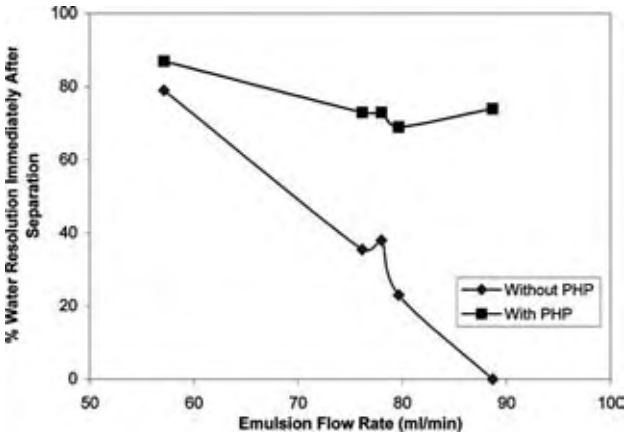

Fig. 8 Process intensification in water-in-crude oil separation under electric field with or without PHP: variation of percentage separation immediately after passing through the electric field in the absence or presence of the sulfonated PHP. Electric field strength of 2.5 kV applied over a distance of 10 cm. (From Ref.[43].) *(View this art in color at www.dekker.com.)*

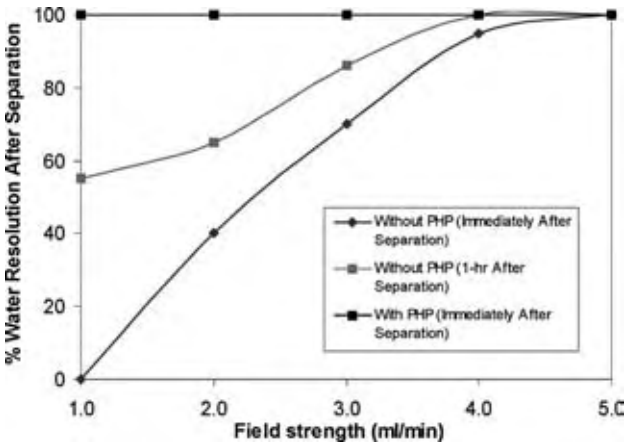

Fig. 9 Process intensification in water-in-crude oil separation under electric field with or without PHP: variation of percentage of separation with electric field strength applied over a distance of 10 cm when the emulsion flow rate is kept constant at 60 ml/min. Percentage separation into oil–water layers is carried out either immediately (within 10 min) or after 1 hr of emulsion passing through the electric field. (From Ref.[43].) *(View this art in color at www.dekker.com.)*

CARRIER-MEDIATED INTENSIFICATION OF SEPARATION PROCESSES

Toxins in the form of heavy metal ions or organic molecules in water (and indeed from gases) can be removed by using carriers with suitable surface chemistry, which can bind the toxic chemicals in their structure and are subsequently removed by filtration. These carriers include small microscopic particles or surfactants.[47–50] Because of their unique ability to form well-ordered molecular aggregates and structures, ranging from a few nanometers to several hundred micrometers, surfactants can be used in the intensification of separation processes, such as the removal of organic and heavy metal ion contaminants from water. Surfactants offer a very large surface area for mass transfer and surfactant assemblies can be modified to be selective.[49] Surfactant-mediated separations can be further enhanced by the orthogonal superimposition of cross-flow separation field and an electric field.[51,52] In such separation processes, both the permeate flux and the surfactant rejection can be enhanced by over 100-fold each.[51,52] However, this enhancement is by no means common, as it depends on the surfactant concentration, as well as surfactant head-group charge density and surfactant phase behavior. Furthermore, surfactants can degrade electrochemically, therefore the selection of surfactant becomes important in electric field enhanced mediation processes.[52]

During the cross-flow microfiltration of dilute surfactant solutions, surfactants form highly stable gel phases within micropores. These gel phases do not dissolve even though they are in contact with surfactant-free water flowing at shear rates in excess of $5 \times 10^4\,\text{sec}^{-1}$. Such stable-strong surfactant phases are expected to form at concentrations over 30 wt%. This phenomenon, first observed by the author, is utilized in cross-flow filtration and forms the bases of the demulsification of highly stable water-in-oil mulsions as well as the removal of tar/water from gases.[22] These observations indicate that microporous materials (with a varying degree of hydrophilicity) preferentially adsorb surface-active species, thus forming the basis of oil–water separation using PHPs.

In the intensification of chromate removal from water, a double-chain cationic surfactant, dioctadecyldimethylammonium chloride (DODDMAC), was used as a carrier and a cross-flow electrofiltration was used, in which both the transient and the steady-state fluxes and the rejection of metal ions and surfactant were measured.[51,52] Dioctadecyldimethylammonium chloride in water forms multilamellar droplets, even at very low concentrations. This structure is shown in Fig. 10. Metal ions are entrapped within the water layers and organic toxins can be immobilized within the surfactant bilayers. Under an electric field, DDOMAC multilamellar droplets with entrapped anions migrate to the negative electrode, forming a stable gel.

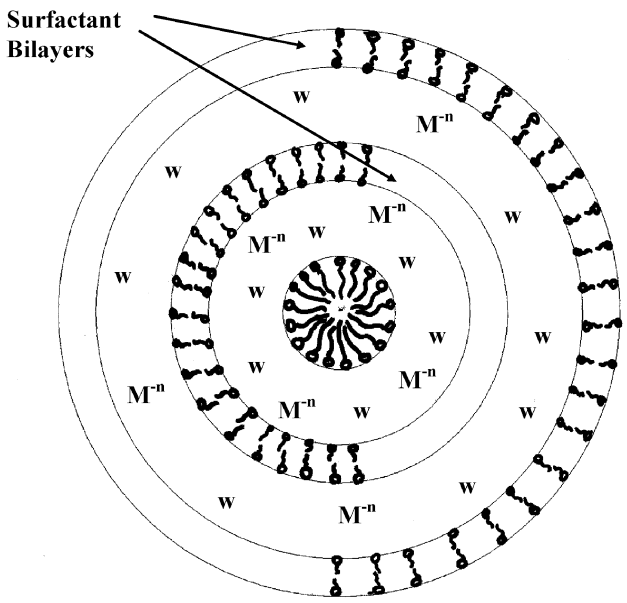

Fig. 10 Schematic representation of surfactant in multilamellar droplet phase with entrapped metal ions (M^{-n}) in the aqueous phase (W) layers, which are separated by surfactant bilayers. The number of layers (hence the size of the surfactant droplet) is dependent on temperature and concentration. When the surfactant head group is positively charged thus encapsulating oppositely charged metal ions, under an electric field, surfactant lamellar droplets migrate to the anode and form a highly stable viscous gel in which the positively charged metal ions are concentrated at the anode only separated by the surfactant bilayer. (From Ref.[52].)

The electric field intensification in the surfactant-mediated separation processes is shown in Table 2.[52] In the feed, surfactant and metal ion concentrations are denoted by C_{SF} and C_{MF}, respectively, while the corresponding concentrations in the permeate under steady-state conditions are denoted by C^*_{SP} and C^*_{MP}. Surfactant and metal ion rejections at a steady state are defined as $R^*_S = (1-C^*_{SP}/C_{SF})$ and $R^*_M = (1-C^*_{MP}/C_{MF})$. The molar ratio of metal ion to surfactant is denoted by Y_{MS}. The separation of the electrodes is 3 mm. In Table 2, the initial current, pH, and solution conductivity are also given. It shows that both metal and surfactant are separated effectively under an electric field in which the permeate flux, surfactant, and metal ion rejections are enhanced. Economic analysis of the process indicates that some 20- to 50-fold efficiency increase is achieved compared with the no electric field case. For the process to be economical, low-solubility surfactants that can form multilamellar droplets should be used as carriers.

PHENOMENON-BASED BIOPROCESS INTENSIFICATION

The most suitable driving force in BI is the reduction of the diffusion path that already operates in transport processes across biological bilayers. Consequently, biocatalyst membranes and specially designed bioreactors, such as jet loop and membrane reactors, are available to intensify biochemical reactions.[4–8,53] Supported biocatalysts are often employed to enhance catalytic activity and stability and to protect enzymes/microorganisms from mechanical degradation and deactivation.[5,6,8,54] Immobilization of the cells is one of the techniques employed to improve the productivity of bioreactors.

Immobilized cells are defined as cells that are entrapped within or associated with an insoluble matrix. Various methods that are used for immobilization include covalent coupling, adsorption, entrapment in a three-dimensional scaffold, confinement in a liquid–liquid emulsion, and entrapment within a semipermeable membrane. Bioreactors with immobilized cells have several advantages over those operating with free cells or immobilized enzymes. Immobilized cell systems permit the operation of bioreactors at flow rates that are independent of the growth rate of the micro-organisms employed. Catalytic stability can be greater for immobilized cells than for free cells. Some immobilized micro-organisms tolerate higher concentrations of toxic compounds compared with free cells, when the cell support media act as a temporary sink for the excess toxin. However, in the current biocatalyst support technology, the presence of the support itself introduces mass transfer restrictions for the substrate/product/nutrient diffusion to and from the biocatalyst. These disadvantages are also valid when supports are used to grow animal cells in vitro.[35,40] In this case, well-designed cell support systems are necessary for cell proliferation and viability. The efficiency of cell function (for example, production of collagen II during the in vitro growth of chondrocytes) is dependent on the microarchitecture, i.e., pore and interconnect size, and surface chemistry of the support.[35,40,54,55]

Microporous polymers with a well-prescribed internal microstructure were prepared in monolithic form to form a flow-through microbioreactor in which phenol degrading bacteria, *Pseudomonas syringae*, were immobilized. Initially, bacteria were force-seeded within the pores and subsequently allowed to proliferate, followed by acclimatization and phenol degradation at various initial substrate concentrations and flow rates. Two types of microporous polymer were used as the monolithic support. These polymers differ with respect to their pore and interconnect sizes, macroscopic surface area for bacterial support, and phase volume. Poly-HIPE polymer with a nominal pore size of 100 μm with phase volume of 90% (with a highly open pore structure) yielded reduced bacterial proliferation while the polymer with nominal pore size of 25 μm with phase volume of 85% (with small interconnect size and large pore area for bacterial adhesion) yielded monolayer bacterial proliferation. Bacteria within the 25 μm polymer support remained monolayered without any apparent production of extracellular matrix during the 30-day continuous experimental period as shown in Fig. 11(A). The microbioreactor performance was characterized in terms of volumetric utilization rate and compared with the published data, including the case where the same bacteria were immobilized on the surface of microporous polymer beads and used in a packed bed during the continuous degradation of phenol.[42] It has been shown that at a similar initial substrate concentration, the volumetric utilization in the microreactor is at least 20-fold more efficient than the packed bed, depending on the

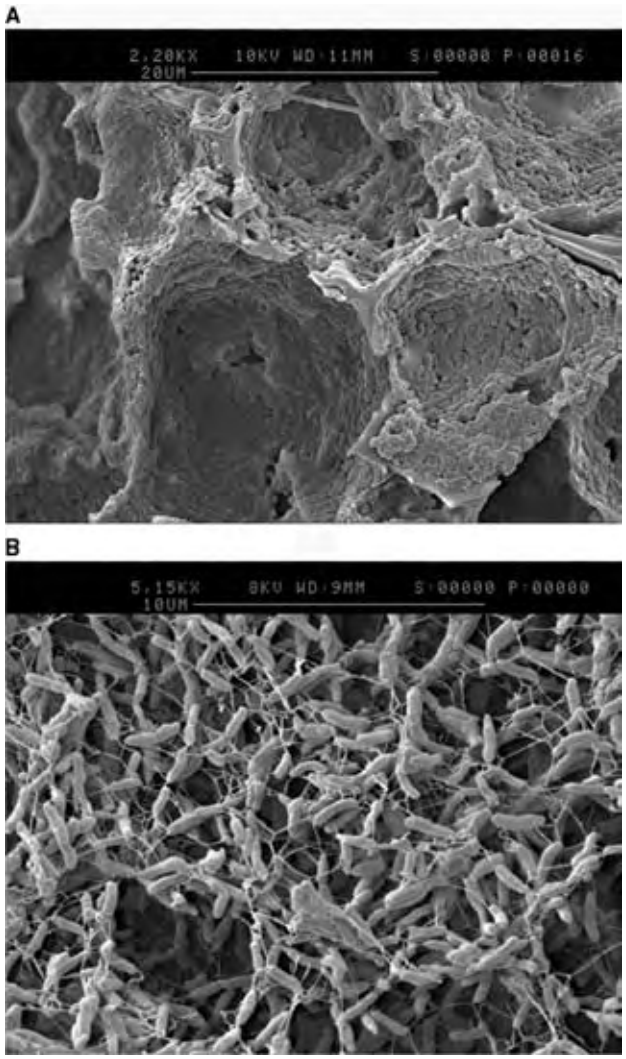

Fig. 11 Pore size dependence of bacterial behavior in microbioreactors. (A) Monolayer bacteria coverage in a small pore size (25 μm) microbioreactor. (B) Biofilm formation by the same bacteria in a large pore size (100 μm) microbioreactor. (From Ref.[8].)

flow rate of the substrate solution. The concentration of the bacteria within the pores of the microreactor decreases from 2.25 cells/μm^2 on the top surface to about 0.4 cells/μm^2 within 3 mm reactor depth. If the bacteria-depleted part of the microreactor is disregarded, the volumetric utilization increases by a factor of 30-fold compared with the packed bed. This efficiency increase is attributed to the reduction of the diffusion path for the substrate and nutrients and enhanced availability of the bacteria for bioconversion in the absence of biofilm formation, as well as the presence of flow over the surface of the monolayer bacteria. When 100 μm pore size PHP is used as a support, or when the flow through the support is absent (i.e., beads used in packed beds), biofilm formation occurs, as shown in Fig. 11(B).[42]

CONCLUSIONS

The combination of process intensification and process miniaturization is an important element of sustainable technology and a platform for advancement in multidisciplinary science and engineering. There are now several examples of intensified processes being utilized in industry, as apparent from patent activity. Some of these intensified processes are confined to a single unit operation, while others integrate several intensified unit operations in the more efficient production of existing/improved/novel products.

Physical PI is limited in the scope and degree of intensification that it can achieve, while phenomenon-based intensifications can result in more impressive levels of intensification. They also provide new opportunities in understanding the behavior of structured matter, macromolecules, and microorganisms within a confined environment with superimposed transport processes. The understanding of the transport processes in human body and organ structures is very useful in PIM, while the application of the techniques and principles of PIM to biology and medicine can result in advances in tissue engineering and biology.

The ultimate aim of PIM is to establish intensified plants by integrating intensified unit operations that are already multifunctional. An example of such a plant is a ''biomass power plant'' in which an intensified gasifier is integrated with an intensified catalyst system and intensified environmental remediation (process water and gas cleaning) to produce electricity through several routes, including internal combustion engine and high-temperature fuel cells.[45,56]

ACKNOWLEDGMENTS

I wish to thank Drs K. Boodhoo, M. Dogru, and A. Harvey for helpful discussions. Bioprocess intensification and PI developed by the author have been supported by the United Kingdom Engineering and Physical Sciences Research Councils (EPSRC) and the Department of Trade and Industry (United Kingdom), as well as by the industry, notably, AstraZeneca, BLC Research, British Nuclear Fuels Ltd (BNFL), BP Amoco, Cytec, Exxon Mobil, ICI, Intensified Technologies Incorporated (ITI), Morecroft Engineers, Norsk-Hydro, Safety-Kleen Europe, Triton Chemicals, Unilever, and Willacy Oil Services. I am grateful for their support.

Bioprocessing

Ryan G. Soderquist
James M. Lee
Department of Chemical Engineering, Washington State University, Pullman, Washington, U.S.A.

INTRODUCTION

Bioprocessing utilizes biological processes to convert raw materials into useful substances. For centuries mankind has converted raw materials into desirable products by harnessing biological processes. In fact the use of baker's yeast, or leaven, to enhance the quality and texture of bread, as well as the fermentation of grape or cereal extracts to generate ethanol, are common bioprocesses that have been utilized since ancient times. Very little was known about the mechanisms responsible for these important conversions, however, until 1856 when Pasteur characterized yeast as a living organism converting sugar to ethanol.[1]

Scientific progress in more recent times has not only revealed the mechanisms of traditional bioprocesses, but has also improved the ability of bioprocessing to generate useful products. Advances in pure culture and other classical bacteriological methods initiated the first commercial production of lactic acid by fermentation in 1881.[1] The subsequent development of the first cholera, diphtheria, and tetanus vaccines from 1885 to 1890 greatly improved human health.[1] The production of penicillin and the subsequent emergence of recombinant DNA technology in the early 1970s, however, significantly enhanced the potential of bioprocessing.

Bioprocessing is now a diverse technology, and the potential of bioprocessing seems to have very few limits. New applications of bioprocessing overshadow its traditional role as the fundamental technology for fermented food and beverage production. Pharmaceutical production is one of the fastest growing fields of bioprocessing. Biological processes facilitate the production of a wide array of pharmaceutical compounds, which are typically proteins that act as enzymes or antibodies. Biological processes are also critical in toxic waste degradation, enhanced oil recovery, and other environmental efforts.[2] Modern bioprocessing has several common components and fundamentals, which are the focus of this entry.

BIOPROCESSING TECHNOLOGY

Biological processes use living cells (microbial, animal, or plant), or components extracted from living cells such as enzymes, to create desired chemical or physical changes.[2] The major products of bioprocessing include bulk organics, organic acids, amino acids, antibiotics, extracellular polysaccharides, nucleotides, enzymes, vitamins, alkaloids, pigments, vaccines, therapeutic proteins, monoclonal antibodies, and insecticides.[3] Biological processes are also used in wastewater treatment, sludge processing, composting, and bioremediation (i.e., the degradation of crude oils and toxic organic chemicals).[1] These more recent applications of bioprocessing are in addition to the manufacture of traditional foods and beverages such as yogurt, bread, vinegar, soy sauce, beer, and wine.

The use of bioprocessing to induce the desired physical or chemical changes has advantages and disadvantages over traditional chemical processes that do not employ living cells and their components. The advantages of biological processes include mild reaction conditions, specificity, and the use of renewable resources.[2] Most biological processes are conducted at temperatures in the range of 25–37°C, at a pH range of 5–8, and at atmospheric pressure. Therefore, the operation is less hazardous and the manufacturing facilities are less complex compared to a traditional chemical process. The use of biomass is also a noteworthy production advantage, as biomass is easily regenerated without deleterious effects on the environment.

The disadvantages of biological processes for industrial-scale processes, however, include complex product mixtures, dilute aqueous environments, contamination, and variability.[2] When living cells are used to produce a desired product, multiple enzyme reactions typically occur, and the final product mixture contains a complex mixture of cell mass and its components, metabolic by-products, and remnants of the original nutrients. The desired product must be separated from this complex product mixture. Biological processes secrete small amounts of a product into an inherently dilute aqueous environment, which further complicates separation techniques. Contamination from unwanted environmental bacteria and molds is a paramount concern with biological processes, particularly when slow-growing plant and animal cells are used. Living cells tend to mutate over time and can lose characteristics vital for the success of a process.[2]

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120025834

Some cellular components are also unstable at room temperatures for long periods of time, which can limit a continuous process. Thus, the advantages and disadvantages of biological processes should be compared against traditional chemical methods on a case-by-case basis.

ENZYME-MEDIATED PROCESSING

To convert raw materials into a desired product, it is advantageous to utilize cellular components instead of complete cells in some instances. Enzymes are the most common cellular components used to catalyze biochemical reactions. They are a class of proteins that increase the rate of a reaction without undergoing permanent chemical changes themselves. Enzymes can be obtained either from a pure culture of micro-organisms or directly from plants and animals.[2] A small amount of enzyme can produce large amounts of a product because enzymes are highly specific and catalyze specific chemical reactions. They also increase the rate of a reaction much faster than nonbiological catalysts.

A historical use of enzymes is the use of cow stomachs, containing the enzyme rennin, to curdle milk and initiate the cheese-making process. Enzymes are now applied commercially on both large and small scales. The three major categories for commercial production are industrial enzymes, analytical enzymes, and medical enzymes.[2] Industrial enzymes are applied in tons, while analytical and medical enzymes are applied in the range of milligrams to grams.

There are several bulk industrial enzymes that are applied on a large scale, as outlined by Ward.[1] Carbohydrases are used to process starches. Cellulase can convert cellulose, the largest component of biomass, into sugars that can be further converted into fuel ethanol via fermentation. Proteases have several industrial applications, particularly in the food processing industry. Lipases and lactases are used in several food processing applications as well.

Ward lists several key enzyme properties that are important for applications in bioprocessing.[1] The primary considerations are the specificity of an enzyme with respect to the type of reaction being carried out, the substrates used, and the nature of the product. Another vital aspect for efficient processing is the enzyme solubility and stability at different pH and temperature conditions. The structure, charge, and shape of an enzyme must also be known when purification and recovery of the enzyme are desirable.

It is necessary to develop rate equations from kinetic studies that quantify how the rate of an enzymatic reaction is affected by various chemical and physical conditions to calculate reaction times, yields, and optimum economic conditions. These studies are typically done by measuring the concentrations of product and substrate with respect to time at different enzyme concentrations. Lee describes the three most common approaches to derive the rate equation for an enzymatic reaction.[2] The Michaelis–Menton method assumes that there is an enzyme–substrate complex that forms much faster than the product-releasing step. In this approach, the rate equation is simplified by assuming that the slow step determines the rate, and that the other step is at equilibrium. The Briggs–Haldane method assumes that the change in the enzyme–substrate concentration with respect to time is negligible. This is also known as the pseudo–steady-state assumption. Finally, the numerical approach determines the overall rate expression for an enzymatic reaction by numerically solving the differential equations simultaneously for substrate and product concentrations.

The reuse of an enzyme can be economically favorable when a high-cost enzyme is used. It can be difficult to separate and reuse an enzyme because enzymes are typically globular proteins that are highly soluble in water. A common technique to facilitate the reuse of a high-value enzyme is to immobilize the enzyme onto a surface, inside of an insoluble matrix or within a semipermeable membrane. Both chemical and physical means can be employed to immobilize enzymes. The former method involves the covalent attachment of enzymes to water-insoluble supports and is the most widely used method for enzyme immobilization.[2]

Lee outlines three different physical methods that are commonly utilized for enzyme immobilization.[2] Enzymes can be adsorbed physically onto a surface-active adsorbent, and adsorption is the simplest and easiest method. They can also be entrapped within a cross-linked polymer matrix. Even though the enzyme is not chemically modified during such entrapment, the enzyme can become deactivated during gel formation and enzyme leakage can be problematic. The microencapsulation technique immobilizes the enzyme within semipermeable membrane microcapsules by interfacial polymerization. All of these methods for immobilization facilitate the reuse of high-value enzymes, but they can also introduce external and internal mass-transfer resistances that must be accounted for in design and economic considerations.

CELL-MEDIATED PROCESSING

Bioprocessing also uses living cells as an alternative to enzymes and other cellular components. Each different cell species contains a variety of cellular components that uniquely transform raw materials into desirable products. The use of living cells thus eliminates the need for production and purification of a specific enzyme.

Living cells, however, can also produce by-products that are potentially harmful to certain products.

Fig. 1 shows a typical biological process that utilizes living cells.[2] First, a culture of the desired cell line is used to inoculate a small flask, referred to as a shake flask. This culture is then used to inoculate a small bioreactor. The culture contents of this small bioreactor are then used to inoculate a larger bioreactor. Inoculums are subsequently transferred to reactors of increasing size until the culture volume is large enough to inoculate a production-scale bioreactor. The cells are then separated from the liquid medium when the culture growth in the production-scale bioreactor is complete. The subsequent recovery steps depend on whether the product of interest was secreted to the supernatant or retained within the cells during production. A series of purification steps are then typically required before a product is ready for packaging.

Ward discusses several considerations in the selection of organisms utilized in a bioprocess.[1] The gaseous requirements of an organism, particularly oxygen and carbon dioxide requirements, can influence reactor design parameters. The nutritional requirements of different organisms are also a consideration. Bacteria, fungi, and yeasts can require nitrogen, minerals, and specific nutrients in addition to the carbohydrates used as a carbon source. Plant cell cultures require only a well-defined mixture of salts and carbohydrates. Mammalian cells, on the other hand, need a variety of complex nutritional requirements that can be very expensive. The strength of an organism's cell wall is a key consideration, because the ability of an organism to withstand shear forces generated from agitation plays an important role in reactor design. The growth rate of a cell line also influences processing considerations. As a general rule, the average growth rate of a cell population decreases with increasing cell complexity. Hence, mammalian cells will grow slower than plant cells, which in turn will grow much slower than yeasts and bacteria.

Small-scale trials are conducted to determine the growth and production characteristics of a cell line as a function of the culture environment once a suitable host organism is selected. A small-scale culture typically requires shake flasks with capacities in the range of 125 ml to 1 L. The primary environmental conditions that are optimized at this stage of the process include the medium composition, pH, and temperature.[3] Other parameters that can be calculated from small-scale experiments include cell growth rates, specific productivities, and product yields.

Understanding the growth kinetics of a cell system is particularly important in bioreactor design. Lee describes a typical growth cycle for the cultivation of cells in a batch process.[2] The lag phase of growth typically occurs immediately following inoculation, and is a period where cellular growth and division is minimal. This lag phase usually occurs because the cells must adjust to the new medium before growth can begin. The cells may increase in size during this period even though the cell density does not increase. The growth of a culture then accelerates and the cell density starts to increase until the cellular division rate approaches a maximum value. During the exponential growth phase, the cellular division rate remains at a maximum and constant value, and the cell density increases exponentially as the cells rapidly divide. At the close of the exponential growth phase, the growth decelerates because the cell density begins to approach a maximum value, and there is a consequent decrease in the cellular division rate. During the stationary phase of growth, the cell density remains at its maximum value and does not increase any further. Finally, during the death phase of growth toxic metabolic by-products accumulate and the cells deplete nutrients, which results in cellular lysis.

BIOREACTOR UTILIZATION

A bioreactor is a device that transforms raw materials into products by means of biological processes conducted by enzymes or living cells.[2] Bioreactors are frequently called fermenters when they generate a product by means of microbial cells, because the growth of microbes in a vessel is commonly called fermentation. There are several different bioreactor designs that can be customized to a desired process.[3] The processing conditions in a reactor, such as temperature, pH, and aeration, depend on the aspects of a particular

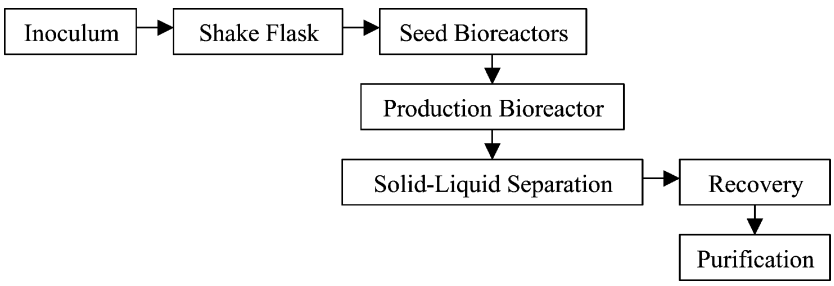

Fig. 1 Steps in a typical bioprocess.

reactor. The mode of reactor operation, such as batchwise or continuous production, is also configured for a specific biological process.

The main challenge in bioreactor design for aerobic cell lines is to provide adequate mixing and aeration. A stirred tank reactor is most commonly employed for large-scale aerobic bioprocesses.[2] In a stirred tank reactor, mechanical agitation by an impeller accomplishes the mixing and bubble dispersion, and there are a variety of impeller configurations available. A conventional stirred tank reactor also contains a number of baffles at the vessel perimeter.[1] When air is introduced at the base of the tank through the use of a ring sparger, the rotating impeller and baffle system facilitate the dispersion of air bubbles throughout the medium.[1] The agitator can, however, damage shear-sensitive systems such as mammalian and plant cell cultures.[2] A common design assumption is that a stirred tank reactor is well mixed at each point in the vessel during all of the production phases.

A bioreactor is referred to as a batch reactor when all of the substrates are added to the vessel before inoculation, and the products are removed only at the end of the process. This definition of batch operation refers to the addition and removal of liquid and solid components from the system, but does not include the continuous addition of oxygen that must be supplied to aerobic systems. Most commercial bioreactors are operated in the batch mode.[3] To comply with manufacturing regulations, a batch process is typically advantageous because contamination or genetic changes in a cell line can occur during a long-term process.

Fed-batch operation incorporates intermittent or continuous feeding of nutrients during production. This type of operation can mitigate the effects of catabolite repression, reduce the viscosity of the medium, lessen the effects of toxic medium components, or extend the production phase of a process for as long as possible.[1] Examples of processes where fed-batch operation is particularly useful include the production of baker's yeast and penicillin.[3]

Stirred tank reactor systems can also operate in a continuous mode. In this configuration, fresh medium is continually supplied to the reactor and the desired products are continuously removed in the course of production. A continuous system is referred to as a chemostat when the flow rate is set to a constant value. It is further known as a turbidostat when the flow rate is set to maintain a constant turbidity or cellular concentration.[2] Continuous reactor systems are commonly abbreviated as CSTR or CSTF and they refer to continuous stirred tank reactor and continuous stirred tank fermenter, respectively.

An important parameter to minimize in the design and operation of a continuous reactor is the residence time, which is the ratio of the reactor volume over the reactor flow rate. When a product is formed during the exponential growth phase, continuous operation is advantageous over batch operation because the residence time is lower in the first scenario. Batch operation is preferred when most of the production occurs during the stationary phase of growth, because the residence time for a batch operation in this scenario is much smaller.[2] Concerns with continuous operation arise from foaming and plugging of the system with large cell aggregates, along with contamination and genetic instability of a cell line. Continuous reactors are particularly useful when a process employs immobilized cells and enzymes, or when cell recycling can be incorporated.

The tubular flow reactor is another common reactor configuration. In this reactor, cells and medium are continuously added at one end of a cylindrical tube and biological processes occur as the reaction mixture flows along the tube. The fluid in a tubular reactor can flow either vertically or horizontally.[3] There is no fluid mixing in this method of operation, and thus the stream composition varies in both the radial and the longitudinal directions. Variations in the radial direction, however, are typically small compared to variations in the longitudinal direction. When radial variations are neglected, the reactor is known as a plug flow reactor, frequently abbreviated as PFR. Plug flow operation can be a simulation of batch operation in a continuous flow system because substrate and product conversions vary as the reaction proceeds along the tube in a manner analogous to batch operation.

Doran lists several considerations between batch, continuous stirred tank, and plug flow reactor configurations.[3] A number of continuous stirred tank reactors configured in series will theoretically approach the same reaction characteristics of those in a plug flow or a batch reactor. For single reactors not in series, the reaction kinetics determine the benefits between reactor configurations. If the reaction is zero order, there is no difference between batch, continuous stirred tank, and plug flow reactors, as far as the reaction considerations are concerned. For first-order reactors, however, batch and plug flow reactor operations will lead to higher conversions than continuous stirred tank reactors with the same volume. This is because high reactant concentrations are optimal for first-order reaction kinetics and the reactants in a CSTR are instantly diluted as they enter the vessel. When a reaction is autocatalytic, which is the case with biological reactions where reaction rates increase as the amount of biomass increases, the rate of conversion in a continuous stirred tank reactor can be significantly greater than in a batch or plug flow reactor.

In addition to the standard modes of reactor operation, alternative reactor configurations also facilitate

complicated bioprocesses. These alternative configurations are typically designed to improve on the disadvantages of traditional stirred tank reactors such as the high-power requirements of impeller operation and shear damage from impeller tips. Additionally, alternative reactor configurations can more efficiently meet the specific requirements of a system, such as better aeration, more effective heat removal, increased cell separation and cell retention, and cell immobilization.[2]

Airlift reactors are an alternative bioreactor in which the agitation is accomplished by a clear cyclic pattern of air flow through both a riser and a downflow reactor compartment. Stirred tank and airlift reactors are most often used for aerobic cell cultures. Airlift reactors are often utilized to culture plant and animal cells because they typically have lower shear levels.[3]

Another alternative bioreactor is the bubble column, which is composed of a long cylindrical vessel with a sparging device at the bottom. In a bubble column, the mixing action of rising bubbles fulfills the oxygen needs of the cells.[2] Bubble columns are used industrially for the production of baker's yeast, beer, and vinegar, and for wastewater treatment.[3] While column reactors are the simplest type of reactor, they are inflexible and limited to a relatively narrow range of operating conditions.[2] For example, if the fluid has a high viscosity, a column reactor cannot provide adequate mixing and mass-transfer characteristics.[3]

Apart from the aeration, mixing, and conversion parameters associated with a particular reactor configuration, there are also several practical considerations that must be accounted for in the design of an industrial bioreactor. Bioreactors must be able to withstand up to 3 atm of positive pressure and temperatures of up to 150–180°C, which is why most large vessels are typically made of steel.[3] The aseptic operation of a vessel is a key concern as 3–5% of industrial fermentations are lost because of a failure in sterilization procedures.[3] Bioreactor control is also an important consideration as deviations in reactor conditions can impact cellular growth and metabolism. Most bioreactors contain on-line measurement devices that determine the temperature, pressure, aeration rate, agitation rate, pH, and other key parameters for a designated biological process.

Doran outlines several of the key parameters involved in the scale-up of a biological process from laboratory-scale shake flasks to production-scale bioreactors.[3] In the first stage of studies a bench-top bioreactor, typically 1–2 L, is used to determine the oxygen requirements of the cells, their shear sensitivity, foaming characteristics, and any limitations that the reactor imposes on the organism. The results of these early studies enable decisions regarding operation in the batch, fed-batch, or continuous mode. A pilot-scale bioreactor, which typically has a capacity of 100–1000 L, is used in the next phase of process development. The pilot-scale reactor maintains an equivalent geometry, method of aeration and mixing, impeller design, and other important features of the bench-top bioreactor. A loss or variation in the performance of a cell line often occurs in the conversion from a bench-top to a pilot-scale bioreactor, even though the described reactor aspects remain constant. Thus, the results of pilot-scale findings often necessitate the reassessment of economic projections and design considerations. The industrial-scale phase of process development commences after the successful completion of the bench-top and pilot-scale phases. During this phase of development, the production-scale bioreactor is tested, along with all of the auxiliary services, such as the air supply, sterilization process, steam and cooling water supply lines, and reactor control devices.

DOWNSTREAM PROCESSING

After biological reactions have generated a product of interest, it is necessary to recover this product from a liquid mixture that typically contains several undesirable components. The treatment of any culture broth after bioreactor cultivation is known as downstream processing. Downstream processing can account for 60–80% of the total production cost, particularly in the production of modern recombinant proteins and monoclonal antibodies.[2,3] A typical downstream process requires several steps in the areas of solid–liquid separation, cell rupture, product recovery, and product purification. It is important to minimize the number of downstream processing steps required because significant product losses inevitably occur during each step.[3]

The product from a desired fermentation is either secreted from the cells into the fermentation broth or is entrapped within the cells themselves. In either case, the first step in downstream processing is to separate the cells from the fermentation broth. This step is typically accomplished by filtration or centrifugation and is known as solid–liquid separation.

Filtration separates cells from a fluid by forcing the fluid through a porous filter medium, which deposits solids as liquids pass through. Vacuum or positive-pressure equipment is used to create the driving force for filtration. The main advantages of filtration include high rates of separation, low cost, mechanical simplicity, and relative ease of maintenance. However, it can have a low retention or poor containment, and can require the addition of a filter aid to ensure good filtration when solids accumulate on the membrane.[4]

Centrifugation is an alternative to filtration. In bioprocessing, centrifugation removes cells from the fermentation broth, eliminates cell debris, and collects precipitates.[3] The equipment used for this purpose is usually more expensive than filtration equipment. It, however, is more effective than filtration when particles are small and difficult to filter. There are two basic types of centrifuges that are employed on a large scale. A tubular centrifuge is a hollow cylindrical tube in which a suspension is fed through the bottom and the clarified liquid is removed from the top.[2] Solids are deposited on the wall of a tubular centrifuge during this process. The solids are removed manually from the wall, which hinders continuous operation. A disk centrifuge is more commonly utilized when continuous operation of the centrifuge is required. This kind of centrifuge is a short and wide bowl that spins on a vertical axis and contains closely spaced cone-shaped disks that increase the capture of particles on the surface. The clarified liquid flows toward the center of the bowl and is expelled through the annulus. The solids are thrown outward and can be discharged intermittently or continuously.[2]

If the desired product is entrapped within the cells themselves, the cells are disrupted by mechanical or chemical means. The former include grinding with abrasives, high-speed agitation, high-pressure pumping, and ultrasonic techniques.[3] The latter include the treatment of cells with surfactants, alkalis, organic solvents, or osmotic shock.[2] In general, the mechanical methods of disruption have the widest application, while the chemical methods are generally cell and product specific and thus not applicable to all systems.[5] While cell rupture techniques have to be very powerful, care must taken not to damage the desired components. For example, low temperatures are often required during cellular disruption procedures to prevent product loss.

The recovery phase of a bioprocess begins once the products are freely suspended in a solution, either in the supernatant from the solid–liquid separation or in the lysate from the cellular disruption. Extraction is the process of separating the desired components in a liquid solution by contact with another insoluble liquid into which the desired product will be selectively extracted. This process is also commonly known as liquid–liquid extraction. The solvent-rich phase is called the extract and the residual liquid from which the desired product has been removed is called the raffinate.

Adsorption serves the same purpose as extraction in the recovery, or isolation, of the desired product from a dilute solution. In adsorption, a specific substance is adsorbed selectively by certain solids as a result of a specific physical or chemical interaction.[2] Three common adsorption methods include conventional adsorption, ion-exchange adsorption, and affinity adsorption. The adsorption of organic chemicals onto charcoal or porous polymeric adsorbents is a broad application of conventional adsorption.[3] Conventional adsorption is a reversible process caused by intermolecular forces of attraction.[2] Ion-exchange adsorption occurs when charged ions reversibly interact with charged surfaces on the molecule of interest, and it is an established practice for the recovery of amino acids, proteins, antibiotics, and vitamins.[3] Affinity adsorption is a very selective process that depends on specific chemical interactions between the molecule of interest and a solid resin.[1]

The product is often purified further after the recovery phase, particularly when the desired product is a protein of pharmaceutical interest. Precipitation is a widely used method that can be induced by the addition of salts, organic solvents, or heats.[2] It can both purify and concentrate a particular protein fraction, and is frequently accomplished by the addition of salts for a ''salting out'' effect.[1] The addition of a salt precipitates proteins because increasing salt concentrations reduce the solubility of a protein in a solution.[2] Even though precipitation is an effective and relatively inexpensive method, it is also a fairly crude step and is often followed by chromatographic separations.[6]

Chromatography is a purification method similar to adsorption as both methods involve an interaction between a solute and a solid matrix. Many principles of adsorption also apply to chromatography. A solution composed of several different solutes is injected at one end of a chromatography column, and each solute moves at a rate dependent on its relative affinity for a solid and immobile resin, which is known as the stationary phase. Solutes with a higher affinity for the stationary phase will move through the column more slowly than those with a lower affinity for the stationary phase. Chromatography differs from adsorption because it is based on the different rates of movement for solutes in a column, rather than the capture of one solute by an adsorbent.[2] The stationary phase in chromatography is commonly packed in a cylindrical column and can be an adsorbent, an ion-exchange resin, an affinity resin, a porous solid, or a gel.[2] A chromatography process is typically scaled up by maintaining a constant column height, fluid velocity, and sample concentration, while increasing the column diameter and the volumetric flow rate in proportion to the column cross-sectional area.[7]

In electrophoresis, the net surface charge and the size of molecules separate them from one another in an electric field.[1] Electrophoresis is one of the most effective methods of protein separation and purification. It has a very high resolving power to clearly separate charged protein molecules. This method of

separation, however, is not amenable to all mixtures as the components must have an ionic form and each component must migrate differently in an electric field.[2]

Membrane separation is a purification step that uses polymeric membranes to separate components primarily on the basis of size. Pressure is the main driving force in membrane separations. Microporous membrane filters are frequently used to sterilize biological solutions and have pores ranging from 0.025 μm to several micrometers in diameter.[1] Reverse osmosis and ultrafiltration membranes can separate on the basis of molecular size with ranges of 500–1000 Da and 1000–1,000,000 Da, respectively.[1] A cross-flow configuration, in which recirculation of the liquid through thin channels provides a constant flow parallel to the membrane surface, frequently reduces the accumulation of molecules on the membrane surface.[2]

After purification, product packaging and marketing complete a bioprocess. Lyophilization is a common packaging technique for long-term storage. Lyophilization utilizes the principle of sublimation to dry a product in a manner that facilitates rehydration.[1] Medical and clinical trials are required before a product can be released as a health-care application if the product is a new pharmaceutical. Most regulatory agencies also require a set of well-documented manufacturing protocols and standards during all of the production phases.[3]

CONCLUSIONS

As the potential applications of biotechnology are vast, bioprocessing will be a key technology in the future. Scientific breakthroughs made in gene expression and protein engineering will rely on bioprocessing techniques to incorporate these breakthroughs into new products and services. Developments in biological processing will not only continue to impact food and beverage production, but will also significantly advance health-care and environmental conservation efforts. A sound understanding of bioprocessing principles will be increasingly important to the scientists and engineers of the future to utilize new biological processes on a large scale.

Bioremediation

Teresa J. Cutright
Department of Civil Engineering, The University of Akron, Akron, Ohio, U.S.A.

INTRODUCTION

Biologists agree that the natural biodegradation of decaying plants, animals, and other organics by organisms has occurred since the beginning of time. The natural degradation of organic matter is the direct result of the microorganism's metabolism to protect itself from the environment, obtain nutrients, produce energy in a usable form, convert nutrients into cellular form, discard unnecessary products, and replicate genetic information. Mankind has been able to manipulate microbial metabolism for his own benefit. The first documented use of this dates back to the use of yeast for bread in ancient Egypt and fermentation of grapes in ancient Greece.[1] The implementation of microbiological processes evolved with man to encompass other food and pharmaceutical applications. By the beginning of the 20th century, bacteria applications had expanded to include the treatment of wastewater. However, it was not until the early 1970s that scientists investigated the viability of the bioremediation of contaminated soil.[2] Although the mechanisms behind bioremediation have existed since the dawn of time, its application for the treatment of hazardous contaminants is still considered a new technology.

Bioremediation as a remedial technology has several advantages. It can:

- Simultaneously treat subsurface soil and water.
- Be completed in less time than traditional pump-and-treat operations.
- Eliminate long-term liability.
- Result in complete mineralization of the contaminants.
- Be conducted under mild operating conditions.
- Easily be combined in a treatment train.
- Be completed with little or minimal stress on environmental and ecological systems.

Because bioremediation is still considered a relatively new technology, it can be scientifically intensive at the beginning of the project. For instance, a thorough site characterization can be required to ascertain the extent of contamination. In addition, extensive monitoring can be required to gain an understanding of the chemical and biological process responsible, and to track degradation by-products. Overcoming the mass transfer limitations during in situ applications and long treatment times are two other common disadvantages. However, the primary limitation to successful bioremediation is that it is often initiated without knowing the full picture. For instance, other unidentified contaminants, or even the degradation by-products may be toxic to the microbes. This can result in increasing the time required for the treatment or stopping remediation altogether. Bioremediation is still an extremely desirable treatment approach as the advantages still far outweigh the disadvantages. Bioremediation is desirable because it is very cost-effective and the most environment-friendly remediation technology. This entry contains an overview of bioremediation including the common terms associated with bioremediation, the requirements for successful applications, the key steps for treatability studies, and an introduction to degradation pathways.

TERMINOLOGY AND CATEGORIES ASSOCIATED WITH BIOREMEDIATION

The most basic definition of bioremediation is the ''use of any living organism to convert contaminants into less harmful compounds.'' Previously this definition was restricted to microorganisms or microbial processes (e.g., microbial mediated enzyme reactions), where microorganisms referred to eubacteria, archebacteria, and unicellular organisms such as bacteria, yeasts, fungi, and protozoa. Although ''living organisms'' encompass multicellular organisms, it was not until the early 1990s that bioremediation applications were extended to include plants (i.e., phytoremediation). As shown in Fig. 1, the bioremediation umbrella contains several classifications depending on the approach implemented, additive(s) introduced, and location of the treatment. The subdivision of organisms based on their metabolic characteristics (i.e., chemotrophs, phototrophs, mesophiles, etc.) are not presented here but can be found in detail in several texts.[3–5]

The top of Fig. 1 contains the most common descriptors applied to bioremediation. Mineralization is the complete conversion of an organic compound into biomass, carbon dioxide, water, and salts. The difference between the degradation of natural organic

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007679

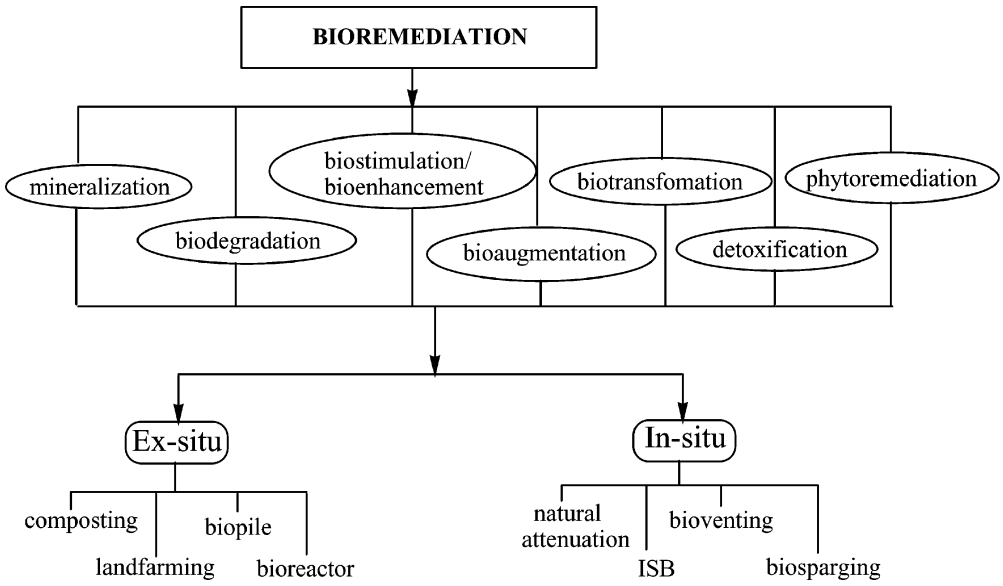

Fig. 1 Descriptive terms for bioremediation applications.

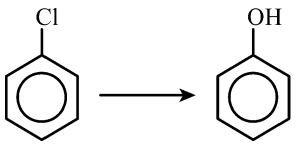
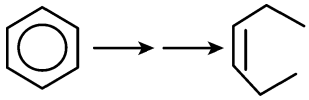
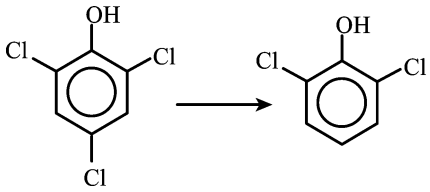
matter and chemical contaminants is the ease of degradation, complexity of the structure to be degraded, and time required for achieving complete mineralization. Biodegradation is also used to describe any of the microbial mediated degradation steps prior to mineralization. It includes substitution or transformation reactions that cause a simplification in the compound structure. For instance, a substitution process would be the introduction of a hydroxyl group in place of chloride [Eq. (1)], while transformation would facilitate the breaking of intermolecular bonds [Eq. (2)]. The generic term of transformation does not differentiate between whether the primary structure of the parent compound is still evident or not. As shown in Eq. (2), the structure of the parent compound is no longer easily discernable. Conversely, biotransformation is the alteration of the molecular structure via microbial mediated enzymatic catalysis where the structure of the parent compound is still evident [Eq. (3)]. The goal of the intermediate steps in both biodegradation and biotransformation is to yield a compound that is more susceptible to microbial attack (i.e., less recalcitrant). Detoxification refers to both abiotic and biotic processes that render the compound less toxic. The biotransformation of 2,4,6-chlorophenol to 2,6-chlorophenol as shown in Eq. (3) is an example of detoxification because toxicity generally increases with the increasing number of chloride substitutions.



(1)



(2)



(3)

The bottom of Fig. 1 contains the subcategories used to describe the application, approach, and location of the bioremediation process. In defining the different approaches, it is important to note that indigenous species are those microorganisms inherent to the contaminated media or site. The terms biostimulation and bioenhancement are often interchangable. Both refer to the addition of a terminal electron acceptor (TEA), supplemental nutrients, auxiliary carbon sources, or substrate analogs to stimulate the activity of the indigenous species. The subtle distinction occurs with regard to the location of the additives. Biostimulation is the delivery of the nutrients and/or TEA to the indigenous microbes. Occasionally, bioenhancement is used to distinguish when the stimulation of the ''natural microbes'' occurs in aboveground containers. There are three instances where the indigenous species cannot be stimulated, viz., the appropriate microbial population is not present, bacterial numbers are too low and cannot be increased in an acceptable time frame, and contaminant concentrations or type

are toxic to the bacteria.[4] When the indigenous species cannot be stimulated, bioaugmentation can be tried. Bioaugmentation is the addition of foreign microorganisms for the remediation of a contaminated site. Foreign does not imply the use of genetically engineered species, but refers to any microbe not inherent to the contaminated site. In selecting the foreign species, it is important to ascertain whether the microbes will survive in the new environment, are effective for the target compounds, and can easily be distributed in the subsurface.[6] Often the addition of supplemental nutrients and TEAs (i.e., biostimulation) occurs in conjunction with bioaugmentation to assist with biomass generation. As previously mentioned, phytoremediation is the use of plants for the direct (phytoextraction) or indirect (stimulation of the rhizosphere) treatment of contaminated media.

The physical location of the bioremediation process is divided into two primary categories, i.e., in situ and ex situ, which can also be used in conjunction with the descriptors defined above. In situ applications are those processes that take place in the contaminated media without excavation. ISB is the acronym commonly used for in situ bioremediation. Natural attenuation is also referred to as intrinsic bioremediation. It is the result of several natural processes (abiotic transformation, biodegradation, sorption, etc.) that reduce contaminant concentrations in the environment without human intervention. Bioventing and biosparging are used to distinguish the location of delivered nutrients/TEAs. Bioventing introduces the TEA to stimulate activity in the vadose zone (i.e., the top 2 ft of the unsaturated soil) at approximately 1/10 the delivery rate of soil vapor extraction. Biosparging introduces the material below the groundwater level. Although biosparging is predominantly associated with TEA delivery, it can also be used to describe the introduction of nutrients and/or microbes.

Ex situ applications are processes that occur after the contaminated media have been excavated. Once excavated the media can be treated on-site or taken off-site for subsequent treatment. Composting is the oldest ex situ treatment that utilizes a mixture of mesophilic and thermophilic organisms. Windrows of soil are constructed to a height of 3–4 ft and length of 50–200 ft. Water is added weekly to provide the necessary moisture and regulate the internal temperature of the compost pile. Landfarming occurs on lined containers of various dimensions. The soil is applied at a maximum of 1 ft and is tilled one or two times a month to enhance aeration and nutrient delivery. Biopiles are 6 ft mounds of excavated soil that were premixed to provide a ''uniform'' dispersion of the contaminant. An array of air ducts is placed within the bottom of the pile to introduce the required TEA. Periodically, the piles are sprinkled with water and nutrients to maintain the required moisture and nutrient levels. As with composting and landfarming applications, biopiles are constructed on engineered liners to contain any contaminant releases. Bioreactors are used to describe any contained ex situ biological treatment that does not fall into the categories mentioned above. These systems can be operated in batch, semibatch, or continuous modes with either attached growth or free suspensions of bacteria.

CONTAMINANT CLASSIFICATIONS APPLICABLE TO BIOREMEDIATION

Bioremediation has been successfully demonstrated for a variety of contaminant classifications. The majority of the studies have focused on petroleum compounds (BTEX, gasoline, diesel, jet fuel, etc.) because of their widespread occurrence as a contaminant. The other major waste classifications where bioremediation has been successful are solvents (toluene, trichloroethylene, etc.), creosote, pulp and paper, pesticides, textiles, polycyclic aromatic hydrocarbons (PAHs), and polychlorinated biphenyls (PCBs). Table 1 contains a partial list of the microbial genus successfully implemented for these contaminants. For aqueous petroleum contaminants, bacteria and yeasts are the most prevalent degraders. In contaminated soil systems, bacteria and fungi are the microorganisms responsible for degradation.[7]

Petroleum compounds have also been widely studied as a result of their susceptibility to microbial attack. There are several rules of thumb associated with the ease of degradation in terms of compound structure. In general, as the compound molecular weight increases or the compound's structure becomes more complex, degradation becomes more difficult. The relative biodegradability of contaminants under aerobic conditions, in order of decreasing ease (i.e., the easiest first, the more recalcitrant last) is:[3,4,8]

- Linear alkanes (C_{10}–C_{19})
- Gases (C_2–C_4)
- Branched alkanes (to C_{12})
- Alkanes without substitutions
- Alkenes (C_3–C_{11})
- Branched alkenes
- Aromatics
- Cycloalkanes
- PAHs
- PCBs.

Polychlorinated biphenyls and other halogens can often be reductively dehalogenated much faster anaerobically (i.e., in the absence of oxygen) as compared to their aerobic counterparts.

Table 1 Select microbial genera with successful demonstration of treating different contaminant classifications

Contaminant	Microbial genus		
Aliphatics	*Achromobacter*	*Bacillus*	*Flavobacterium*
	Acinetobacter	*Micrococcus*	*Pseudomonas*
	Arthrobacter	*Mycobacterium*	*Vibrio*

Pesticides, herbicides	*Achromobacter*	*Athiorocaceae*	*Penicillium*[a]
	Alcaligenes	*Corneybacterium*[a]	*Methylomonas*
	Arthrobacter	*Flavobacterium*	*Zylerion*[a]
	Pseudomonas		
Dyes	*Aeromonas*	*Phaneorchaete*[a]	*Trametes*[a]
	Micrococcus	*Pseudomonas*	
	Klebsiella	*Shigella*	
Food, dairy, and meat	*Acinetobacter*	*Brevibacterium*	*Rhodococcus*
	Arthrobacter	*Nitrosomonas*	*Vibrio*
	Bacillus	*Pseudomonas*	
PAHs	*Aeromonas*	*Brevibacterium*	*Phanerochaete*[a]
	Achromobacter	*Cunninghmella*[a]	*Pichia*[a]
	Acinetobacter	*Corneybacterium*	*Candida*[a]
	Anthrobacter	*Flavobacterium*	*Pseudomonas*
	Bacillus	*Penicillium*[a]	*Sporobolmyces*[a]
PCBs	*Acinetobacter*	*Corneybacterium*	*Ralstonia*
	Arthrobacter	*Pseudomonas*	*Vibrio*
	Alcaligenes[a]		
Pulp and paper	*Arthrobacter*	*Sporotrichum*[a]	*Trichoderma*[a]
	Eisenia	*Talaromyces*[a]	*Xanthomonas*
	Chromobacter		
Solvents	*Alcaligenes*	*Morganeela*	*Pseudomonas*
	Citrobacter	*Mycobacterium*	*Rhodococcus*
	Desulfomonite	*Nitrosomonas xanthobacter*	
	Enterobacter	*Nocardia*	

[a]Fungi.

It is important to note that there are specific bacteria-contaminant combinations that will be the exceptions to the trend. In addition, this list does not include the impact of bioavailability or concentration. For instance, normal alkanes are considered the most biodegradable of all petroleum hydrocarbons. However, at elevated concentrations the C_5–C_{10} compounds inhibit the activity of several hydrocarbon degraders.[9] Furthermore, the number, type, and position of substitutions will also influence the ease of degradation in branched chains, aromatics, and multiple ringed compounds. As the complexity of the compound's structure and the number of compounds present at a site increase, one microbial strain will not be able to facilitate the complete bioremediation of target compounds and degradation by-products. In these situations, the use of a consortium, or mixed population of bacteria, should enable complete mineralization via cometabolism. Cometabolism is the indirect metabolism of a nongrowth substrate or recalcitrant compound during the transformation of the required growth substrate.

ELEMENTS ESSENTIAL TO BIOREMEDIATION

There are several basic microbial requirements that must be in place if bioremediation is to be successful.

They are essential for supporting any microbial ecosystems and include the appropriate microbes, a substrate for carbon and energy source, TEA, an inducer to facilitate enzyme production, nutrients for microbial maintenance and growth, mechanisms to degrade metabolic by-products, the absence of toxicity and competing organisms, and the appropriate environmental conditions.

Adequate Microbial Population

The primary requirement for any successful biological treatment is the presence of an adequate microbial population. As shown earlier in Table 1, there are a wide variety of microbial species with demonstrated success at remediating an array of contaminants. Soils that have favorable growth conditions will exhibit viable microbial numbers of greater than 10^4 colony forming units (CFU)/g of dry soil. Normal activities in ''clean'' groundwater are in the range of 10^6–10^8 CFU/L. Soils and groundwaters depicting activities $<10^3$ CFU/g soil and $<10^6$ CFU/L are considered nonviable for growth. Such low numbers indicate the lack of an essential nutrient/TEA, the presence of toxic material, an extremely high contaminant concentration, or a combination of all of the above. The cause of nonviable populations can be determined, and possibly corrected for, by a thorough site characterization and treatability study.

Terminal Electron Acceptor and Redox Potential

Aerobic bacteria complete most of the petroleum bioremediation applications, particularly those above the groundwater table. Aerobes are those bacteria that require an oxygen source as their TEA. Conversely, anaerobic species require the absence of oxygen (anoxic conditions) for their respiration. In situ anaerobic bioremediation is typically only conducted in the saturated zone because of the difficulty in maintaining a strict anaerobic environment. In some instances, facultative anaerobes are utilized because they can alter the respiration to be metabolically active under both anaerobic and aerobic conditions. As such, the type of TEA available will dictate the metabolism and subsequent degradation mode. The most common TEAs used for bioremediation are listed in Table 2. Careful selection of microbe–TEA combinations can enable a specific degradation pathway to facilitate cometabolism and prevent undesired degradation by-products.

Appropriate TEA selection is also essential for establishing redox conditions near the microbes.[2] During normal cell metabolism, energy for growth is obtained from the transfer of electrons from the donor to the acceptor. The redox potential is used to describe the availability of electron donors (preferably the contaminants). Reported redox potentials (in millivolts) for each respiration mode vary; however for ISB, redox potentials decrease and become more anaerobic as the depth below the surface increases. For instance, redox potentials >400 mV are representative of aerobic conditions in the vadose zone. Values from 100 to 50 mV are facultative, while those $\leq$300 mV are associated with obligate anaerobic environments.

Table 2 Common TEAs used for aerobic, anaerobic, and fermentation respiration

Respiration mode	Terminal electron acceptor
Aerobic	Oxygen
	H_2O_2
	Various organics
Anaerobic	NO_3^-
	SO_4^{2-}
	Various organics
Methane fermentation	CO_2
	Various organics

Nutrient Requirements

Nutrient amendments are often listed as the most effective approach for increasing biodegradation efficiencies with nutritional requirements being approximately the same as the bacteria's cell composition.[10,11] Using *Escherichia coli* as the reference bacterium, the generic formula for biomass (i.e., bacteria cells) is $C_5H_7NO_2$.[2–4,12] Thus, carbon and nitrogen represent 53% and 12% of the cell, respectively, and are the two nutrients needed most for cellular maintenance and growth. Heterotrophic bacteria can utilize organic contaminants as their primary carbon source. In some instances, the microbe may need greater levels of carbon than is readily available from the contaminant. In these situations, an auxiliary carbon source may be required to either induce degradation or compensate for when contaminant concentrations are too low (not bioavailable). During soil remediation, if the soil organic content is too high it may serve as the preferred carbon source, thereby limiting degradation of the target compound.

Nitrogen is the most commonly added nutrient for bioremediation processes. It is added primarily, in the form of ammonium or nitrate ions, for cellular growth. Nitrate can also be used as an alternative TEA. However, it is often difficult to manage subsurface nitrogen levels because of the microbial conversion of ammonia

to nitrate, nitrate to nitrite, etc. Phosphorus is the second most common nutrient added for cellular growth and maintenance. Potassium phosphate can also serve as a buffering agent. Currently, there is no exact method to predetermine the exact nutrient sources to use at a site. The general rule of thumb for groundwater amendments is to employ a supplement that will result in a carbon : nitrogen : phosphorous ratio of 100 : 10 : 1. During the remediation of contaminated soils, the nutrients may be present, but not bioavailable or in a preferred form. In these situations, the nitrogen : phosphorous ratio is changed to 10 : 5 or 10 : 10, depending on the soil characterization results.[3] For both groundwater and soil remediation, the introduction of supplementary nutrients is limited to $3\,lb/yd^3$ soil to prevent osmotic shock.[4] In other words, if too many salts are added at the same time, the change in osmotic pressure can rupture the cell wall. Terminal electron acceptor and nutrient amendment deliveries are staggered to prevent fouling of the injection well and the occurrence of localized population growth.

Moisture and Other Environmental Parameters

Moisture is also required for microbial activity as the primary component in bacteria protoplasm is water. If the bacteria do not receive enough water, they will die. However, oversaturation conditions can be detrimental. Too much water can inhibit gas exchanges, thereby depleting the airborne oxygen and rendering an anaerobic zone.[9] Moisture levels are typically maintained by using water as the delivery medium for nutrient amendments and removal of degradation by-products.

The pH level of the surrounding environment can affect microbial growth, cellular functions (fluidity, membrane transport, etc.), equilibrium of enzymatic reactions, and availability of nutrients. Most bacteria can exist in pH ranges between 5 and 9, with an optimal growth around 7. Maintaining the soil pH near 6.5 has the added advantage of preventing the solubilization of heavy metals that are often toxic to bacteria. However, natural bacterial adaptations have enabled successful bioremediation for soils outside the optimal pH range.[2]

The surrounding temperature will also have a great impact on microbial activity. Most of the microorganisms identified for the bioremediation of petroleum contaminants are mesophilic (i.e., optimal growth temperature of 30°C). Although microbes have an optimal growth temperature, they may be able to thrive over a 10°C or a 40°C range, depending on whether they are stenothermal or eurythermal, respectively. The cation exchange capacity and soil type (organic matter, clay content, etc.) will also affect achievable bioremediation efficiencies. The impact of each of these parameters, optimal levels, and examples of potential methods to alter subsurface conditions can be found in several standard textbooks.[2–5,9]

Compound Specific Factors

Compound dependent factors that impact bioremediation efficiencies are the contaminant concentration, adaptation of microbial community, co-oxidation, and cross-acclimation because of substrate analogs.[12] The contaminant concentration is a direct function of the available concentration and solubility, often reported in terms of bioavailability. Depending on the contaminants' inherent physicochemical characteristics, it may be toxic at parts per billion concentrations.[13] In other situations, a contaminant may be considered toxic only when present at high concentrations (>10,000 ppm). The exact impact of concentration is dependent on the micro-organism(s). Typically, biodegradation rates are modeled as first order but will change with time. Rate changes occurring over a long period of time (months and years) are often the result of the time required by the bacterium to alter its metabolism for inducing enzymes essential for that catabolic pathway.[12] Conversely, short time frame changes are often associated with those systems that can be represented as Michaelis–Menton kinetics.[9]

The number of active species as well as the dominant genus in a microbial population can change (i.e., shift) significantly over time. For example, hydrocarbon degraders are typically <1% of the total organisms in clean areas but comprise almost 100% of the active species in a contaminated area.[14] Population changes can be because of nutrient amendments, TEA availability, competitive inhibition within the community, or metabolic stresses posed by the contaminant or degradation by-products.[15] Co-oxidation and cross-acclimation are prevalent at sites with multiple contaminants. Both processes can contribute to changes in the microbial community and are a direct example of why consortiums are advantageous over pure cultures.

Once all of the ''controllable'' factors are in place, it is critical to select the proper bacterial combination(s) that enables the appropriate rate of biomass growth and enzyme production. For instance, the primary step in trichloroethylene bioremediation is the production of oxygenases, such as toluene dioxygenase (tod). However, oxidation of trichloroethylene generates intermediates that inactivate the tod enzyme and can even be toxic to the cells themselves, i.e., catabolite repression.[16,17] Thus, the biomass growth rate and

enzyme regeneration must be high enough to exceed enzyme inactivation and cellular toxicity if the bioremediation process is to be successful.

METABOLIC PATHWAYS

Understanding the metabolic, or degradation, pathways involved in the bioremediation of contaminants can be invaluable. For certain contaminants, only after the responsible pathway(s) is known can mineralization be considered a possibility.[18] Metabolic pathways can provide critical information regarding the:

- Intermediate metabolites' form, concentration, toxicity, and rate limiting steps that may occur.
- Blockage in a reaction sequence (i.e., dead end pathway).
- Potential health concerns.
- Degree of remediation that can be/has been achieved.

Aliphatic and Alicyclic Metabolic Pathways

The aerobic degradation of both nonhalogenated and halogenated alkanes, alkenes, and cycloalkanes has been widely studied.[2,4,7,14,18–21] As such, only an example of the general pathway and summary of key findings is presented. The reaction(s) is initiated by the production of mono- and dioxygenase enzymes. Aliphatic compounds are susceptible to enzymatic attack at either end and will follow the generic pathway depicted in Eq. (4). Further degradation at one end (β-oxidation) or at both ends (ω-oxidation) of the compound results in smaller fatty acids that are easily degradable.[12]

$$\text{aliphatic} \xrightarrow{O_2} \text{alcohol} \rightarrow \text{aldehydes} \rightarrow \text{carboxylic acid} \quad (4)$$

Degradation of the parent compounds and intermediates is predominantly an aerobic process. Most of the contaminated sites typically contain adequate indigenous populations and may, therefore, require only supplemental nutrients or TEA. Other generalizations pertaining to alkane, alkene, and alicyclic degradation include the following:

- Long-chain compounds are easier to degrade.
- Compounds with less than nine carbon atoms typically have to be degraded via cometabolism.
- Degradation rate of saturated compounds is much greater than that of unsaturated compounds.
- Rate of straight chain degradation is much greater than that of branched chain compounds.

Aromatic Metabolic Pathways

Biodegradation of an aromatic compound can be divided into two primary steps: activation of the ring and subsequent ring cleavage. Ring activation incorporates molecular oxygen into the ring structure by either mono– or dioxygenase enzymes. The first primary intermediate from mono-oxygenase reactions is an epoxide followed by the formation of transdihydrodiols.[9] Aromatics degraded by the catalysis of aromatic ring dioxygenases, such as tod, incorporate two oxygen molecules to form dihydroxy intermediates.[12,22] Ring activation can be completed under both aerobic and anaerobic conditions. In general, degradation of halogenated aromatics occurs at a faster rate under anaerobic conditions. However, there are a few dehalogenase-mediated mechanisms that can remove a halogen prior to ring cleavage, thereby making it more susceptible to aerobic degradation.[18,23]

A key step in the anaerobic degradation of nonoxygenated aromatics is the incorporation of oxygen into its structure. This rate limiting step typically occurs by the introduction of a hydroxyl group via hydrolysis reactions. Anaerobic degradation of nonoxygenates can occur; however, the primary intermediate is more thermodynamically stable and therefore more resistant to subsequent degradation. For both oxygenated and nonoxygenated compounds, degradation rates are higher under denitrifying than under methanogenic conditions.

An essential criterion in any metabolic pathway is that the metabolism of the contaminant will eventually result in an intermediate that can enter the tricarboxylic acid (TCA) cycle.[13,24] For the aerobic or anaerobic degradation of aromatic compounds, the pivotal point in ring activation to ensure that this will happen is the formation of either catechol or protocatechuate.[4,24–26] Examples of some of the aromatics that can be aerobically degraded to catechol and protocatechuate are contained in Figs. 2 and 3, respectively. After the formation of the pivotal compound, ring cleavage will occur at either the ortho or the meta position.[24] Typical pathways associated with the ortho cleavage of catechol and protocatechuate are shown in Fig. 4, with muconic acids and mucolactones as the primary end products. The meta-cleavage pathway (Fig. 5) yields pyruvate and acetaldehydes. The intermediates formed by ortho and meta breakage then enter the 3-ketoadipic acid cycle (i.e., Krebs cycle). As shown in Fig. 6, the Krebs cycle results in the formation of either succinate or coenzyme A compounds (acetyl-coenzyme A or succinyl-coenzyme A), which can easily enter the TCA cycle. As a result, most practitioners will track the biodegradation byproducts until either catechol or protocatechuate is formed. Once these intermediates are formed,

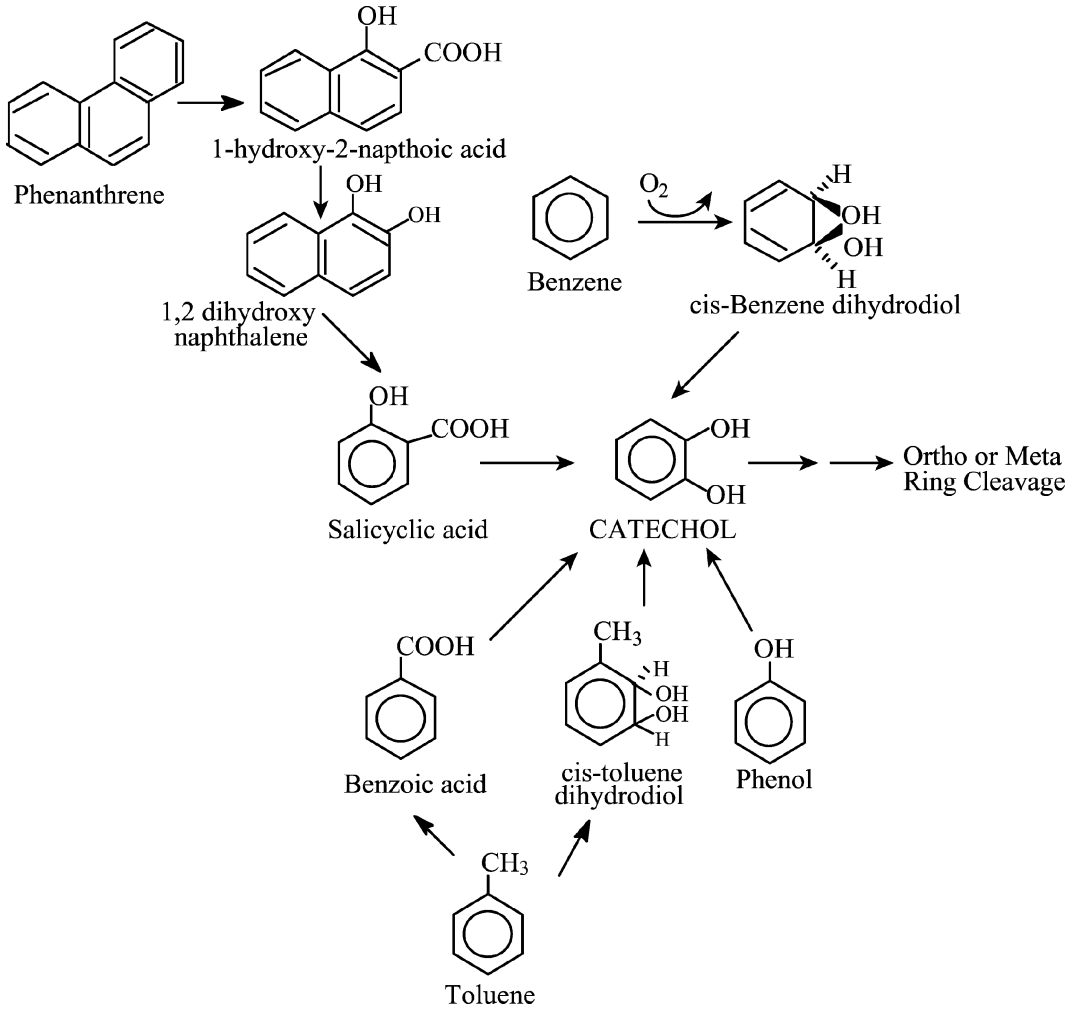

Fig. 2 Representative schematic aerobic degradation of aromatics to catechol.

mineralization is almost a certainty as long as the bacterial activity is maintained by adequate nutrients and TEA.

The degradation of aromatic compounds has demonstrated success under both aerobic and anaerobic conditions. For simple aromatics, such as benzene and toluene, all modes of anaerobic degradation (sulfate reducing, methanogenic, and nitrate respiration) have been successful.[4] However, this is not the case for more complex aromatics such as PAHs and PCBs. For all aromatics, the number, type, and location of substitution will influence the ease of degradation. A few of the other generalizations for multiringed aromatics include the following:

- Polycyclic aromatic hydrocarbons degrade one ring at a time by mechanisms similar to that of monoaromatic compounds.[12,13]
- As the number of rings increases, ease of degradation decreases.[27]
- Cometabolism and analog substrates are required for compounds with 4+ rings.[2,27]
- Initial ring oxidation is the rate limiting step.[4,24,28]
- Degradation decreases with increasing saturation.[2,28,29]
- The effectiveness of aromatic or anaerobic degradation of halogenated compounds is compound bacteria specific (i.e., no universal applications).

Additional information on microbial mediated reactions for a host of xenobiotics can be found at http://umbbd.ahc.umn.edu. The database contains information on some of the key degradation pathways associated with bioremediation.

TREATABILITY STUDIES

The primary objective of a treatability study is to evaluate the overall feasibility of bioremediation. The

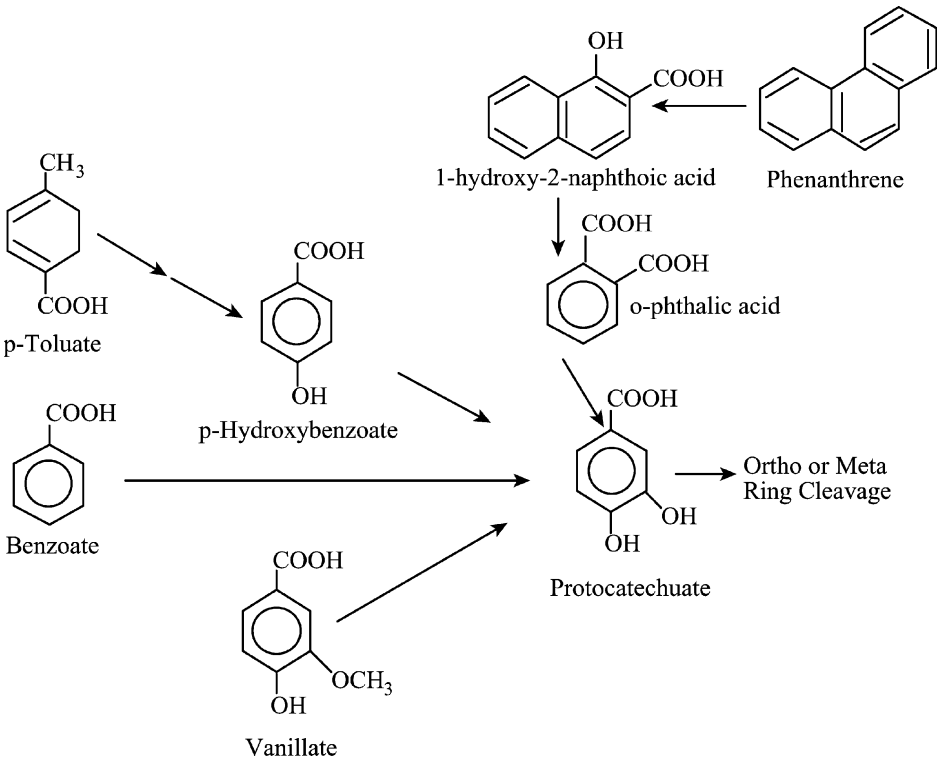

Fig. 3 Representative aerobic degradation of aromatics to protocatechuate.

studies can be conducted either in laboratory setting or in field tests. One of the goals of a treatability study is to characterize the microbial population that can ascertain the critical metabolic pathways. It can also determine if a change in respiration mode (TEA) is needed for complex, highly substituted compounds (e.g., PCBs). The second goal is to ascertain biodegradation potential. The potential can be as simple as whether bioremediation will or will not occur. Studies to evaluate potential can also

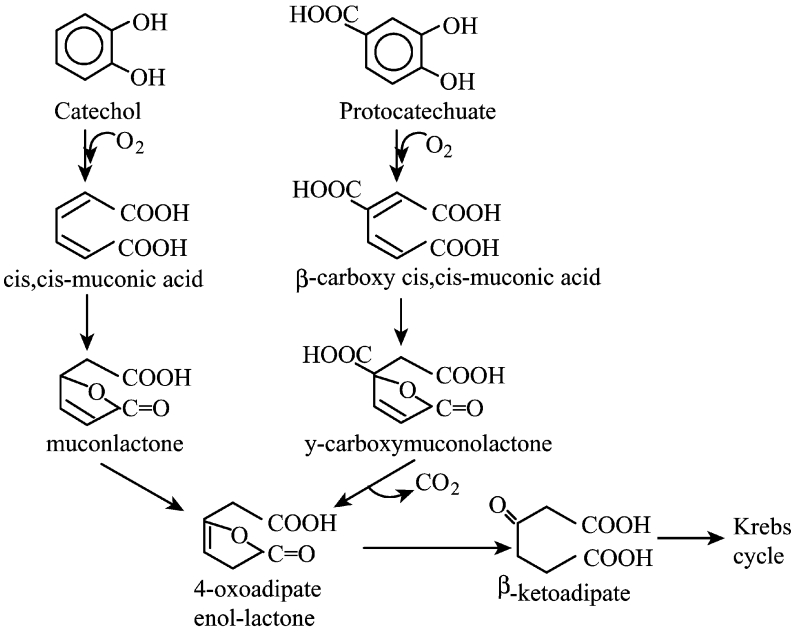

Fig. 4 Ortho ring cleavage of catechol and protocatechuate.

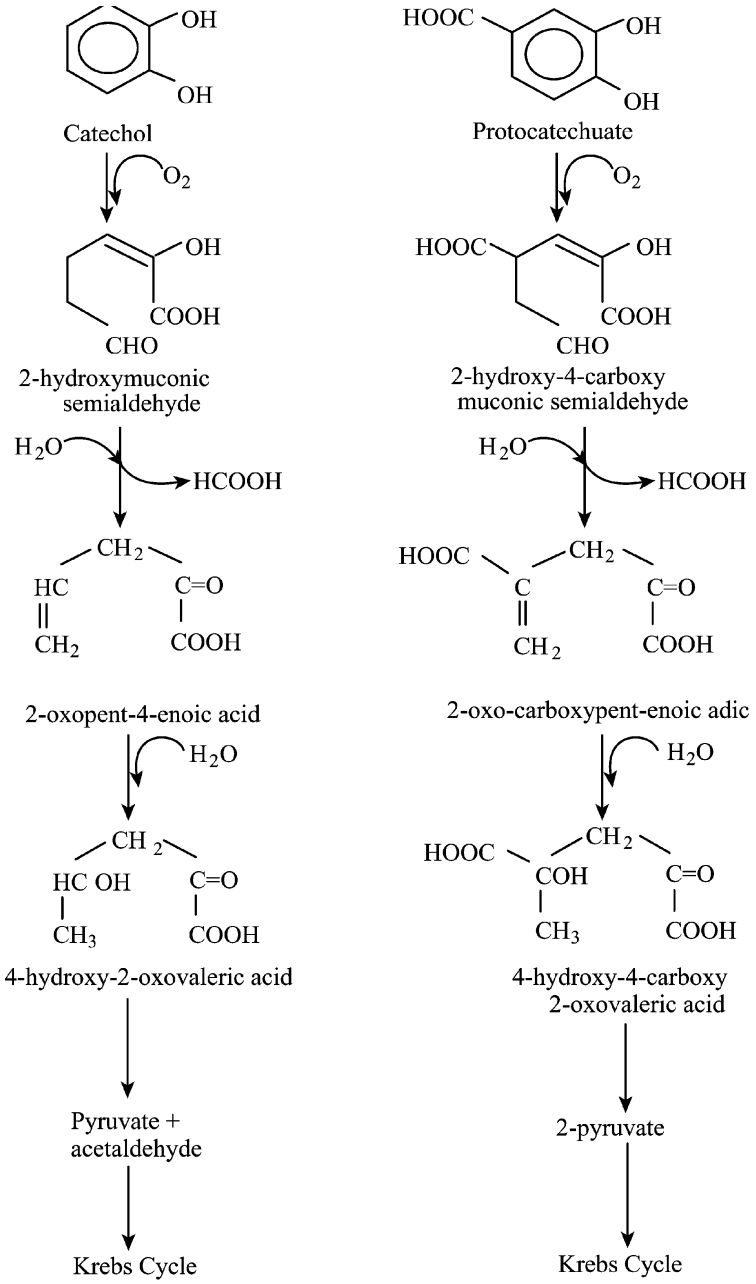

Fig. 5 Meta ring cleavage of catechol and protocatechuate.

be more rigorous to determine the actual biodegradation rates, achievable threshold levels, required time, etc. The third key application of treatability studies is for process optimization. These tests can determine the source, amount, and dosage frequency of the supplemental nutrients and/or TEA. It may also assess if the site will require bioaugmentation or if biostimulation suffices. In evaluating bioaugmentation approaches, a treatability study can test novel designs (i.e., designer microbes for specific enzyme induction) at cost-effective, safe environments. Last, a treatability study can assist with the monitoring of ongoing projects. For instance, the results can identify what key degradation by-products need to be tracked to prove that the treatment is proceeding as expected.

LONG-TERM CHALLENGES

Although bioremediation has been very successful over the past decades, it is still faced with several long-term challenges. The first one facing researchers and practitioners is the accurate, quantitative determination of in situ degradation rates. Almost all of the published degradation rates have been based on laboratory

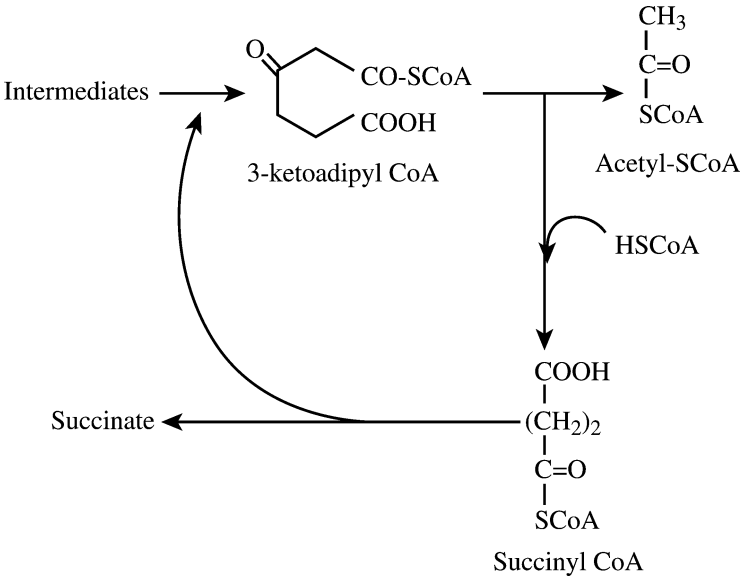

Fig. 6 Representative Krebs cycle.

studies that do not reflect subsurface environments. In fact, a 15–20% loss in efficiency is expected to occur when going from the laboratory to the field scale.[4] The lack of information pertaining to ISB rates is confounded by the fact that efficiencies of ISB treatments are typically site specific, even when the same bacteria consortium–contaminant combination was in place. This is largely because of the nonheterogeneity of soils leading to mass transfer limitations, which interferes with remedial and monitoring activities. Current rate assessment techniques implement either ex situ methods (i.e., laboratory scale methods) or in situ methods with their own inherent limitations (in situ respiration, tracer studies, etc.).[30]

Assessing in situ rates is directly related to the issues surrounding bioavailability (sorption to soils). Even at highly contaminated sites, pollutant transfer and availability may be limited, thereby decreasing achievable degradation rates. This has led to in situ bioremediation being incorrectly classified as ''ineffective'' because of the required time for treatment. One approach to decrease treatment time is to increase contaminant bioavailability. The introduction of commercial surfactants, such as Tween 80®, or utilization of biosurfactants is one method of enhancing solubility/bioavailability. For example, *Pseudomonas auerigenosa* is prevalent in subsurface soils and will produce rhamnolipid surfactants when in the stationary phase. However, increasing a contaminant's bioavailability too much can also be detrimental. For instance, the commercial surfactant may bind to the soil, thereby becoming a contaminant itself. Conversely, the new elevated concentration may be toxic to the degrading organisms. Thus, the challenge with bioavailability pertains to the appropriate selection (synthetic vs. biosurfactant) and application/production of a surfactant to enhance contaminant solubility in a cost-effective, environment-friendly manner without exceeding substrate utilization rates and toxic levels.

Another long-term challenge for ISB is determining how to address sites with multiple contaminants. A large fraction of National Priority List sites still await cleanup because of the problems associated with one of the multiple contaminant classifications inhibiting one or more of the remedial options.[4,5] For instance, most sites contain a mixture of solvents, petroleum products, and heavy metals.[4] At moderate to high concentrations, heavy metals are toxic to microbial activity. One approach to overcome the toxicity would be to stimulate or introduce microbes with natural metal resistance mechanisms. Several strains of the *Sphaerotilus*, *Aspergillus*, and *Pseudomonas* species can oxidize specific metals to less toxic forms (e.g., $Fe^{6+} \rightarrow Fe^{3+}$) or even precipitate the metals by altering the surrounding pH.

In addition to potential metal toxicity, sites with multiple contaminants have difficulty meeting regulatory cleanup levels within acceptable time frames. It is important to note that at these highly contaminated sites, one remedial approach will not be able to address all of the contaminants and media. The key will be to employ remedial treatments that can be easily adapted as a part of the treatment train.

CONCLUSIONS

As shown by the brief examples presented here, bioremediation is extremely versatile. It has demonstrated

success with almost every contaminant classification across all media—soil, water, sediment, and even air. Given adequate time, microbes can adapt to almost any environment. As such, bioremediation is the only other treatment method besides incineration that can result in the complete mineralization of a contaminant. This is particularly advantageous in that mineralization is the end treatment. As scientists and engineers learn more about micro-organisms and their metabolic pathways, the long-term challenges will be overcome and bioremediation will move to the forefront of remediation technologies. For instance, advances in catalysis and microbiology may enable the implementation of bacteria specifically designed to produce key enzymes for the degradation of highly recalcitrant compounds.

Bioseparations

Shubhayu Basu
Shang-Tian Yang
Department of Chemical and Biomolecular Engineering, The Ohio State University, Columbus, Ohio, U.S.A.

INTRODUCTION

A series of downstream processing and separation steps have long been used in food, chemical, pharmaceutical, and biotechnology industries in the recovery and production of biologically derived products, including enzymes, antibiotics, polysaccharides, organic acids, amino acids, vitamins, and alcohols. This sequence of recovery steps constitutes the field of bioseparation, which applies fundamental engineering principles and biochemistry to the design of new, or modification of, conventional chemical engineering unit operation processes. Since the invention of recombinant DNA technology and the birth of modern biotechnology industry in the late 1970s, bioseparation has faced a much greater challenge in dealing with more complicated recombinant protein products that require an extremely high purity to satisfy the stringent Food and Drug Administration (FDA) regulation for therapeutic and other clinical applications. Today, bioseparation is a significant and separate discipline in itself.

Although there are a wide variety of bioproducts that need to be separated and purified after fermentation, this entry focuses on the downstream processing of recombinant protein products, which are taking the pharmaceutical world by storm. Currently, a plethora of recombinant human proteins with immense therapeutic value are being produced in fermentation by various host organisms, including bacteria, fungi, and animal cells. Depending on the protein products and the host organisms, different bioseparation processes need to be designed to suit their specific needs. Here, a general bioseparation process design flowsheet is discussed first, followed by two case studies to help the reader understand better how each method can be integrated to obtain a product. These studies outline the design of the downstream processing units for obtaining recombinant human glial cell line derived neurotrophic factor (rhGDNF), which is produced commercially as an inclusion body (IB) in *Escherichia coli*, and erythropoeitin (EPO), a secreted protein from an engineered Chinese hamster ovary (CHO) cell line. Companies producing these recombinant protein products do not release their actual patented processes. However, the two flowsheets presented here are simulated based on the general process design principles to closely resemble the actual processes. The two case studies should help the reader in understanding the difference in strategy in purifying intracellular and extracellular protein products.

CLASSIFICATION OF BIOPRODUCTS

Bioproducts generally can be classified on the basis of their physical, chemical, and biological properties, which together with their concentrations present in the fermentation broth usually dictate how they can be separated and purified. Table 1 shows some industrial bioproducts with their concentrations produced from fermentation and typical downstream processing methods used for their separation and purification. Small molecules such as sugars, amino acids, vitamins, alcohols, and organic acids have sizes less than 2 nm and molecular weights (MW) less than 1000 Da. Large ones such as proteins and polysaccharides can be as big as 3–20 nm and have MW ranging between 10^3 and 10^7 Da. These small and large molecules are soluble in water and are usually present in the liquid phase during the fermentation. On the other hand, ribosomes, viruses, bacterial cells, yeast cells, and animal cells are much larger (18 nm to 10 μm) and are usually found as particulates or suspended solids in the fermentation broth.

The choice of bioseparation methods depends on the type of bioproduct, but the sequence of unit operations can often be dictated by the location of the products with respect to the cells. Whole cells like single-cell proteins, bacterial, yeast, and animal cells are relatively easy to separate and purify from the fermentation broth, and generally require only a few simple downstream processing steps. Extracellular products like some secreted enzymes, antibiotics, organic acids, and alcohols are slightly more complex to isolate and purify from the fermentation broth, but their relatively high concentrations and good stability render their recovery and purification easier and amenable for large-scale industrial operation. However, recombinant proteins for therapeutic use and other

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120016151

Table 1 Some bioproducts produced by fermentation and downstream processing steps used in their recovery and purification

Product	Concentration (g/L)	Steps used in downstream processing	Reference
Ethanol	70–120	Stripping, distillation	[1]
Citric acid	50–100	Precipitation/solvent extraction, crystallization	[2]
Antibiotics (e.g., penicillin G)	10–30	Filtration, solvent extraction, crystallization, centrifugation, drying	[1,2]
Amino acids	1–100	Filtration, precipitation, crystallization, membrane filtration	[3]
Single-cell protein	30–50	Flocculation, filtration, centrifugation, drying	[1]
Xanthan gum	25–50	Alcohol precipitation, centrifugation, drying	
Extracellular enzymes	2–5	Precipitation, adsorption, chromatography sequence	[1]
Monoclonal antibody	0.01–1	Precipitation/centrifugation, chromatography, diafiltration, ultrafiltration	[4]
Tumor plasminogen activator	0.045	Mainly a sequence of chromatography steps	[5]
Vitamin B_{12}	0.02–0.06	Flocculation, filtration, drying, adsorption, elution, two-phase separation, crystallization	[1]

clinical applications usually are produced in a relatively low concentration but must be purified to a near-100% purity. Therefore, they require the most cumbersome purification steps and are usually difficult and costly to produce. The degree of difficulty in recovering the recombinant proteins also depends on whether they are present in IBs, or as extracellular or intracellular proteins.

BASIC BIOSEPARATION STEPS

The steps in purifying any bioproduct are governed by its properties, cellular location, initial broth characteristics (viscosity, concentration, impurities) and final product concentration, and the physical form desired. The unit operations also differ from their counterparts in the chemical industry because most biological molecules are temperature and pH sensitive, and are produced in low concentrations.

Some bioproducts are derived from fermentation by living organisms but immobilized enzymes can also catalyze a biotransformation. If the product is extracellular, then the initial steps of recovery include removal of the cells and other particulate matters from the broth. If the product is intracellular, it would be necessary to lyse the cells to release the product into the broth. The cell debris is then separated before the product is recovered from the broth. In certain cases, proteins produced as IBs need to be solubilized and the proteins renatured before further recovery steps. In the case of biotransformed products, the immobilized cells or enzymes and their support need to be removed initially.

Fig. 1 illustrates the various key steps required in downstream processing and the characteristic pathways used for recovery of cellular, extracellular, and intracellular products. Their function in downstream processing can be summarized as follows:

1. *Separation of cells and other particulates*: Filtration, sedimentation, centrifugation, and decanting are common methods.
2. *Cell disintegration*: In the case of intracellular products, cells need to be lysed by high-pressure homogenization, by wet milling, or by enzymes, detergents, and other chemicals that disintegrate the cell wall and membrane.
3. *Clarification*: With or without cell lysis, the fermentation broth consists of a mixture of components from which the final product needs to be clarified. Primary steps in clarification usually involve centrifugation and filtration to remove cell debris and other particulates. The product purity in the outlet stream is usually still low, between 1% and 10% (w/v), at the end of these steps.
4. *Enrichment*: More sophisticated separation techniques such as solvent extraction, precipitation, adsorption, and ultrafiltration (UF) are commonly used to concentrate and partially purify the product. The purity of the product usually reaches 10–80% (w/v) at the end of these steps.
5. *Protein refolding*: For recombinant proteins present as IBs in bacterial cells, they need to be solubilized first and then properly refolded to renature the proteins to regain their biological activities.
6. *Purification*: These operations are usually high-resolution techniques that are often difficult to scale up beyond the laboratory or pilot scale.

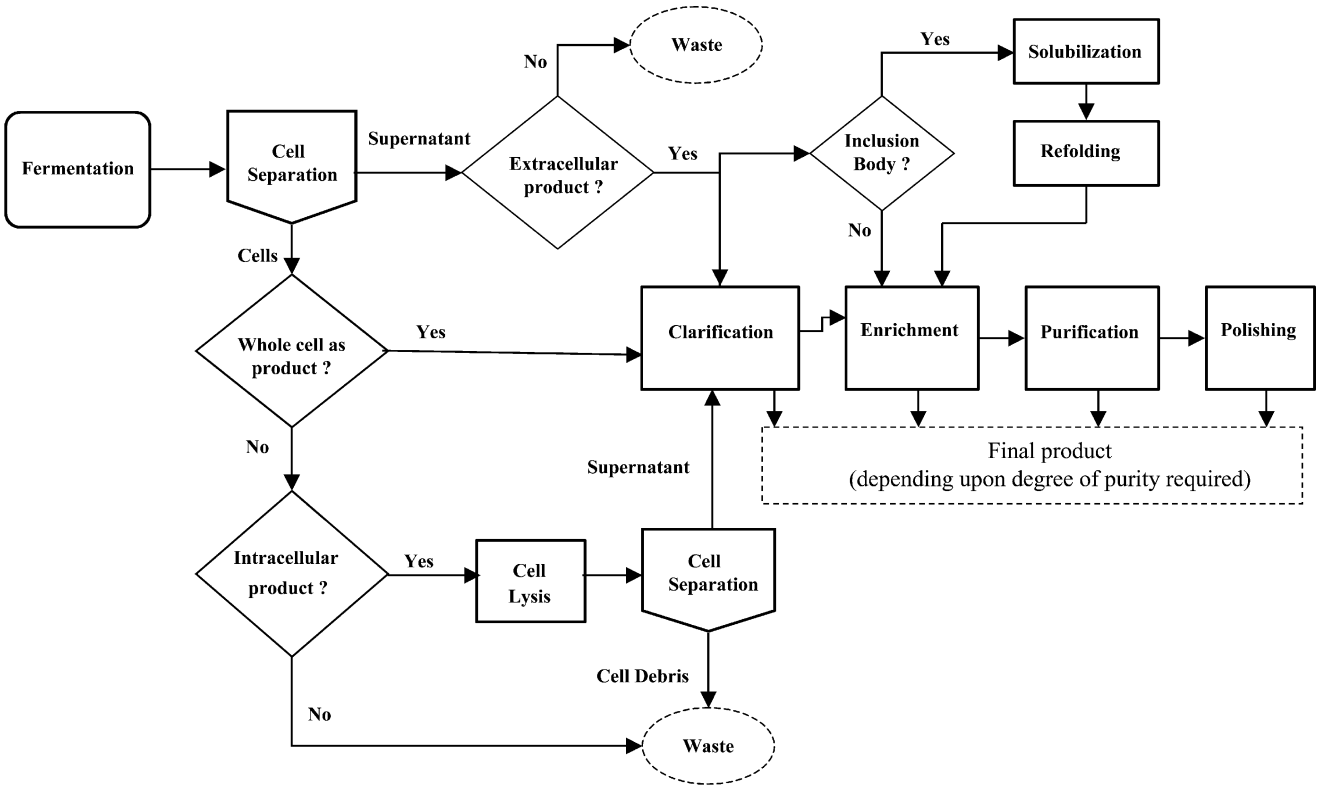

Fig. 1 A general process flowsheet for bioseparations.

However, various kinds of chromatography techniques utilize various physicochemical properties of the desired product to purify it. Product purity is often greater than 90–99% (w/v) at the end of a series of chromatography steps.

7. *Polishing*: The last steps provide the product at the desired concentration, purity, and physical form. These steps may consist of sterile filtration, diafiltration, UF, crystallization, freeze drying, lyophilization, and spray drying.

It is important to note that the design of a downstream process depends on the intended use of the product, the final concentration and purity needed, its marketable price, and the speed of recovery required because of the labile nature of most biological substances.

CELL SEPARATION

Common methods to separate cells and other particulates from the fermentation broth are sedimentation, centrifugation, and filtration. Sedimentation and centrifugation utilize the difference in density of the particle and its surrounding fluid to separate particulates from the fermentation broth. Sedimentation is settling in a gravitational field, whereas centrifugation uses centrifugal forces to amplify the settling velocity.

Sedimentation

Sometimes cells have a normal tendency to flocculate or aggregate based on charge differences. This allows for a simple and cost-effective cell recovery system. Although numerous studies have been done on the principles that govern sedimentation, it is worth noting that when settling occurs the particle has no net acceleration. The opposing drag and buoyancy forces negate gravity so that the particle settles at a velocity known as the terminal velocity, v_g, which is a function of the particle diameter, the density difference between the particle and the fluid, and the viscosity of the fluid. Sedimentation is often used in large-scale wastewater treatment processes as well as in traditional biosynthetic pathways involving fermentation. However, settling gives rise to a sludge that still contains ample amount of the fluid. Settled sludge biomass might need to be further dewatered using centrifugation.

Centrifugation

In the process of centrifugation, the applied centrifugal force accelerates the settling velocity of a particle. The settling velocity, v_ω, is additionally dependent on the angular velocity and radius besides the parameters governing v_g. The empirical equations governing the

settling velocity vary at different Reynolds numbers (Re) and are given elsewhere.[6] In brief, an Re below 0.4 is defined as the Stokes' regime, whereas that greater than 500 is defined as the Newtonian regime. Allen regime applies for all Re in between these values.

Although most protein settling occurs in the Stokes' regime, where the centrifugation efficiency is purely dependent on the particle size, shape, and density, things become a little more complicated in the Allen and Newtonian regimes, where high particle velocities, wall effects, and hindered settling occur. Hindered settling velocities are correlated to v_ω and are usually dependent on the particle volume fraction, shape, and size.[7]

Various types of centrifuges exist and choosing the correct one to achieve a certain separation efficiency is important. Table 2 summarizes the types, applications and advantages.

The choice of the correct centrifuge is always difficult, but keeping the parameters outlined in Table 2 in mind, one can design the downstream operation in an efficient way. It is important to remember that a decanter or a scroll-type centrifuge is less efficient for separation of micro-organisms, but it can handle large solid particles. Hence, this type can be used in series before another centrifuge to prevent clogging in the latter. In general, tubular bowl centrifuges are better for protein precipitates, disk centrifuges for cells and cell debris, and decanter centrifuges for noncellular, large particles such as antibiotic crystals.[8] It is important to sterilize and contain centrifuges as contamination of a bioproduct at any stage of recovery can be disastrous for the process.

Filtration

Filtration can be used to separate cells or cell debris, concentrate cells or protein solution, and remove or exchange salts. Two broad categories of filtration are conventional dead-end filtration, where fluid flow is normal to the plane of the membrane, and cross-flow filtration (or tangential flow filtration), where the fluid flows parallel to the membrane surface.

It is beyond the scope of this entry to review the basic principles governing filtration. However, it is interesting to note that filtration produces a more concentrated and dewatered cell sludge (20–35% w/v) or cell solids ($\geq$40% w/v) than settling. A variety of filter media, membranes, and equipment are commercially available. In the case where the deposited cake is compressible with low permeability and thereby adds more resistance to filtration, filter aids or precoats often alleviate the problem. Two of the most widely used filter aids are diatomaceous earth and perlite.

Various types of filtration equipment are available commercially and can be operated in batch, semicontinuous, or continuous modes. Among the commonly used types are the plate and frame filter, rotary drum filter, leaf filter, plate filter, and tray filter. Apart from the plate and tray filters, all other are enclosed and therefore are easy to work with when sterility of the solids is an important issue. Moreover, all these filters are examples of dead-end filters. Cross-flow filtration is mostly used in the purification stage through membranes with very low pore sizes and is discussed later.

CELL LYSIS

To obtain intracellular products, the cells need to be disintegrated and the cell debris discarded. The product then has to be purified from the supernatant. Cell lysis can be achieved by different methods, and the level of harshness required depends on the rigidity of the cell wall and hence the type of cell. Sometimes products are stored in the periplasmic space of the cells and complete cell lysis is not necessary. Prokaryotes, fungi, and plant cells have rigid cell walls, while animal cells do not. This makes disruption of the former category more difficult than in animal cells. Ironically though, most animal cells are efficient in secreting the product they synthesize.

Cell lysis methods can be broadly classified into mechanical methods using homogenizers, bead mills, and sonicators, and chemical methods involving osmotic shock, enzymes, and detergents. As the name suggests, mechanical methods rupture the cell membrane by shear forces or compression forces generated in homogenizer valves or by the grinding between glass spheres in bead mills, while sonicators rupture cell membranes using ultrasound waves. Nonmechanical methods can use osmotic shock, which can burst cells without a cell wall. A rapid decrease in the extracellular solute concentration can lyse cells. Enzymes like lysozyme can digest the cell wall of prokaryotes and plant cells, and make the resulting protoplasts susceptible to rupture by osmotic shock. Detergents and solvents can also be used to dissolve cell membranes. However, it is important to remember that addition of any chemical to lyse cells also warrants its separation from the broth to purify the desired product. In such a case where the presence of detergents or other chemicals can destabilize proteins, mechanical methods are more advantageous.

CLARIFICATION

Primary clarification steps usually employ centrifugation or filtration to partially purify the products from

Table 2 Comparsion of various types of centrifuges

Type	Mode of operation	Centrifugal force (*g*)	Particle size (μm)	Maximum throughput (m^3/hr)	Advantages	Disadvantages	Applications
Tubular bowl	Batch or semicontinuous	20,000	0.1–100	0.01–5	1. High centrifugal force 2. Good dewatering 3. Easy cleaning 4. Simple operation	1. Limited solid capacity 2. Foaming 3. Solid recovery is cumbersome	Pilot-scale separation of animal, plant, and microbial cells
Multiple-chamber bowl	Batch	5,000–9,000	0.5–20,000	150	1. Large solid boiling capacity 2. Good dewatering 3. Bowl cooling possible	1. Cleaning more difficult than for tubular bowl 2. Solid recovery difficult	Separation of human blood plasma components
Basic disk type	Batch or semicontinuous	5,000–11,000	0.5–500	30–60	1. Big discharge under pressure eliminates framing 2. Bowl cooling possible	1. Poor dewatering 2. Difficult to clean	Production of glucose isomerase from *Bacillus coagulans*
Disk with nozzle discharge	Continuous	6,000–9,000	0.5–500	300	1. Column solid discharge 2. Bowl cooling possible	1. Poor dewatering 2. Difficult to clean	Production of baker's yeast
Basket	Batch	400–1,300	10–1,000	—	1. Good dewatering 2. Large solid holding capacity	1. Low centrifugal force 2. Recovery difficult 3. Cannot separate fine particles	Removal of adsorbents such as cellulose and agarose
Scroll/decanter	Continuous	—	5–50,000	200	1. Continuous solid discharge 2. High-feed solid concentration	1. Turbulence created by scroll 2. Low centrifugal force	Antibiotic production

the fermentation broth. The operating principles for both unit operations are exactly the same as discussed earlier. However, filtration processes involved in this step are more refined and usually perform separation on a much smaller scale. As discussed before, there are two modes of operating a filtration unit: dead-end filtration and cross-flow filtration. While dead-end filtration is typically used for removal of macrosized particles (50–1000 μm), cross-flow filtration membranes can have different pore sizes, which dictate the type of filtration being performed.

Microfiltration (MF) is usually used to separate micrometer-sized particles (between 0.1 and 20 μm) from the fluid. Ultrafiltration is used to separate macromolecules or polymers such as proteins and polysaccharides with MW much greater than 1000, nanofiltration (NF) for oligomers with MW between 100 and 1000, and reverse osmosis (RO) for small solutes such as salts from water. The UF, NF, and RO membranes are semipermeable and are the finest forms of filtration presently known. Their separation mechanism is mainly based on the pore size of the membrane as characterized by their MW cutoff. Reverse osmosis membranes have the smallest pores and usually allow only the passage of water through the membrane. This process requires a high pressure to overcome the osmotic pressure, which could be several hundred atmospheric pressures under a high salt concentration. Ultrafiltration membranes are comparatively the largest in pore size and require a relatively low pressure as the driving force because there is negligible osmotic pressure and the pressure difference across the membrane is low. This process is useful for separating proteins from smaller molecules and is an important primary clarification technique as it helps pretreat and concentrate the broth before other forms of purification such as chromatography. It is also a vital procedure in desalinating the protein and, if used, is done as a purification step. The dilution mode filtration or diafiltration is usually placed after UF units to remove salts from the concentrated protein solution. Diafiltration is done by keeping a constant volume upstream of the membrane. Water is added at the same rate as the solution is being removed through the membranes. This decreases the salt concentration in the protein solution. Fig. 2 illustrates the operations of UF and diafiltration and how they change salt and protein concentrations in the feed solution.

A simple centrifugation or MF step in the primary clarification may directly be succeeded by a secondary clarification or an enrichment step, such as extraction, precipitation, or adsorption. The concentrated product may then be subjected to membrane filtration processes. Ultrafiltration might be done earlier and then followed by extraction or precipitation with salts. Diafiltration units can subsequently be used to remove the salts. This flexibility in rearranging various unit operation steps is common and varies between products.

ENRICHMENT

Extraction

Extraction is a process that utilizes the difference in solubility of the product of interest between two immiscible phases. Liquid–liquid extraction is commonly used in classical biotechnological downstream processing for production of antibiotics and other small molecules. The second liquid phase is usually a water immiscible organic solvent. Reciprocating plate, Podbielniak centrifugal extractors, Delaval contactors, and Westfalia extraction-decanters are examples of some of the equipment available for carrying out extraction.

For the extraction of proteins, aqueous two-phase systems (ATPS) are preferred over organic solvents, which usually denature the proteins and render them biologically inactive. They consist of polyethylene glycol (PEG), and a salt (e.g., potassium phosphate) or dextran in water. At concentrations above a critical value, the mixture separates into two phases—one rich in PEG and the other in dextran or salt. In industrial systems, salts are more commonly used because they are relatively inexpensive as compared to dextran. The MW, charge and surface properties of the protein decide how the protein partitions in the system. The nature of the phase components, the MW of the polymer, and the concentration and type of salt used also affect the distribution.[9]

The partition coefficient of proteins can be increased selectively by chemically attaching affinity ligands to the hydroxyl groups of the PEG. The protein can then be back-extracted from this phase by adding a fresh salt phase under conditions where the protein prefers the salt phase or by immobilizing the ligand complex in Sepharose beads, which separate into the top phase.[10,11] Liquid–liquid extraction is commonly used in the industry because of its low cost and easy scale-up potential, but it is rarely used for protein separation even though some proteins can be effectively partitioned in ATPS.

Precipitation

Precipitation is a simple yet large-scale method of purifying proteins and polysaccharide bioproducts. Except for therapeutic recombinant proteins, most proteins such as industrial enzymes can usually be efficiently recovered and concentrated using precipitation techniques. Precipitation utilizes the physical interaction

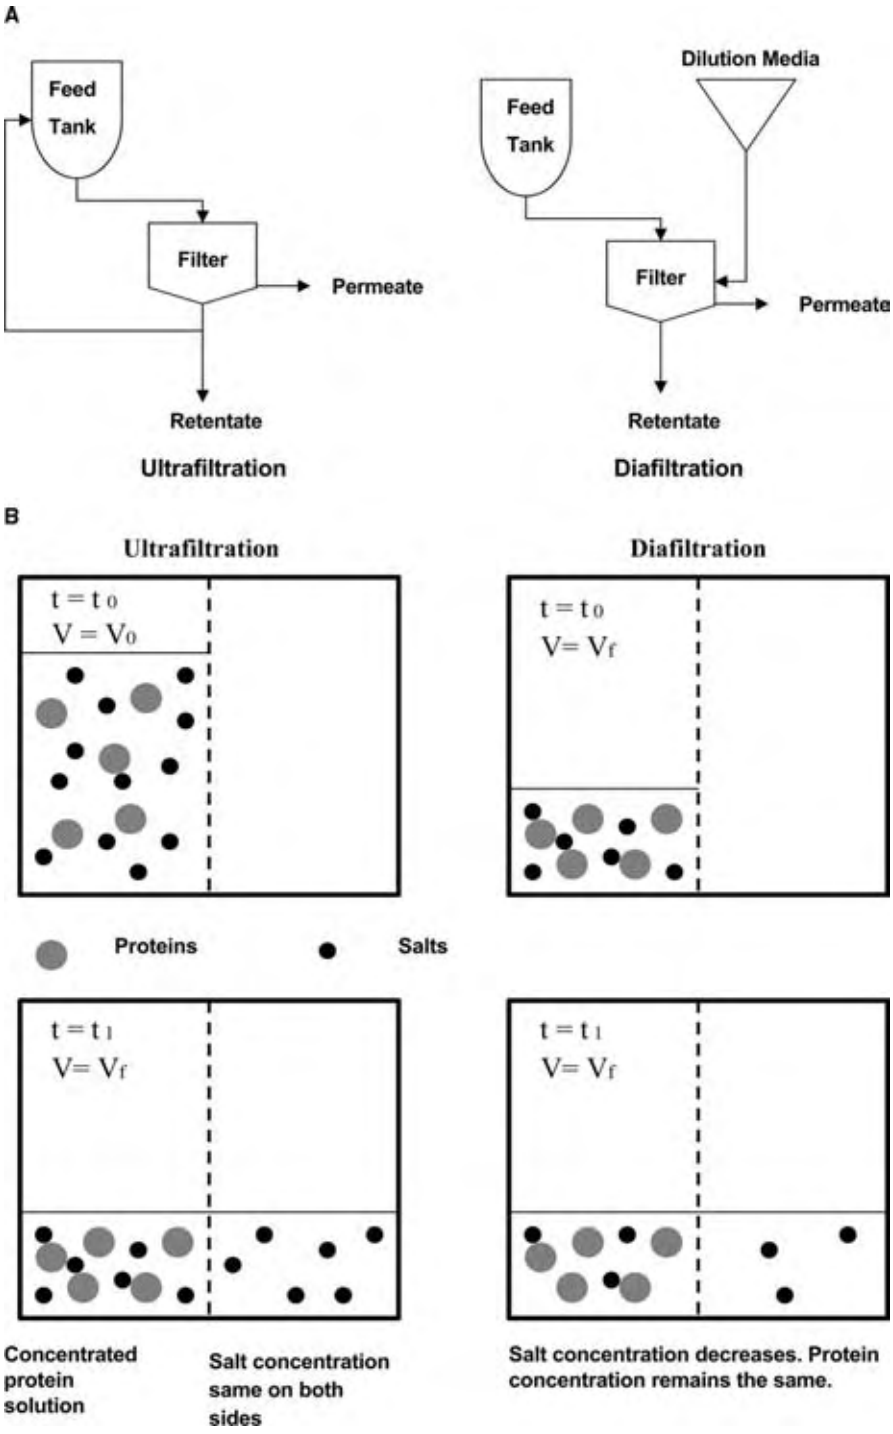

Fig. 2 (A) Schematic of the flow streams involved in UF and diafiltration. (B) Schematic of the process governing UF and diafiltration.

forces like hydrophobic and electrostatic forces and solvation effects to bring solutes out of solution. Table 3 outlines the different ways to precipitate proteins.

Protein precipitation using a change in pH is usually successful for concentrated systems. It may not be efficient for low concentrations however. In general, protein solubility rises with increasing salt concentration up to 0.2 M. This process is known as salting in. Under such a condition, a protein in solution can be precipitated out just by diluting the solution. A low temperature increases precipitate yield in such a case and avoids denaturation. For proteins that are thermolabile and yet can be easily renatured, selective precipitation by thermal methods is a very suitable option. This is a classic example of a ''kinetic'' as opposed to an ''equilibrium'' based separation method. As temperature increases, denatured protein selectively

Table 3 Methods of protein precipitation

Method	Example	Theory or principle
Change in pH	pH = p*I*	At pH other than p*I* polar interactions with the solvent or nonionic interactions with the salt keeping the protein in solution; at pH = p*I*, the protein has no net charge and therefore minimum solubility
Heat denaturation	70°C	As one increases the temperature, denatured protein selectively precipitates out
Salting out	Citrate salts, $(NH_4)_2SO_4$	At higher salt concentrations the water of hydration near the hydrophobic patches on proteins is used for solvating the ions; this exposes the hydrophobic regions of two or more protein molecules, which spontaneously aggregate together and precipitate out of solution
Addition of organic solvent	Acetone, ethanol	Hydrophobic patches are solvated by the solvent but the charged regions interact via electrostatic forces, causing precipitation
Addition of nonionic polymer	PEG	Very efficient for low-MW proteins like globulins; it precipitates protein by effectively reducing the amount of water required for protein solvation
Addition of ionic polymer	Polyacrylic acid, polyethyleneimine	Opposite charge on polymer and proteins cause complex formation

precipitates out at a rate proportional to the concentration of the denatured protein.

Salting in is dependent on surface charges and the polar interactions between the proteins and the solvent. In contrast, salting out is greatly dependent on hydrophobic forces. The addition of salt needs water molecules to solvate the ions. While the free water is used at first, higher salt concentrations use the ordered water molecules near the hydrophobic patches on proteins. This exposes the hydrophobic regions, which spontaneously interact and cause the proteins to form aggregates and precipitate. Most proteins precipitate out of solution over a narrow range of salt concentrations. Ammonium sulfate is widely used for precipitating proteins because it has a high efficacy of precipitation, high solubility in water ($\sim$533 g/L at 20°C), low cost, and a low density as compared to protein aggregates, which helps in protein recovery. Potassium salts have a lower solubility and higher density than ammonium salts in general, and are therefore less desirable than ammonium salts. Citrate salts are very effective in precipitation only above a pH of 7.0. Below that, they cannot be used because of their buffering action.

Organic solvents reduce the dielectric constant of the medium and solvate the hydrophobic regions of the protein molecule. Hence, the charged regions are exposed and interact to precipitate the protein. The mechanism is in a way similar to that of salting out. The solvent should neither interact directly with the protein nor denature it. Also, solvent requirement increases considerably at high ionic strengths.

Polyethylene glycol is available over a large range of MW (6000–20,000) and is widely used in precipitating proteins. Most water-soluble polymers lead to large increases in viscosity at concentrations >20% (w/v). Polyethylene glycol is an exception and is useful for precipitation of low-solubility proteins like globulins. With higher-solubility proteins like albumins, the difference in density between the aggregate and solution is negligible. This makes centrifugation impossible. Recovery of protein from the PEG–protein complex after precipitation is, however, very slow using dialysis.

Crystallization differs from precipitation in that it produces a regular lattice of molecules of the product. As biological products can be obtained at very high purity by crystallization, it is also often used as a polishing step. Sometimes, crystallization as a purification step can obviate the need for expensive chromatographic steps. Crystallization can be induced by pH adjustment, lowering ionic strength, or adding seed crystals of the desired protein to the solution.[8]

Adsorption

Adsorption is based on the principle of the differential affinity of dissolved solutes in a mobile liquid phase to a stationary solid phase. Adsorption columns usually have a smaller capacity but higher specificity than extraction. Various adsorbents have been in use, including activated charcoal (usually from vegetable sources), and more recently, customized resins that can have either positive or negative charges on them, or

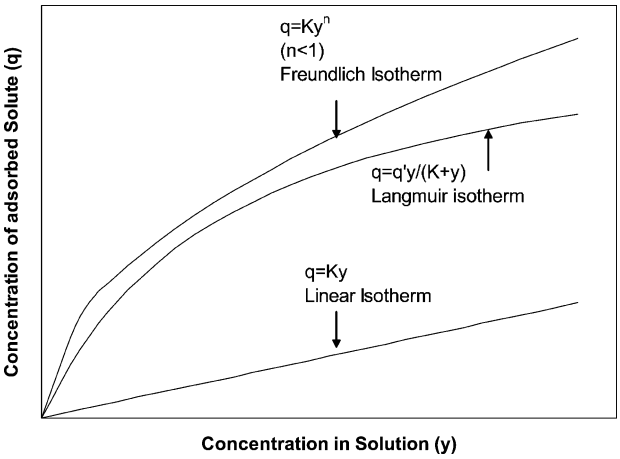

Fig. 3 Three different types of adsorption isotherms.

are hydrophobic in nature. Polystyrene, methacrylate, and acrylate based adsorbents are used for low-MW compounds, cellulose based adsorbents for proteins, poly(styrene-divinylbenzene) resins for nonpolar solutes, and acrylic esters for hydrophobic solutes.[2,12]

Mathematical analysis of adsorption is beyond the scope of this entry, but it is important to point out that the equilibria used are often based on adsorption isotherms. The three isotherms shown in Fig. 3 occur in practice, although linear isotherms are very rare. The nonlinearity of the Langmuir and Freundlich isotherms makes scale-up and analysis tedious. The Freundlich isotherm is based on empirical data analysis and occurs more commonly in practice than the Langmuir isotherm, which has a theoretical basis.

Adsorption is usually done in a batch mode in fixed, agitated, or expanded bed adsorption units. The process usually consists of cyclic operations of adsorption and desorption in two steps. Desorption or recovery of the adsorbed solutes from the adsorbents can be done by either changing the temperature or pH, or using a solvent, which also regenerates the adsorbents for use in the next operation cycle.

PROTEIN REFOLDING

Formation of IBs during protein expression poses a bottleneck in the efficient downstream processing of therapeutic proteins. The reasons for IB formation are not fully known. Because translation is a slower process than protein folding, it is likely that the misfolding of translation intermediates plays some role. Further, since post-translational modifications, such as glycosylation and lyposylation, which are known to affect the secondary structure of proteins, are absent in bacteria, the non-modified protein structure may cause misfolding. The recovery of soluble active protein from purified IBs requires the denaturation of the polypeptide by a denaturing agent such as 8 mol/L urea or 6 mol/L guanidine HCl and its subsequent refolding back to an active form. Fig. 4 depicts the protein configuration during the refolding step. There is no universal method to refold any protein. The conditions needed to properly refold the protein of interest remain an empirical science and need to be optimized for each protein.[13] In general, a solubilized protein solution is usually added into a large volume of a refolding buffer to reduce the concentration of the denaturing agent and also to avoid aggregate formation of protein molecules in the course of renaturation.[14] Refolding can also be done by dialysis against a refolding buffer and buffer exchange by gel chromatography.[15,16] The dilution method is usually the easiest but greatly decreases the concentration of the target protein. Also, the requirement of a large volume and the consequent inefficient mixing in large tanks lead to heterogeneity in folding conditions.[17] Often, the refolding conditions optimized for a protein in the laboratory scale might not work on a large scale.

PURIFICATION

Chromatographic techniques are the sole method for high-resolution purification of proteins and many other bioproducts. As opposed to adsorption, where the feed is continuously passed through the column until breakthrough of the strongly adsorbed components occurs, chromatography separates components in samples that are injected in a pulsatile manner. Elution of the components is achieved either in an isocratic mode, where the same mobile phase is maintained throughout, or by the gradient elution mode. In the former, the separation of components depends on the differences in the retention time of each component in the column. In the latter, the sample is introduced as a pulse and is followed by a different mobile phase containing a displacer.

Conventional batch chromatography is relatively simple and offers operating flexibility, but suffers from several drawbacks as well. To obtain high purity and yield (>99%), a large amount of solvent is needed and column utilization is inefficient.[18,19] To get around these disadvantages, continuous countercurrent chromatographic methods were developed. This mode of operation maximizes the mass transfer, but it is difficult to maintain a stable solid phase velocity.[19,20] An alternative to continuous countercurrent chromatography is to simulate the movement of the solid phase by periodically moving the inlet and outlet ports, while keeping the bed stationary. This mode of operation is called simulated moving bed chromatography and has the advantage of significantly higher

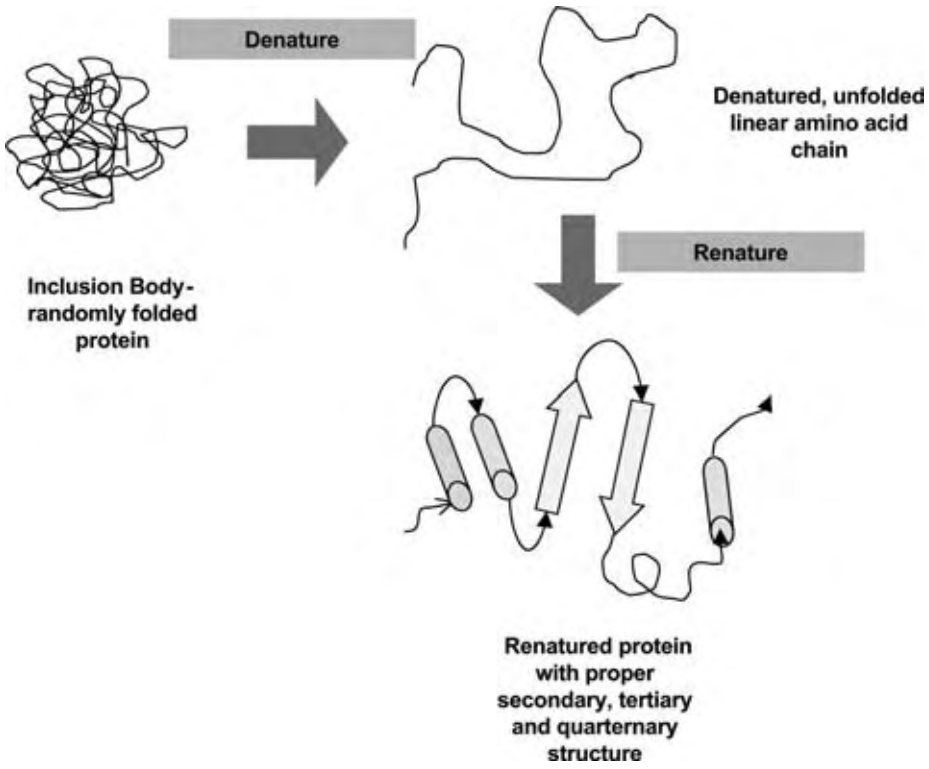

Fig. 4 Schematic depiction of the protein refolding process. *(View this art in color at www.dekker.com.)*

throughput per bed volume and low solvent use.[19] Column switching, chromatography with recycle, and reciprocating size exclusion chromatography in a semi-continuous frontal mode are refinements to conventional methods and can further reduce solvent use, increase peak resolution, and facilitate faster recovery of large molecules.[21–23]

The type of matrix in the column dictates the various kinds of chromatography techniques. All matrix materials need to be inert, chemically and physically stable to withstand the harsh cleaning procedures, be rigid to withstand the high flow rates, and have the porosity to provide a high surface area for adsorption. Matrices can be inorganic like porous silica, controlled pore glass, and hydroxyapatite, synthetic organic polymers like polyacrylamide, polymethyl methacrylate, or natural polysaccharides like cellulose, dextran, and agarose. The type of matrix often defines the basis of chromatography, be it size exclusion, ion exchange, hydrophobic interaction, or affinity. Table 4 summarizes the different types of chromatography and their basis of separation.

The pattern of separated proteins obtained on the detector is termed a chromatogram. The quality of a chromatographic separation can be quantitatively appreciated by calculating the hypothetical number of plates in the peak of a chromatogram (N). The theoretical plate height (H) is also often used as a parameter to quantify a chromatogram. Fig. 5 shows a typical peak in a chromatogram. N for such a peak and is given as:

$$N = 16\left(\frac{t_r}{t_w}\right)^2 \quad (1)$$

Table 4 Various types of liquid chromatography

Types	Basis	Application
Ion exchange	Ionic charge	Proteins
Gel filtration/size exclusion	Size	Desalting, large molecules
Affinity	Specific binding	Antibodies, antigens
Reverse phase	Hydrophobicity	Peptides
Hydrophobic interaction	Hydrophobicity	Proteins
Chromatofocusing	Isoelectric point	Proteins
Ligand exchange	Adsorption	Sugars

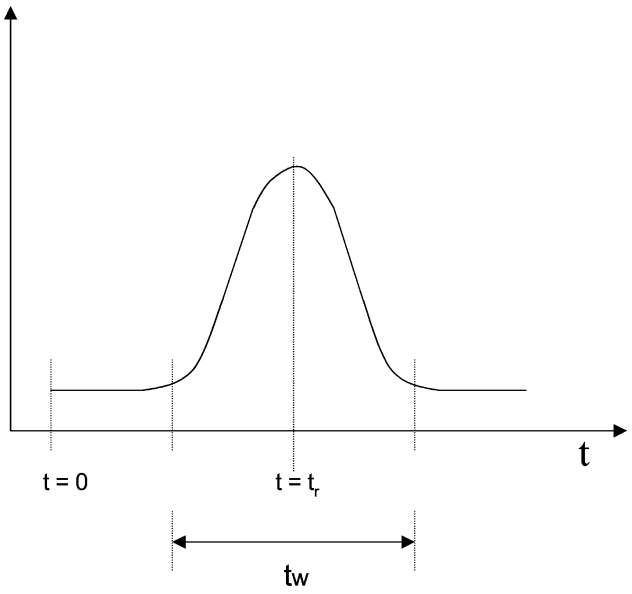

Fig. 5 Typical chromatogram peak characteristics.

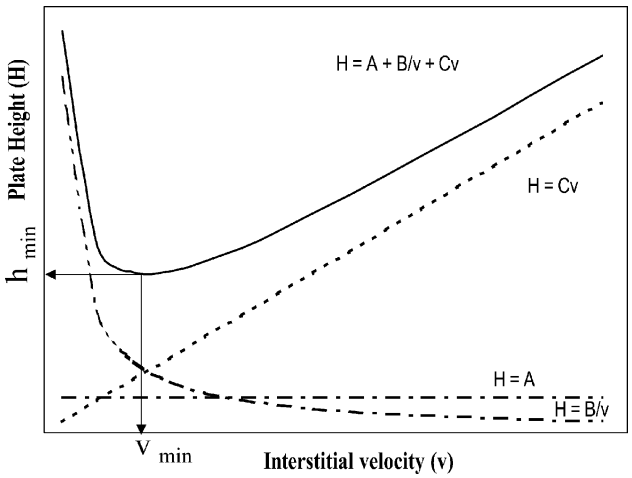

Fig. 6 Graphical representation of the van Deemter equation showing the effect of eluent velocity on the plate height of a chromatography column.

A greater number of plates indicate higher efficiency of separation. This implies that a smaller base width (t_w) will indicate a better resolution. Further, if each plate has a height H, then,

$$H = L/N \tag{2}$$

where L is the length of the column. Obviously, a lower plate height indicates a better resolution. H also depends on the interstitial velocity v of the mobile phase. The relation between H and v is given by the Van Deemter equation:

$$H = A + \frac{B}{v} + Cv \tag{3}$$

where A, B, and C are constants. Knowing the Van Deemter constants for a system can give an idea about the operating velocity at which resolution of the eluting peaks will be the best. As shown in the plot of H vs. v (Fig. 6), there is an optimum v at which H is minimum. Numerically, H is minimum when $v = (B/C)^{1/2}$.

POLISHING

After a series of chromatography steps yield a highly pure product in the liquid state, the product needs to undergo one or more steps to convert it to the form in which it will be sold. Drugs need to be formulated and mixed with binders, colors, and other excipients if they are sold in a solid form. They can also be sold as liquids or aerosols, suspensions or emulsions. In such a case, they need to be diluted and mixed at the correct concentration.

Bulk biochemicals like organic acids and solvents are often formulated as concentrated solutions after removal of water from the stream exiting from the final separation step. Antibiotics are usually crystallized from solution to a very high purity. Recombinant proteins are usually sensitive and can lose bioactivity if not stored in a proper manner. Proteins are formulated mostly as dry powders, and a variety of stabilizing agents are added to preserve the bioactivity of the protein.[12] Enzymes are usually freeze dried or lyophilized to obtain a solid form. Lyophilization basically sublimes the water to vapor under vacuum. It is a nondenaturing process and is used for drying pharmaceutical products, therapeutic proteins, food items, viruses, and bacteria. If the product is not very sensitive to heat, it can be dried by spray dryers, vacuum shelf dryers, or rotary dryers. These are well-known and widely used unit operations in the chemical industry. Details about these unit operations can be found in many classic chemical engineering handbooks.

CASE STUDIES

In this section, we try to develop downstream processing strategies for two different products: rhGDNF as an IB in *E. coli* and EPO as a protein secreted from CHO cells. The genomes of the two different organisms used have been genetically engineered to produce the proteins. The purpose of such an exercise is to learn to integrate the basic steps discussed so far in simulating an actual process. The cases will combine the spectrum of both intracellular and extracellular proteins as well as prokaryotic and eukaryotic expression.

Production of rhGDNF by *E. coli*

GDNF is an approximately 20 kDa, glycosylated polypeptide that exists in its native form as a homodimer.[24] The gene for GDNF has been mapped to human chromosome 5 at p12–p13.1 and gives rise to two alternatively-spliced forms that code for prepropeptides of 211 and 185 amino acid (aa) residues, respectively.[25] Both the long (alpha) and the short (beta) forms yield equivalent 134-aa residue mature forms after proteolytic cleavage.[24,26] Although the native molecule contains two potential glycosylation sites, nonglycosylated rhGDNF has full biological activity.[24]

GDNF has the ability to promote the survival and differentiation of dopaminergic neurons in primary cultures of the embryonic ventral midbrain.[24] It has also been found to have trophic effects on dopaminergic neurons (increasing the number surviving in culture, dopamine uptake, cell size, and extension of neurites). It also protects mecencephalic dopaminergic cells against the deleterious effects of the neurotoxin 1-methyl-4-phenylpyridinium (MPP^+).[27] This finding is central to the development of GDNF for the treatment of Parkinson's disease because the primate model of Parkinson's disease relies on the use of 1-methyl-4-phenyl,1,2,3,6-etrahydropyridine, a precursor to the neurotoxin MPP^+. By virtue of its effects on cell culture and efficacy in animal studies, GDNF constitutes a powerful therapeutic candidate for several neurodegenerative diseases, especially Parkinson's.[25,28]

For large-scale production of GDNF, *E. coli* is a very good choice as a host. It has several advantages in this case. First, nonglycosylated GDNF, though highly potent as a therapeutic agent, has a relatively small size (134 aa, MW ~15 kDa) and simple structure. Second, the recombinant nonglycosylated form is as functionally active as the glycosylated native form found in the human brain. In general, bacterial host systems cannot reproduce the authentic glycosylation of eukaryotic proteins, and in such cases where glycosylation is important for the protein to function, a more complex host system has to be chosen. For this case, therefore, *E. coli* is very suitable as a host for the production of rhGDNF. However, the recombinant protein often forms an IB in such a bacterial system. This causes problems in the extraction and downstream processing of the protein.

A flowsheet of the steps in downstream processing is given in Fig. 7. At the end of the fermentation, the cells are transferred into a blending tank, which isolates the upstream from the downstream section of the plant. The broth is then fed into a disk stack centrifuge and centrifuged to harvest the cells. The supernatant is centrifuged again and the cell sludges from both streams are resuspended in ice-cold buffer. The buffer facilitates the separation of the cell debris from the IBs. The suspension is maintained at 4°C to prevent heating and subsequent proteolytic degradation of the target protein during the cell lysis steps, which is done in a high-pressure homogenizer. The cell lysate from the homogenizer is a viscous extract. To reduce the viscosity, the lysate is treated with lysozyme (added to a final concentration of 100 μg/ml) and then homogenized again.

The second homogenized stream is then treated with half the volume of protease inhibitor cocktail (without ethylenediaminetetraacetic acid) to inhibit any proteolytic degradation of the target protein. It is then centrifuged and the IBs are recovered in the heavy phase while most of the cell debris remains in the supernatant. This is possible because the density (1.3 g/L) and the size (φ: 1 μm) of the IBs are significantly larger than the cell debris. The IB sludge is then washed with wash buffer containing Triton X100 to remove any loosely associated contaminants. The mixture is centrifuged, and the IB sludge is then resuspended in phosphate buffer solution (PBS) in a blending tank. The PBS is drained in a microfilter, and the IBs are transferred to a glass-lined blending tank and mixed with a solubilizing buffer. The solubilizing buffer contains urea solution, a chaotropic agent that dissolves the denatured protein in the IBs.

At the end of the solubilization, the solution is concentrated in a diafiltration unit. All the remaining fine particles (biomass debris and IBs) are removed using a polishing dead-end filter. This polishing filter protects the chromatographic units that are used next. The filtered stream is purified using anion exchange chromatography. Two quaternary amine Sepharose columns (Q-Sepharose, Pharmacia) work in parallel. The feed is applied with 10 mM Tris-HCl (pH 8.0) containing 4 M urea and the column is developed with a linear gradient of 0–0.5 M NaCl in this buffer.[24] The next step involves the removal of the SO_3 moieties from the cystine side chains in the rhGDNF to allow proper disulfide bonding and correct refolding of the protein to its native form. Pooled fractions from the Q-Sepharose column are mixed with 19 volumes of refolding buffer in a blending tank.[24] Dilution is necessary both in the solubilization and in the refolding steps to minimize the intermolecular interactions that can lead to protein inactivation.

At this stage, the stream contains the dissolved rhGDNF, which is then concentrated using a diafilter followed by a dead-end polishing filter to remove any non-native protein aggregates, and then subsequently fed with 50 mM Tris–HCl (pH 8.0) into two S-Sepharose (sulfonate based cation exchanger) columns working in parallel. The column is developed with a linear gradient of 0–1 M NaCl in this buffer.[24] Fractions containing rhGDNF are applied to a hydroxyapatite column in 25 mM sodium phosphate (pH 6.8). The purified protein

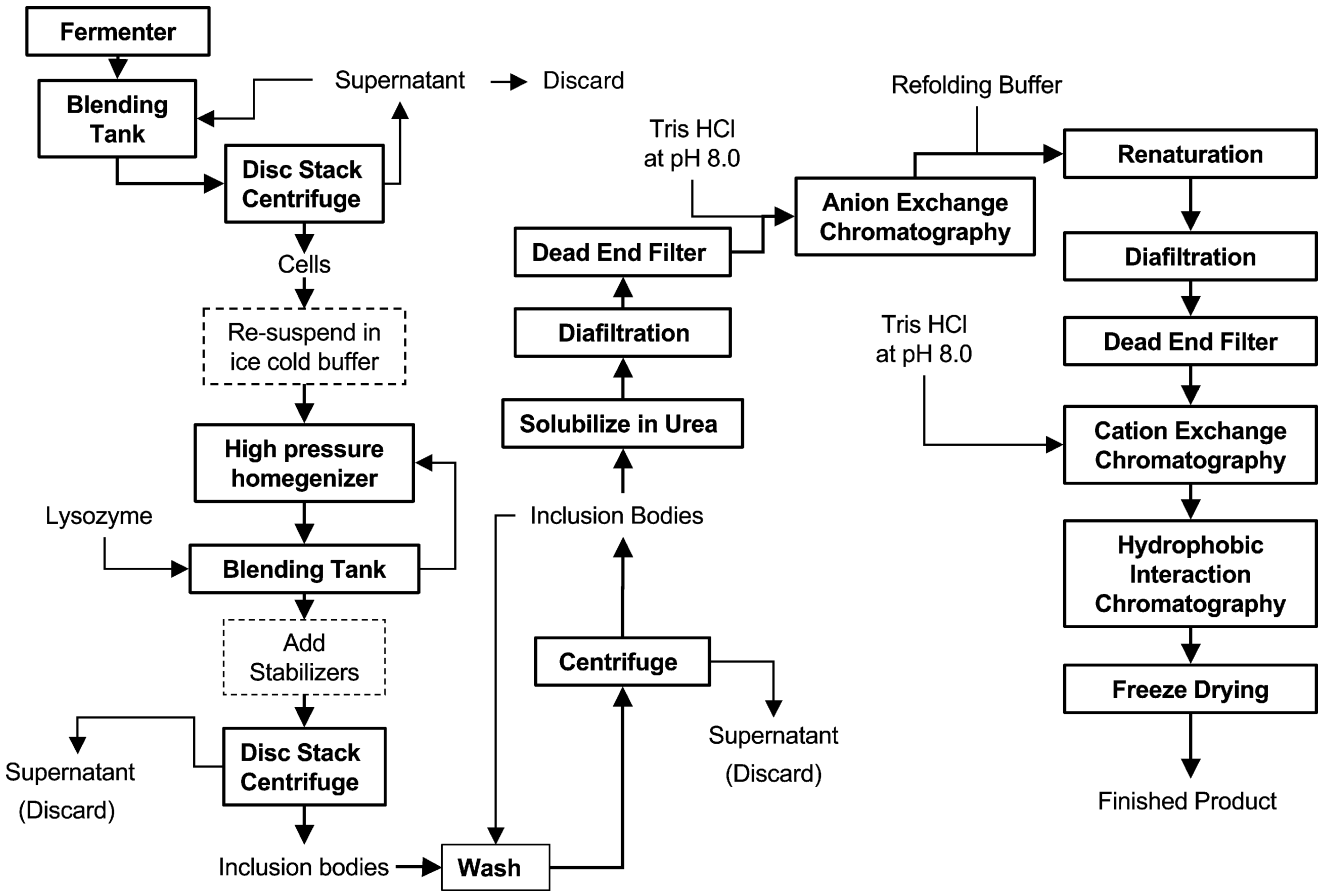

Fig. 7 A process flowsheet for rhGDNF production.

is lyophilized to yield a powdered form. It is 99.99% pure and contains <0.01% bacterial proteins and <5 pg/mg bacterial endotoxins.

Liew et al. reported that GDNF was a recalcitrant protein with a strong tendency to form IBs in *E. coli*.[29] However, insolubility has its advantages too:

a. Inclusion bodies can represent the highest yielding protein fraction of the target protein.
b. They are easy to isolate as an efficient first step in a purification scheme. Nuclease treated washed IBs are usually 75–95% of pure target protein.
c. Target proteins in IBs are generally protected from proteolytic breakdown.
d. The target protein is inactive and cannot harm the host if it is a potential toxin.

The steps followed in downstream processing of rhGDNF expressed in *E. coli* are very similar to any conventional method used to purify target proteins expressed as IBs in bacteria. However, the specific reagents used at different stages are decided after optimization at a lower scale. Alternative methods exist to substitute various steps in the process, but their applicability depends on the specific protein under consideration. For example, if we produce rhGDNF as a fusion protein with markers such as thioredoxin or glutathione *S*-transferase, then the protein is more soluble and, therefore, the purification strategy would be different and less cumbersome. Also, depending on the chemical properties of these markers, the chromatography steps would also change.

Production of EPO by CHO Cells

Epotein alpha or Epogen is an aqueous formulation of recombinant human EPO expressed in CHO cells. Erythropoietin is a 166-aa glycoprotein with an MW of 34 kDa.[30] It is heavily glycosylated with carbohydrates accounting for 38% of the MW.[31] Human EPO has three *N*-glycosylation sites and one *O*-glycosylation site.[32] Epogen is the trade name for recombinant EPO manufactured by Amgen and is formulated as a sterile colorless liquid in an isotonic sodium chloride/sodium citrate buffered solution for intravenous or subcutaneous administration in both preservative-free

single-dose and preservative (benzyl alcohol) containing multiple-dose vials. Johnson and Johnson, Ortho Biologics, and Kirin Pharmaceuticals (Japan) are some of the other companies manufacturing EPO.

The 2.7 billion dollars earned by EPO sales accounted for ~48% of Amgen's total revenue in 2002. However, with the market growing at ~23% by the last quarter of 2002, the sale of EPO products made nearly $7.8 billion in the U.S. market alone in 2004, making it by far the largest selling biopharmaceutical product ever.[33] In fact EPO sales in the United States is projected to reach a whopping $15 billion in 2010.[33] Erythropoiesis, the formation of red blood cells in the body, is regulated by EPO. Recombinant EPO expressed by CHO cells has a structural conformation similar to that of the native human protein and the market for recombinant EPO has been created because of its efficacy in relieving anemia in patients suffering from chronic renal failure.[30,31] Epogen increases the RBC levels in such patients, thereby alleviating the need for blood transfusions. Besides this well-established activity, EPO also has therapeutic potential in the treatment of stroke, head trauma, and epilepsy.[30]

Erythropoeitin is heavily glycosylated and its carbohydrate moiety has been shown to be important for its biological activity.[34] It is also sialylated, and this is crucial for in vivo biological activity.[35] Although almost all the EPO obtained earlier was just purified from human urine, the advent of recombinant DNA technology had many groups trying different methods to produce recombinant EPO.[36] However, the complex glycosylation pattern of the protein and the need for high sialic acid content make mammalian cell culture the best available option to produce EPO.

In large-scale production, EPO is produced by a CHO cell line under serum-free conditions by fed-batch fermentation.[36,37] The use of serum-free media makes the subsequent recovery of EPO much easier. CHOpDSVL-gHuEPO cells are grown as a suspension culture in bioreactors to produce EPO at a concentration of 200–300 mg/L.[32,36]

A flowsheet of the downstream processing steps is given in Fig. 8.[36] Postfermentation, the broth is cooled and clarified using a disk stack centrifuge followed by filtration. Care should be taken when choosing cell separation equipment because cell lysis at this point can contaminate the supernatant and make purification of the EPO difficult. Cell separation equipment specially designed for separating fragile eukaryotic cells, e.g., CSC6 [6000 m^2 ECA (which stands for effective calrification

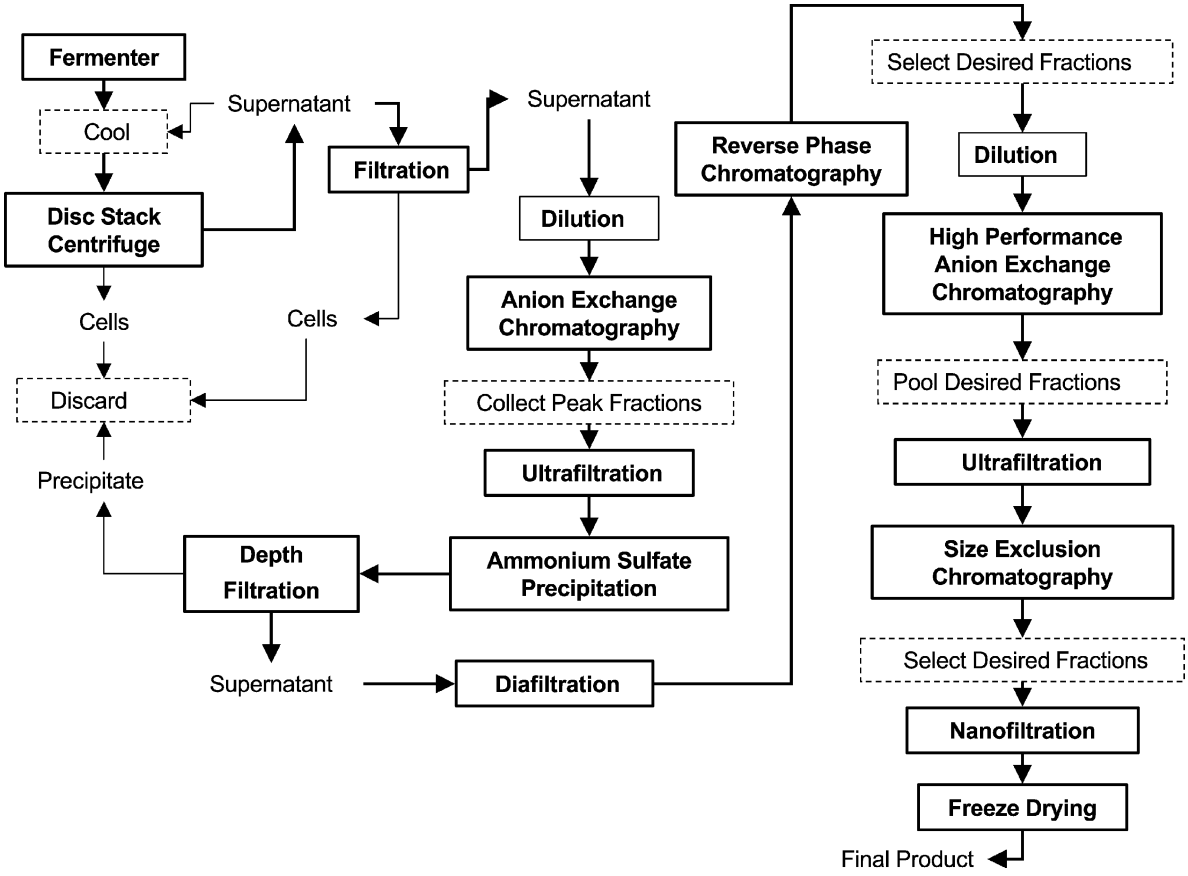

Fig. 8 A process flowsheet for rhEPO production.

area), 15,500× *g*, 200 L/hr, WestFalia], with hydrohermetic feed inlet, or BTPX 250 (11,000 m^2 ECA, 13,000× *g*, 300 L/hr, Alfa Laval), with gentle disk inlet, should be used to minimize shear stress induced lysis of the cells. Filtration is followed by another centrifugation step to further clarify the broth.

The crude extract after clarification is then diluted with water before being applied to an anion exchange chromatography column equilibrated with 20 mM Tris (pH 7.5) and 50 mM NaCl. The product is eluted by step elution and pooling the peak fractions gives a yield of ~50–60%. It is important to note that the capture step works at a neutral pH because a pH less than 6 would activate the endogenous proteases. The pooled fractions obtained from the anion exchange column are concentrated by UF and then further purified by using 2.4 M ammonium sulfate to precipitate the contaminating host cell proteins. At this concentration of ammonium sulfate, almost none of the EPO precipitates out. The salt concentration is then reduced using diafiltration to less than 240 mM.

The reversed phase chromatography step is then performed to remove different isoforms of the protein according to their sugar moiety and degree of sialylation, as well as viruses and the remaining host cell proteins. Acetonitrile is used as a solvent to elute out the protein, and because the heavily glycosylated and sialylated forms elute first, the first half of the eluting fractions is pooled together and diluted. The high-performance anion exchange chromatography then separates the different isoforms again, but this time according to their isoelectric point, and not the degree of hydrophobicity. As the degree of sialylation affects the isoelectric point, the column is an efficient way to separate the desired isoforms. The correct fractions are pooled together, concentrated by UF, and then subjected to size exclusion chromatography to remove any potential dimers or higher aggregates. The final step of dead-end NF removes any potential viral contaminants from the purified protein, which is then freeze-dried and sent for formulation.

CONCLUSIONS

To engineer living organisms to produce bioproducts of our choice is a relatively easy task compared to the process of recovering them from the fermentation broth. In most cases, the bioproduct is produced in very small quantities. Every single step in a downstream processing sequence not only increases the cost, but also decreases the product yield. Although novel chromatographic methods are increasing the specificity and yield for the products of interest, they are costly and difficult to scale up. However, it is to be realized that not all bioproducts need to go through every step outlined in this entry. Commercial enzymes are usually prepared as crude extracts, while polysaccharides and biogum recovery do not require as sophisticated purification steps as recombinant proteins.[7] Economics drives the industry, and therefore, innovation needs to be made both in the upstream part to increase productivity as well as in the downstream processing section to purify the product in as few steps as possible and yet to the highest degree achievable. In the foreseeable future, bioseparations will remain a challenging engineering field that must continue to develop to economically produce a myriad of recombinant therapeutic protein products currently under development and clinical trials.

Blowing Agent

Kyung W. Suh
Midland, Michigan, U.S.A.

INTRODUCTION

Cellular plastics, also known as plastic foams, or foamed plastics can be produced primarily by extrusion, injection molding, rotational molding, blow molding, thermal expansion, calendaring, mechanical frothing, or spray-on conveyors, using physical blowing agents (PBAs) or chemical blowing agents (CBAs). Most plastic foams are blown with inert gases (CO_2, N_2, H_2O), CBAs that release inert gases, hydrocarbons (HCs) containing three to six carbon atoms, chlorinated HCs, chlorofluorocarbons (CFCs) such as CFC-11 (R-11), CFC-12 (R-12), CFC-113 (R-113), and CFC-114 (R-114), hydrochlorofluorocarbons (HCFCs) such as HCFC-141b (R-141b) and HCFC-142b (R-142b), and hydrofluorocarbons (HFCs) such as HFC-152a (R-152a) and HFC-134a (R-134a). Since the theory of ozone depletion by chlorofluorocarbons was first published in 1974, extensive research has been conducted by government, academia, and industry to define the science and develop alternatives.[1–4] Emission of certain volatile organic compounds (VOC) generates smog photochemically. Because CFCs have low reactivity in the lower atmosphere, they will migrate to the stratosphere in about 10 yr, depleting ozone in the upper atmosphere and possibly affecting global climate change. Substitution of more photochemically reactive compounds such as HCs, HCFCs, and HFCs for CFCs may reduce the ozone depletion potential (ODP), as well as global warming potential (GWP) in the stratosphere, but may adversely affect indoor air quality in the lower atmosphere. Therefore, interaction with the total environment must be considered in developing nontoxic, environmentally acceptable blowing agents that are sustainable and economically viable.

NOMENCLATURE

A cellular plastic is defined as a two-phase gas–solid plastic system whose apparent density is decreased substantially by the presence of numerous cells or voids disposed throughout its mass. These cells or voids are chiefly formed by using CBAs, PBAs, microballoons, or fillers containing gases or liquids. If these cells are discrete and the gas phase of each is independent of that of the other cells, the material is termed closed cell. If these cells are interconnected, the material is termed open cell. The nomenclature of cellular polymers is not standardized; classifications have been made according to the properties of the base polymer, the methods of manufacture, the cellular structure, or some combination of these. According to an ASTM test, foamed plastics are classified as rigid or flexible.[5] A flexible foam is one that does not rupture when a 20 cm × 2.5 cm × 2.5 cm piece is wrapped around a 2.5 cm mandrel at a uniform rate of one lap per 5 sec, at 15–25°C. Rigid foams rupture under this test. This classification is used here. The term structural foam has not been exactly defined, but is used here to refer to rigid foams produced with densities greater than 320 kg/m^3. In the case of cellular rubber, the ASTM uses several classifications based on the method of manufacture.[6,7] Cellular rubber is a general term covering all cellular materials that have an elastomer as the polymer phase. Sponge rubber and expanded rubber are cellular rubbers produced by expanding bulk rubber stocks, and are open cell and closed cell, respectively. Latex foam rubber, which is also a cellular rubber, is produced by frothing a rubber latex or liquid rubber, gelling the frothed latex, and then vulcanizing it in the expanded state. Various blowing agents used to prepare cellular polymers may be classified according to the properties of the resultant foamed plastics. High-density structural foams are usually produced with CBAs. On the other hand, low-density foams with density less than about 320 kg/m^3 are typically produced with PBAs or a combination of both CBAs and PBAs. Cross-linked polyolefin foams can be produced with CBAs by heating rather than decompression.

PHYSICAL BLOWING AGENT

Selection of suitable blowing agents for each polymer is very important for producing dimensionally stable foams with the desired cellular structures and physical properties in various end-use applications. Some of the desirable properties of suitable blowing agents are as follows.

1. High solubility of blowing agents at high processing temperatures and low solubility at the

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120016152

ambient temperature are desirable for improving processability due to lower system pressure, better blowing agent mixing, better cell size control, and also for improving physical properties due to less plasticization of cellular polymers at the ambient temperature.

2. The permeability of the blowing agent or blowing agent mixtures through cellular plastics should be similar to or higher than that of air through the same cellular plastics. Nakamura showed in his patent that to produce a dimensionally stable foam, the permeability of a mixed blowing agent system should be between 0.75 and 6 times that of air through the same styrenic polymers.[8] However, this range of blowing agent permeability may be different depending on the type of polymer foams.
3. The heat of vaporization of a suitable blowing agent should be high at the foaming temperature to reduce the time to stabilize or solidify the foam after expansion by decreasing the temperature of the polymer phase as the blowing agent vaporizes and expands to produce cells or voids.
4. The rate of temperature drop with respect to the corresponding rate of pressure drop in an adiabatic expansion, known as Joule–Thompson co-efficient, should be large enough to make the expanding foam cool faster, and thereby the foam solidifies or sets up faster to produce low-density, dimensionally stable foam. The total internal cooling of the expanding foam consists of evaporative cooling by the heat of vaporization of the blowing agent and the adiabatic expansion cooling by the Joule–Thompson effect.
5. A suitable blowing agent or blowing agent mixture for the thermal insulation foam containing at least one or more insulating blowing agents should have low vapor thermal conductivity (preferably lower than about 0.015 W/m/K) and low gas permeability to produce a thermal insulation foam with low long-term K-factor. The long-term K-factor is defined as the aged K-factor when the foam is saturated with one atmosphere of air inside the cells. Suh showed that an insulating blowing agent as defined should have low permeability, less than about 1.0 cm^3mil/day per 100 in^2. atm [6.0×10^{-13} cm^3 (STP) cm/cm^2/sec/cmHg].[9,10] This will insure that a dimensionally stable low-density insulation foam with low long-term K-factor can be produced by using about 30/70 to 70/30 mixture by weight of one or more noninsulating gases [fugitive blowing agent = permeability greater than about 1.0 cm^3 mil/day per 100 in^2 atm or $6.0 \times 10^{-13}$$cm^3$ (STP) cm/cm^2/sec/cmHg] and one or more insulating gases.
6. A suitable blowing agent should have low toxicity, low odor, low flammability, low corrosiveness, low molecular weight, high specific gravity, non-VOC (photochemical reactivity not greater than that of ethane), low ODP, low GWP, and low cost.
7. A suitable blowing agent should have low vapor pressure at room temperature, which will facilitate easy handling under ambient condition.

Environmental Issues

A successful selection of blowing agent depends on many factors as described earlier and also on the ability to produce foams with the desired cellular structures, cross-sectional size and shape, and properties required in end-use applications. Therefore, foam developments often have been motivated by issues associated with the blowing agents. Currently, there are three environmental issues facing the blowing agents: plant emission of VOC, ozone depleting potential, and GWP. Table 1 shows the physical properties of potential blowing agents. In response to the growing scientific consensus that CFCs would deplete the ozone layer in the stratosphere, the U.S. government banned the use of CFCs in aerosols in 1979 and the United Nations Environmental Programme (UNEP) made a concerted effort to obtain international agreements aimed at protecting the ozone layer from 1981. In March 1985, the Vienna Convention for the protection of the ozone layer was convened and developed a framework for international cooperation in research, environmental monitoring, and information exchange. In September 1987, the Montreal Protocol on ozone depleting substances was signed by 24 nations and took effect on January 1, 1989. This treaty called for limiting production of specified hard CFCs, including CFC-11, -12, -113, -114, and -115, to 50 % of the 1986 levels by 1998. Dow was the first polystyrene foam producer to develop a formulation that replaced ozone depleting substances like CFC-12 with HCFC-142b, which has substantially reduced the ODP of the insulating blowing agent used to make insulation foams.[9,10,15,16] The Montreal Protocol was followed by further agreements to eliminate the use of HCFCs and also to reduce the release of greenhouse gases by reducing energy consumption (Kyoto Protocol). Many countries have since taken a more aggressive schedule for eliminating blowing agents that have ODP values greater than zero. Since the ban of CFCs in foam applications, polystyrene foam producers started to switch to HCFC-142b in 1989, and the polyurethane and phenolic foam industry made the transition to HCFC-141b. Of the common HCFCs, 141b has the highest ODP. As a result, it was targeted for phaseout

by January 1, 2003, while other products had until 2005. Recently, attention has been focused on the GWP of the blowing agents. This is an area that is unsettled at the present time, but is expected to become a significant consideration in the use of certain blowing agents. An especially important point to consider is that the best alternatives for desirable insulating gases are HFCs.[9,10,17] The HFC alternatives have zero ODP and, furthermore, GWP values much lower than those of hard CFCs or HCFCs. Dow and BASF have independently developed polystyrene foam formulations that do not contain HCFC or HFC blowing agents.[18–22] Because these foams do not contain captive blowing agents that have desirable insulating properties, infrared attenuators have been employed to improve the thermal conductivity of the foam products.[23,24] Certain organic compounds generate smog photochemically (VOC). Because halogenated HCs have low reactivity in the lower atmosphere, substitution of photochemically reactive compounds for the current blowing agents may reduce the ozone depletion in the stratosphere, but could adversely affect the indoor air quality. Therefore, interaction with the total environment must be considered in developing environmentally acceptable blowing agents.

Solubility and Permeability

The solubility of a blowing agent in a polymer at any temperature and pressure can be approximately predicted by using the Flory–Huggins equation as a first approximation:[25–29]

$$\ln a = \ln v_o + (1 - 1/m_n)v_p + xv_p^2 \quad (1)$$

where

$$a = f/f^o = p/p^o \quad (2)$$

and a = activity, f = fugacity, f^o = fugacity of pure blowing agent, p = vapor pressure above the polymer solution, p° = vapor pressure of pure blowing agent, v_o and v_p = volume fraction of blowing agent and polymer, respectively, m_n = number average chain length of the polymer, and x = Flory–Huggins interaction parameter, which can be expressed as

$$x = 0.34 + V_o(d_o - d_p)^2/RT \quad (3)$$

where $V_o$is the molar volume of the blowing agent, and d_o and d_p are the solubility parameter of blowing agent and polymer, respectively. For high molecular weight polymers, $m_n$becomes very large and $(1 - 1/m_n)$ is reduced to 1. For blowing agent mixtures, the above equations may be expressed as follows:[26–28]

$$\ln a_m = \ln v_m + (1 - 1/m_n)v_p + xv_p^2 \quad (4)$$

where

$$a_m = f_m/f_m^\circ = p_m/p_m^\circ \quad (5)$$

$$p_m = \sum_{i=1}^{n} p_i y_i \quad i = 1, 2, 3, \ldots, n \quad (6)$$

$$p_m^\circ = \sum_{i=1}^{n} p_i^\circ y_i \quad i = 1, 2, 3, \ldots, n \quad (7)$$

$$x = 0.34 + V_m(d_m - d_p)^2/RT \quad (8)$$

$$v_m = \sum_{i=1}^{n} v_i \quad i = 1, 2, 3, \ldots, n \quad (9)$$

$$v_o + v_p = 1 \quad (10)$$

$$v_m + v_p = 1 \quad (11)$$

$$1/V_m = v_1/V_1 + v_2/V_2 + \cdots \quad (12)$$

$$d_m = d_1v_1 + d_2v_2 + \cdots \quad (13)$$

Here, Scott's ''single-liquid'' approximation was used in evaluating d_m and V_m values. This is a good approximation if the interaction of blowing agents with the polymer is very small as compared to the interaction between the two blowing agents.[30] For more accurate approximation, the equation of state proposed by Sanchez and Lacombe or by Panayiotou and Vera may be used but may require experimentally determined interaction constants for specific compounds.[31–33] For most engineering purposes, however, the Flory–Huggins equation may be sufficient for predicting the solubility of potential blowing agents in a given polymer. Accurate prediction of solubility of blowing agent in a molten polymer flowing through the extrusion process is very difficult because of the fact that the blowing agent and molten polymer mixture are not in an equilibrium state but in a dynamic state. Therefore, dynamic solubility rather than equilibrium solubility is required to predict the solubility of potential blowing agents in the extrusion process. This may be one of the reasons why it is so difficult to predict the rheology, pressure drop in the process equipments, foam nucleation, and foam expansion rate. In the mid-1970s, Suh developed a concept and coined the term ''critical dynamic system pressure'' over the blowing agent/polymer mixture in the extrusion process in Dow and used the dynamic solubility for the process control in producing low-density extruded

foam products of good quality.[34,35] The critical dynamic system pressure is defined as the minimum system vapor pressure required to keep the equilibrium amount of blowing agent dissolved in the molten polymer, which is considerably higher than the equilibrium vapor pressure above the solution. Details of this predictive method are not within the scope of this chapter. Permeability of blowing agents through plastic foams depends on the diffusivity of the blowing agent through the foam, its solubility in the polymer, open cell content, foam density, and cellular structure.[36–40] The permeability of the gaseous blowing agents through the plastic membrane can be expressed as a product of diffusion constant and solubility in the polymer as follows:

$$P = DS \tag{14}$$

Permeation of the blowing agent through a plastic membrane can usually be treated as an activated process with an activation energy E_p and permeability at the standard or room temperature

$$P(T) = P_o \exp(-E_p/RT) \tag{15}$$

There are many empirical correlations and theoretical treatments for predicting solubility, diffusivity, and permeability constants.[41] Table 2 shows the permeability and solubility data for gases in polystyrene and low-density polyethylene. In the extrusion process, the polymer is plasticated in the extruder and the blowing agent is mixed with molten polymer, which is cooled down to the foaming temperature and expanded against atmospheric or subatmospheric pressure to produce a low-density extruded foam. The pressure inside the cells decreases from the system pressure at the beginning of the foam expansion to slightly higher than ambient pressure as the foam expands to the final density. As the foam temperature decreases, the foam begins to solidify and reaches ambient temperature. The cell pressure experiences a partial vacuum as a result of PVT relationship. If a blowing agent or any major component of the blowing agent mixture has a permeability higher than that of air, the cell pressure decreases further before increasing as the air starts to permeate into the foam. On the other hand, if a blowing agent or any major component of the blowing agent mixture has a permeability much lower that that of air, the cell pressure starts to increase continually and reaches a maximum pressure considerably higher than the atmospheric pressure when the foam becomes saturated with one atmosphere of air and then the cell pressure decreases to atmospheric pressure as the low-permeability blowing agent diffuses out during the aging period. Therefore, one has to consider dimensional stability during aging at these cell pressure extremes depending on the permeability of the blowing agent used and also on the strength of the polymer. If the cellular polymer does not have enough strength to withstand these pressure extremes, the foam

tends to collapse at the minimum cell pressure and also tends to expand at the maximum cell pressure. The permeability of a blowing agent through polyethylene can be modified to improve the dimensional stability of the foam by combining the polymer with low-permeability polymers or by adding a small amount of a partial ester of a fatty acid to the polymer.[42–45] These formulation and process innovations have allowed Dow to make blowing agent changes from CFC-114 to HCFC-142b in 1989, which in turn was replaced with hydrocarbon blowing agent in 1994.[46–48] Hydrocarbons have several drawbacks including flammability, high permeability, and VOC concerns.

Organic PBA

The original concept of cellular polystyrene is credited to the Swedish inventors Munters and Tandberg, who filed a patent on ''Foamed Polystyrene'' in 1931, and subsequently obtained U.S. patent 2,023,204 in 1935 using methyl chloride, CO_2, and others. In 1941, The Dow Chemical Company began to develop a commercial process known as the Tower Process for the production of cellular polystyrene using a low-boiling compound such as butylene or methyl chloride.[49] In the late 1940s through 1950s, the first continuous extrusion process for producing a polystyrene foam was developed, and it is still the basis for the manufacture of polystyrene foams and polyolefin foams developed by Rubens using CFC-114 as well as other thermoplastic foams.[50,51] In 1963, Dow converted the process to a mixed blowing agent containing methyl chloride and CFC-12 to improve the dimensional stability of polystyrene foam board by attempting to match the permeability of blowing agent mixture with that of air through the foam. Polyurethane foams were developed by Otto Bayer and associates in Germany in the early 1940s using water-generated carbon dioxide as a blowing agent.[52] This blowing agent was subsequently replaced with CFC-11 to improve the cell uniformity and the K-factor of polyurethane foam or polyisocyanurate foam. The first cellular synthetic plastic was phenol–formaldehyde resin produced unintentionally by Baekeland and others in this field.[53] The elimination of cell formation produced by steam generated during the reaction of these resins, as described by Baekeland in his 1909 patent, is generally considered the beginning of the plastic industry. Foams produced in this way have nonuniform and coarse cell structures with large voids or blowholes. Therefore, volatile liquids or CBAs are incorporated into phenolic foam formulations to control cell size, cell morphology, and foam density. Volatile liquids such as CFC-113 and other polyhalogenated saturated fluorocarbons with a boiling point between 30°C and 100°C were preferred blowing agents for producing phenolic foams with more uniform, finer cell sizes having improved flame retardancy and thermal insulation value.[54] The ideal CFC replacement must be non-VOC, nontoxic, and must have zero ODP and a short atmospheric lifetime to ensure a low GWP. The general strategy of The Dow Chemical Company was to develop a two-stage replacement program in co-operation with Pennwalt Corp. (now AtoFina), Du Pont, and Allied Chemical Corp. (now Honeywell). The first stage of the program was to incorporate at least one hydrogen in the proposed CFC substitute's structure, which provides a destruction mechanism via hydrogen atom abstraction by troposphere hydroxyl radicals.[9,10] The HCFCs, especially HCFC-141b, HCFC-142b, HCFC-22, were selected as the optimum intermediate replacements for CFC-11 and CFC-12, respectively.[10,15,16] The second stage of the program was to replace all chlorine atoms in the structure with hydrogen (HFC-134a, -143a, -152a) to obtain zero ODP.[17] The HFCs such as HFC-245fa, -365mfc, and HFC-134a, -143a, -152a have been considered as the optimum replacements for HCFC-141b and HCFC-142b, respectively.[55]

Hydrocarbons with C_1–C_6 and chlorocarbons such as methyl chloride and ethyl chloride have been also used for producing plastic foams as a single blowing agent or as a coblowing agent to facilitate the processability and to provide the performance and structural properties required in the end-use applications. Some of these compounds have concerns with flammability, VOC, toxicity, or cellular structures. There are many techniques to introduce fluorine into organic compounds, but hydrogen fluoride (HF) is considered to be the most economical source of fluorine for many industrial applications. Although HF is a relatively ineffective exchange agent when used alone, it readily replaces only active halogens as shown below for the commercial production of CFCs and HCFCs by the successive replacement of chlorine with fluorine using HF:[56]

$$CHCl_3 \xrightarrow{HF} CHCl_2F + CHClF_2 + CHF_3 \quad (16)$$

$$CCl_4 \xrightarrow{HF} CCl_3F + CCl_2F_2 + CClF_3 \quad (17)$$

$$CCl_3CCl_3 \xrightarrow{HF} CCl_2FCCl_3 + CCl_2FCCl_2F + CClF_2CCl_2F + CClF_2CClF_2 \quad (18)$$

$$CH_3CCl_3 \xrightarrow{HF} CH_3CCl_2F + CH_3CClF_2 + CH_3CF_3 \quad (19)$$

Hydrofluorocarbons are also produced from acetylene or olefin and HF. A commercial production of 1,1-difluoroethane, HFC-152a, is conducted in the

vapor phase over an aluminum fluoride catalyst:

$$C_2H_2 + 2HF \xrightarrow{\text{catalyst}} CH_3CHF_2 \quad (20)$$

Inorganic PBA

The most widely used inert inorganic PBAs are CO_2,N_2, and water. Although these compounds are environmentally acceptable, each has some drawbacks as a single blowing agent. CO_2 and N_2 have very low solubility in most polymers and zero heat of vaporization at their foaming temperatures. Therefore, they require very high system pressure to dissolve enough blowing agent to produce a low-density foam. They also tend to produce a very small cell size and ''hot foams'' at the center of the foam board, which makes it very difficult to produce an extruded low-density foam with a large cross section without possible thermal collapse at the center of foam boards of very low density. The CO_2 blowing agent was first used commercially by The Dow Chemical Company in 1982 as a coblowing agent to produce the Styrofoam brand polystyrene insulation foam products.[15] Since then, Dow has led the development of blowing agent technology and the process innovations necessary for successful implementation of HCFC-142b globally to reduce the ODP and subsequently HFC-134a or 100% CO_2 blowing agent systems in some countries of Europe to entirely eliminate ozone-depletion concerns.[17,19,20,34] The use of cell size enlarging agents may be necessary with HFC-134a or 100% CO_2 blowing agents to control the cell size for different applications.[57,58] Water blowing agent is corrosive, especially when used with a halogenated flame retardant. It also lacks the blowing power to produce low-density extruded thermoplastic foams. However, it should be considered as an alternative blowing agent because of its environmental acceptability and low cost.[23,59–62] Water can also be used for producing polyurethane foams by reacting with isocyanates to generate urea and CO_2, which acts as a foaming agent. This water-generated CO_2 may increase the density and flammability of the resultant polyurethane foams.

Mixtures of organic and inorganic PBAs

There are advantages and disadvantages in using one or more organic PBAs or one or more inorganic PBAs. Organic PBAs provide processability and performance properties, whereas inorganic PBAs provide better environmental acceptability at the expense of processability and performance properties. However, mixtures of organic and inorganic PBAs may provide the best possible options to minimize the environmental issues while maintaining the performance properties required in end-use applications. Mixtures of water or CO_2 with HCs, chlorocarbons, HCFCs, or HFCs may be such examples.[15,21,22]

CHEMICAL BLOWING AGENT

Chemical blowing agents are normally used in producing high-density structural foams such as polyolefin insulation materials for coaxial wires and cables, polystyrene extrusion profiles, sheets, pipes, and other flexible or semiflexible cellular polymers such as cellular rubbers, latex foams, PVC foams, etc. In chemical foaming process, the expanding gas is generated in situ as a by-product of a chain extension or cross-linking of the polymer, as in the decomposition of CBA by adding CBAs to the polymer under heat, or as in the formation of polyurethane foams or polyisocyanurate foams by adding water reacted with isocyanate groups generating CO_2, or as in the condensation of phenol and formaldehyde producing water as a by-product in the form of steam, which is capable of foaming the resulting phenolic resin. The process for producing low-density polyolefin foams normally has three separate stages: sheet formation, cross-linking, and foaming. In real situations, there may not be three distinct separate stages depending on the process and the type of polymer, but there may be some overlaps and sometimes concurrent operations may take place at different rates to control the process and product properties. The selection of a suitable CBA depends on the type of polymer and process used, the type of cross-linking, radiation or chemical cross-linking, and the shape and form of the final foam products desired. The key desired properties of suitable blowing agents are given below:

1. The decomposition temperature of the CBA should be higher than the melting point (T_m) or glass transition temperature (T_g) of the polymer. The blending operation of CBA and the polymer should be conducted at a temperature sufficiently above T_m (close to the order–disorder temperature $T_{od} = T_m$ or $T_g + 55°C$) but preferably below the decomposition temperature of the CBA.
2. The amount of gas yield should be large.
3. The gas should be released within a narrow temperature range.
4. The rate of gas release should be rapid, and controllable by temperature, pressure, and the type and concentration of decomposition activators.
5. The decomposition products of CBA should be noncorrosive, nontoxic, nonflammable, colorless, and environmentally acceptable.

6. The CBA and the gas released should be readily dispersed in the polymer.
7. The decomposition products of CBA should not affect the rates of nucleation, polymerization, cross-linking, and decomposition of CBA.

Various CBAs are used in producing cellular polymers. They are either organic or inorganic compounds that decompose under the influence of heat to yield at least one gaseous decomposition product. They are either exothermic or endothermic but the effect of heat release or heat intake should not be large enough to cause polymer degradation or polymer temperature control. Table 3 shows the physical properties of potential CBA.

Organic CBA

The most widely used organic CBA is azodicarbonamide (ADC), also known as azobisformamide (ABFA). The decomposition of this compound is first order according to the following reaction:

$$H_2N–CO–N=N–CO–NH_2 \longrightarrow NH_3 + CO + N_2 + HNCO \quad (21)$$

For all practical purposes, ADC and its residues are odorless, nondiscoloring, and have low flammability, good storage stability, and good dispersability in all elastomers and plastics. Although the ADC decomposition temperature is relatively high, it can be modified by adding numerous activators such as heavy metal salts to reduce the decomposition temperature range to as low as 130–220°C from 190–220°C. This decomposition range makes it particularly suitable for producing a wide range of cellular polymers including styrenic and olefinic polymers, vinyls, rubbers, and elastomers. Because the gas yield of ADC is the highest among commercially available organic blowing agents, it is very economical to use for many applications. However, caution should be used in the generation of NH_3, which may cause rusting and staining of molds as well as polymer degradation. Various grades of modified ADC are available from the manufacturers for improving flow characteristics, dispersability, mold plate-out, and storage stability. Different particle sizes are also available from the manufacturers for improving dusting, cell size control, activator efficiency, and compatibility with polymer matrix. Both activators and particle size affect the decomposition rate. The smaller the particle size, the more effect activators will have on the decomposition rate. Common examples of strong activators are zinc oxide, zinc stearate, dibasic lead phthalate, and dibasic lead phosphite, while dibutyl tin dilaurate and barium/cadmium stearate combinations are mild activators. Table 4 shows the effect of activators on the decomposition temperature of ADC. Among other aliphatic azocompounds, azobisisobutyronitrile and dinitrosopenta-methylene tetramine may deserve some consideration. The former has limited applications owing to toxicity of the residue, and the latter is a widely used blowing agent in the rubber industry but of limited use in the plastics industry owing to its high decomposition exotherm and the unpleasant odor of its residue.[11] However, *N*,*N*′-dimethyl-*NN*′-dinitrosoterephthalamide has a low-decomposition exotherm, which is very suitable for producing thick cellular vinyl polymers without concern for the polymer degradation inside the thick sections of the foam caused by the high-decomposition exotherm of most organic CBAs. Of the many commercially available sulfonyl hydrazides, only 4,4′-oxybis(benzenesulfonyl hydrazide) (OBSH) is of commercial importance in the extrusion of cellular polyethylene for wire insulations, in casting PVC foams, and in rubber-resin blends.[11] It is also used to simultaneously expand and cross-link the polymer.

Inorganic CBA

The most important inorganic CBAs are sodium bicarbonate and sodium borohydride, which decompose by endothermic reaction, generating water/CO_2 and hydrogen, respectively. The former takes advantage of the chemical reactivity of inorganic bicarbonates with acidic compound to generate carbon dioxide, which is much faster than the thermal decomposition of sodium bicarbonate in the absence of acidic compound. The latter is based on the reaction with water or steam to generate copious amounts of hydrogen gas at very high rates. The most common acid and bicarbonate systems are based on sodium bicarbonate and citric acid, which are available as 100% powders or as concentrates in low molecular weight polystyrene or polyethylene carriers. The concentrate products are available in up to 70% of active concentrates and may contain various additives to improve the dispersability, cell size uniformity, screw slippage problem, and so on. The acid/bicarbonate systems are typically used as nucleators and also as blowing agents in the extrusion process as well as in the injection molding process or structural foam molding process.

The other bicarbonate system of some importance is ammonium bicarbonate, which decomposes in the range of 40–60°C. This material is difficult to process owing to the low decomposition temperature and high rate of decomposition with liberation of strong ammonia odor in the extrusion or injection molding processes. However, ammonium bicarbonate can be

Table 3 Physical properties of potential chemical blowing agents

Blowing agent	Trade symbol	Decomposition temperature (°C)	Gas yield (cm^3/g)	Decomposition products		Trade name (supplier)
				Gas type	Residue type	
Azodicarbonamide (1,1′-azobisformamide)	AZ (ABFA)	200–215	220	36 wt%	64 wt% Biuret, cyanuric acid, cyamelide, urea, triuret	Kempore (Uniroyal)
				N_2 65%		Celogen (Uniroyal)
				CO 32%		Porofor (Mobay/Bayer)
				CO_2 3%		Azofoam (Biddle Sawyer)
						Unicel (Dong Jin)
						Azo (Dong Jin)
						Ficel (Schering Berin)
N,*N*′-Dimethyl-*N*, *N*′-dinitrosoterephthalamide	DTA	90–105	126	N_2	Esters of terephthalic acid	Nitrosan (Du Pont)
Dinitrosopenta-methylenetetramine	DNPT	200–205	240	N_2, NO	Water, formaldehyde, amines	Opex (Uniroyal)
						DNPT (Dong Jin)
						Unicell (Dong Jin)

Table 4 Activators for ADC

Activator system	Decomposition temperature (°C)	Polymers
None	200–220	PP, PS, HDPE, EVA, ABS, SMA, polyolefin copolymers, blends, cross-linked polymers
Silica/ZnO	190	LDPE, EVA, LLDPE
Dinitrosopentamethylene tetramine	155	EVA, LDPE, ionomer
Zinc sulfide	170	Polyolefin, LLDPE, HDPE, ionomer

PP, polypropylene; PS, polystyrene; HDPE, high-density poylethylene; EVA, ethylene vinyl acetate; ABS, acrylonitrile–butadiene–styrene; SMA, styrene maleic anhydride; LDPE, low-density polyethylene; LLDPE, linear low-density polyethylene. (From Ref.[12].)

used as a blowing agent and cross-linking agent that consumes ammonia, eliminating the odor problems associated with ammonia liberation. Caution should be used in handling ammonium bicarbonate for the possible liberation of ammonia during storage and its effect on health and corrosive properties.

SOLID ADSORBENT CONTAINING VOLATILE LIQUID

Many solid adsorbents liberate gas as a result of desorption of volatile liquids under the influence of heat. Typical adsorbents with microporous structures such as activated carbons, or precipitated silicas and renewable resources have been used as a coblowing agent in producing low-density extruded polystyrene foam boards.[63–65] Incorporation of corn cobs or other renewable vegetable matter containing about 10% water together with a primary PBA into polystyrene in the extrusion process produced a low-density polystyrene foam board with bimodal cellular structures. This type of foam with bimodal cell structures has about 10–15% lower K-factor than similar foams without bimodal cellular structures.[65] Similar results were obtained with a precipitated silica for producing a low-density extruded polystyrene foam with bimodal cellular structures.[63,64]

SAFETY AND ENVIRONMENTAL ASPECTS

Flammability

Among the blowing agents, HCs and some of the HCFCs and HFCs are flammable and pose a fire hazard in handling at the manufacturing plants. Plastic foams are organic in nature and, therefore, are combustible. All plastic foams containing flammable blowing agents should be handled, transported, and used according to the manufacturers' recommendations and local and national regulations.

Atmospheric Emissions

Certain organic compounds are found to be smog generating substances (VOC) because of their high photochemical reactivity at ambient conditions, Substitution of photochemically reactive compounds for the current blowing agents may reduce the ozone depletion in the stratosphere, but may have unacceptable GWP and air quality in the lower atmosphere. Therefore, the interaction of the blowing agent with the total environment needs to be considered in developing environmentally acceptable alternative blowing agents.[66]

CONCLUSIONS

In the past decade, significant advances have been made in the selection of environmentally acceptable alternative PBAs for a given polymer to comply with government regulations and local codes. However, there has been very little change in the use of CBAs except that much improvement has been made in the areas of product quality and formulation flexibility.

Some of the important factors to consider in the development of alternative physical blowing agents are solubility, permeability, boiling point, vapor pressure, flammability, toxicity, VOC, ODP, GWP, availability, and cost. Similarly, the key important factors to be considered in the selection of CBAs for a given polymer are decomposition temperature, gas yield, rate of gas release, environmentally acceptable decomposition products, toxicity, and dispersability in the polymer matrix.

Finally, the processability, performance properties, and cellular morphology of the products play key roles

in the successful commercialization of alternative blowing agents that are environmentally sustainable.

INTRODUCTION

Long-chain branching (LCB) affects a variety of polymer properties from dilute to melt state. Because many commercial polymers often contain a fraction of branched material, understanding the relationship between polymer properties and molecular architecture is of tremendous importance. This entry deals with the detection of branching in polymers in two parts. It begins with a description of the most important and the most well established solution and rheological properties influenced by branching. Solution studies have shown that a branched molecule is more compact than a linear analog and that various contraction factors can be used to quantify the reduction of a molecule's size because of branching. Rheological investigations have revealed two opposing effects attributed to LCB. Branching leads to a reduction in the size of a polymer molecule and, in turn, fewer entanglements. However, when the branches reach a critical length, the overall number of entanglements is increased. With an understanding of the impact of branching on polymer properties, methods to detect or estimate LCB can be devised. Methods based on spectroscopic, chromatographic, and rheological techniques are the focus of the second section of this entry. Although both spectroscopic and chromatographic methods are extremely useful in the characterization of polymers, they are unable to detect the very low levels of branching that can still alter a polymer's flow behavior. The drawback of rheological methods is that the rheology of such polymers is still not fully understood. As a result, the analysis by such methods is frequently qualitative.

BACKGROUND

The occurrence of branching was postulated, roughly 70 years ago, by Staudinger and Schulz to explain certain unexpected observations with polystyrene.[1] Flory later showed that transfer reactions during the free radical polymerization of styrene could produce long-chain branches.[2] Already by the early 1950s, a noteworthy amount of work dealt with the mechanism and kinetics of branching reactions, the effect of branching on polymer properties, and the possible determination of LCB. In 1953, Stockmayer and Fixman reviewed the state of dilute solution properties of branched polymers.[3] Since that era, numerous reviews of branching have been compiled. In 1968, Graessley summarized the methods for the detection of branching based on dilute solution methods.[4] In the same year, Dexheimer et al. compiled a list of studies dealing not only with the effects of branching on polymer properties but also the kinetics and mechanism of branching.[5] Small wrote a notable review of long-chain branching, examining its influence on various polymer properties, and its estimation.[6] More recent reviews include works by Burchard[7,8] and Mays and Hadjichristidis,[9] who examined the solution properties of branched macromolecules, and Roovers,[10] who provided a comprehensive survey of the literature for branched polymers in general. Reviews on the effect of branching in the melt state include those of Graessley[11] and Vega et al.[12]

Branched polymers can have various structures depending upon their synthesis. A great deal of research has involved the synthesis of model branched polymers[13,14] with narrow molecular weight distributions (MWD) to specifically observe the effect of branching. These results help to construct fundamental theories, which can be used in the investigation of randomly branched polymers.

BRANCHED POLYMER PROPERTIES

Dilute Solution Properties

Mean-square radius

The size of a macromolecule is one of its most fundamental properties. Although there are several ways to

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120027021

represent the dimensions of a polymer chain, the mean-square radius is a typical measure of size, given by the following:

$$\langle s^2 \rangle = \left\langle \sum_{i=1}^{N} \frac{r_i^2}{N} \right\rangle \quad (1)$$

where the polymer molecule is considered to be comprised of N small elements of identical mass and r_i is the distance of the ith unit from the polymer molecule's center of gravity. The use of angled brackets denotes that the summation is averaged over all possible conformations that the polymer chain can assume. The term radius of gyration is widely used when referring to a polymer molecule's size and is simply the square root of the mean-square radius:

$$R_g = \langle s^2 \rangle^{\frac{1}{2}} \quad (2)$$

Theoretical calculations for the mean-square radius of gyration usually assume that a polymer molecule can be represented by a random flight chain made up of N freely jointed units. Discrepancies between the model and actual chains arise for two reasons, known as short- and long-range effects. The short-range effects are because of units not being completely free to rotate but having bond restrictions, while long-range effects occur because intersections of units are impossible. Short-range effects are addressed by dividing the polymer chain into longer segments of several bonds so that each unit can be considered to be freely jointed. If long-range effects, also known as volume exclusion, are absent, then chains obey the random flight model and take an ''unperturbed'' state. In this case, the mean-square radius is represented by $\langle s_0^2 \rangle$ (the subscript 0 denotes an unperturbed value). From the work of Flory,[15] it can be seen that long-range effects are nonexistent at the θ point (particular temperature, T_θ, for a specific solvent) and

$$\langle s_0^2 \rangle = \langle s_\theta^2 \rangle \quad (3)$$

Compared to a linear chain of the same number of units, a branched chain is more compact. As a result, the impact of branching on the size of a polymer chain is to decrease the mean-square radius as branching increases. To assess the decrease in size because of branching, the mean-square radius of a branched polymer is compared to the size of a linear analog of identical molecular weight. Quantitatively, this was defined by Zimm and Stockmayer[16] with the following branching or contraction factor:

$$g = \left. \frac{\langle s^2 \rangle_{br}}{\langle s^2 \rangle_l} \right|_M = \left. \frac{R_{g\,br}^2}{R_{gl}^2} \right|_M \quad (4)$$

The subscript M indicates that both the branched (br) and the linear (l) chains have identical molecular weights. Because branched polymers are more compact and have smaller dimensions, g will always be less than unity with smaller values being an indication of a higher amount of branching. Theoretical equations for the calculation of contraction factors for various types of branching have been developed and are given in Table 1. Although it is not a complete list of the results in the literature, Table 1 does summarize the earlier work which provided expressions for more common types of branching. The equations for g given in Table 1 are based on the random flight model where chains are assumed to be in an unperturbed state. If Eq. (3) is assumed to hold, these equations can be compared to experimental values of g_θ, where the mean-square radius for both linear and branched chains is measured at the θ point.

Values of $\langle s^2 \rangle$ can be obtained experimentally from radiation or neutron scattering experiments. By measuring the angular dependence of the intensity of scattered radiation between the particles and the probing radiation, the particle size can be determined. Well developed techniques for determining a particle's size include light scattering (LS), small-angle x-ray scattering (SAXS), and small-angle neutron scattering (SANS).[17] The theory of light scattering from macromolecular solutions is provided in the works of Debye[18] and Zimm[19,20] and is reviewed and applied to branched polymers by Burchard.[8] Light scattering experiments provide a z-average estimate of the radius of gyration ($R_{g(z)}$). For samples with a narrow molecular weight distribution, this does not provide a problem and $R_g = R_{g(z)}$. However, when samples with a broad molecular weight distribution are analyzed, the increase in polydispersity (M_w/M_n) has a substantial effect and $R_{g(z)}$ will increase. This increase in the z-average radius of gyration is significant enough that it will counterbalance the decrease in size because of branching. As a result, $R_{g(z)}$ for a polydisperse branched polymer may seem identical to that of a polydisperse linear sample. Therefore, some fractionation method must be used to obtain monodisperse fractions where the contraction factor can be calculated. Further discussion concerning the determination of g for polydisperse samples is provided in the section for detecting LCB.

The radius of gyration can be related to molecular weight by an equation of the following form:

$$R_g = K_{R_g} M^v \quad (19)$$

where K_{Rg} and ν are constants. The exponent can vary between 0.33 for hard spheres and 1 for a rigid rod. In the case of linear chains, an exponent of 0.5 refers to an unperturbed state, while in good solvents, ν is closer to 0.6.

n varies	$g_3 = \left[\left(1 + \frac{\bar{n}}{7}\right)^{\frac{1}{2}} + \frac{4\bar{n}}{9\pi}\right]^{-\frac{1}{2}}$ (14)	[16]
	$g_4 = \left[\left(1 + \frac{\bar{n}}{6}\right)^{\frac{1}{2}} + \frac{4\bar{n}}{3\pi}\right]^{-\frac{1}{2}}$ (15)	
n varies polydisperse	$\langle g_3 \rangle_w = \frac{6}{n_w}\left[\frac{1}{2}\left(\frac{2 + n_w}{n_w}\right)^{\frac{1}{2}} \times \ln\left(\frac{(2 + n_w)^{\frac{1}{2}} + n_w^{\frac{1}{2}}}{(2 + n_w)^{\frac{1}{2}} - n_w^{\frac{1}{2}}}\right) - 1\right]$ (16)	
	$\langle g_4 \rangle_w = \frac{1}{n_w}\ln(1 + n_w)$ (17)	[16]
	$\langle g \rangle_z = \frac{1}{1 + \frac{(f - 1)(f - 2)n_w}{6}}$ (18)	

Notes: f is the functionality of the branch point (i.e., the number of chains attached to branch point); α is the number of unreacted functional groups; λ is the fraction of polymer in the backbone chain; n is the number of branch points per chain; $\bar{n}$ is the average number of branch points per chain; n_w is the weight-averaged number of branch points per chain; π is 3.14159 . . . ; g_3 and g_4 denote trifunctional and tetrafunctional branch points, respectively; subscripts n, w, or z represent the number, weight, and z-averages, respectively.

An excellent summary of $R_g - M$ data by Fetters et al. provides estimates for these parameters in both θ and good solvents for a number of linear polymers.[25] The parameters in Eq. (19) are not only influenced by the experimental conditions (solvent, temperature) but are also affected by the polymer's structure. For monodisperse stars, it has been found that increasing the number of arms decreases K_{Rg} while ν remains identical to that of the linear polymer (see Fig. 1). However, for randomly branched polymers, it has been found that ν is closer to 0.5 and in some cases much lower. Such low values of this exponent might be considered as an indication of the branched polymer being in an unperturbed state; however, this is not the case. An explanation as to why ν is so small for randomly branched polymers has been found using fractal behavior, and an overview is given by Burchard.[8]

Intrinsic viscosity

The increase in viscosity with the addition of a polymer into a solvent is an important property. By measuring the solution viscosity as a function of polymer concentration, useful information about the polymer's molecular properties can be determined. From the solution data, the intrinsic viscosity (also known as the limiting viscosity number or Staudinger index) can be calculated:

$$[\eta] = \lim_{c \to o} \frac{1}{c} \left(\frac{\eta}{\eta_0} - 1 \right) \tag{20}$$

where c is the concentration of polymer in solution, η the solution viscosity, and η_0 the viscosity of the pure solvent. The presence of branching leads to smaller intrinsic viscosity values. Comparable to Eq. (4), a branching factor can be also defined using the intrinsic viscosity:

$$g' = \left. \frac{[\eta]_{\mathrm{br}}}{[\eta]_l} \right|_{\mathrm{M}} \tag{21}$$

Because of the ease in measuring intrinsic viscosity relative to the radius of gyration, considerably more experimental works have reported intrinsic viscosity data for branched molecules. As a result, attempts have been made to relate the two contraction factors. However, the efforts to find an encompassing relationship have not been completely successful. Thurmond and Zimm[26] proposed the following equation:

$$g' = g^{\varepsilon} \tag{22}$$

with a value of 1.5 for ε, but found results supporting and opposing the use of such a value for their polystyrene star samples. Zimm and Kilb[27] later came to the numerical conclusion that $\varepsilon = 0.5$ for certain star polymers. Burchard proposed that the relationship between the two branching factors could not be adequately described by a simple power law and proposed the following equation for star polymers:[8]

$$g' = (a + (1 - a)g^p)g^{\varepsilon} \tag{23}$$

with $a = 1.104$, $p = 7$, and $\varepsilon = 0.906$.

Overall, studies have found that ε varies with experimental conditions and the type of branching.

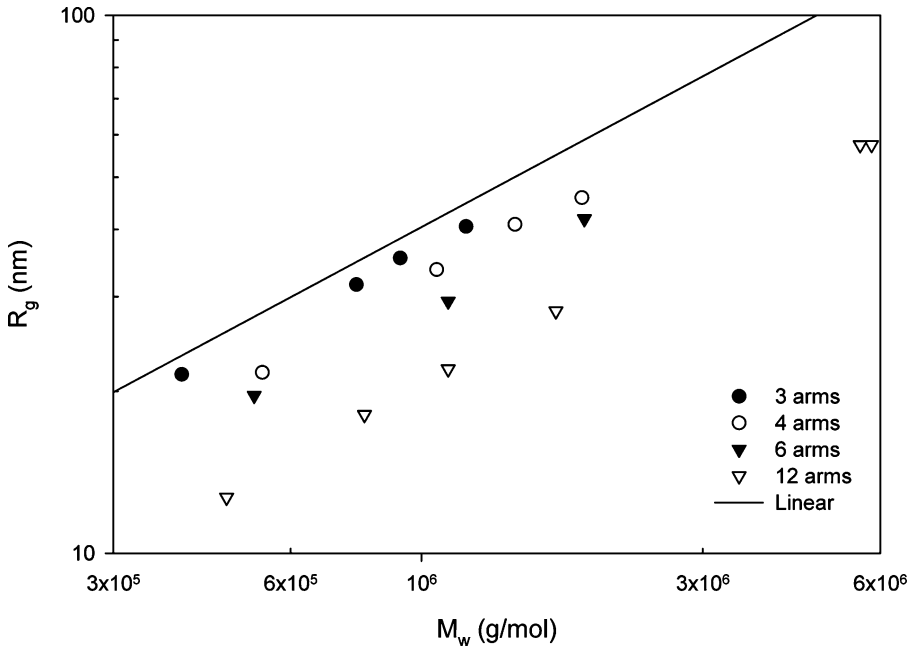

Fig. 1 Radius of gyration as a function of molecular weight for monodisperse polystyrene stars. (Data from Refs.[23,24]. Parameters for linear polystyrene from Ref.[25].)

Typically, stars have been found to have the lowest values ($\varepsilon = 0.5$), while combs are in the upper limit ($\varepsilon = 1.5$). Results for randomly branched polymers tend to fall somewhere in between these limits. However, these are only general trends and upon examination of the results for polyethylene, a variety of values for ε can be shown (see Table 2). For randomly branched polystyrene with tetra-branch points, values ranging from 0.5 in cyclohexane to 0.72 in toluene have been found.[28] Further work found that styrene copolymerized with divinylbenzene produced polymer with an exponent varying from 0.65 at low conversion to 1.41 at higher conversions.[29] Berry and Orofino determined that for their poly(vinyl acetate) combs in benzene, ε varied from 0.5 to 1.0, while randomly branched poly(vinyl acetate) in benzene exhibited a range of 0.7–0.9.[30] Foster et al. also found $\varepsilon = 1$ for randomly branched poly(vinyl acetate) in tetrahydrofuran.[31] Values of ε greater than 1.5 have been observed, including the work with styrene–butadiene graft copolymer where ε was estimated to be 2.[32] An extensive review on the dilute solution properties of star polymers has found that over a large range of functionalities, no constant exponent could be found.[33]

The intrinsic viscosity in turn can be related to a molecular weight with a power law expression known as the Kuhn–Mark–Houwink–Sakurada (KMHS) equation:

$$[\eta] = K_{[\eta]} M^{\alpha} \tag{24}$$

Similar to the behavior of $R_g - M$ for stars, the exponent α does not vary with star functionality (see Fig. 2). However, for randomly branched polymers, it is found that α is smaller when compared to the exponent for a linear polymer. In fact, α decreases with increasing molecular weight for randomly branched polymers. Because of the nature of branching reactions in randomly branched polymers (e.g., transfer to polymer), the number of branches per macromolecule increases with molecular weight. It is for this reason that α decreases with increasing molecular weight.

Rheological Properties

Rheological properties of polymers are highly sensitive to macromolecular structure. In some cases, the incorporation of minute amounts of branching can alter the flow properties of a polymer even though the dilute solution properties are unchanged. The rheological behavior of branched polymers is influenced by a variety of factors including the number, location, architecture, and length of branches.[11] Similar to dilute solution properties, the differences between the viscoelastic behaviors of linear and branched polymers can be masked by large polydispersities.

There has been a considerable amount of research on the rheological properties of polymers with uniform model structures such as stars and combs with narrow molecular weight distributions. These studies provide insight into the effects of branching. The presence of branching has two opposing effects. First, branching is known to decrease the size of polymer molecules compared to a linear chain of identical molecular weight. In such a case, a smaller size will result in fewer chain entanglements. Second, at a critical molecular weight, the branches become long enough to get entangled and the overall number of entanglements increases. It is because of these two opposing effects that the impact of branching on rheological properties is highly dependent upon the nature of branching present in the polymer.

Zero-shear properties

The zero-shear viscoelastic properties of concentrated polymer solutions or polymer melts are typically defined by two parameters: the zero-shear viscosity (η_0) and the zero-shear recovery compliance (J_e^o). The former is a measure of the dissipation of energy, while the latter is a measure of energy storage. For model polymers, the influence of branching is best established for the zero-shear viscosity. When the branch length is short or the concentration of polymer is low (i.e., for solution rheology), it is found that the zero-shear viscosity of the branched polymer is lower than that of the linear. This has been attributed to the smaller mean-square radius of the branched chains and has led to the following relation:[40,41]

$$\eta_{0\mathrm{br}} = g^a \eta_{0l} \begin{cases} a = 1 & \text{when } M < M_c \\ a = 3.4 & \text{when } M > M_c \end{cases} \qquad (25)$$

where g is the ratio of mean-square radii of the branched and linear polymers of identical molecular weight in the unperturbed state, and M_c is a critical molecular weight where the exponent in Eq. (25) changes from 1 (unentangled linear polymers) to 3.4 (entangled linear polymers). Experimental evidence of a smaller zero-shear viscosity for branched polymers has been shown for a variety of polymer architectures such as stars,[38,42] combs,[43,44] and randomly branched polymers.[45] In some cases, a reduction in zero-shear viscosity has been observed at higher polymer concentrations[42] and even in the melt state.[11]

In certain cases, the behavior of branched polymers cannot be described by Eq. (25). These situations can arise for higher molecular weights, higher polymer concentrations, longer branch lengths, or longer spacing between branch points (i.e., situations where branching can increase the number of chain entanglements). For these conditions, it has been found that the zero-shear viscosity of the branched polymer can be considerably higher than that of the linear. This viscosity enhancement has been detected for several polymers of varying branching structure such as randomly branched polybutadiene,[46] randomly branched poly(vinyl acetate),[47] star poly(α-methylstyrene),[48] comb polystyrene,[48,49] H-shaped polystyrene,[39] star polyethylene,[50] comb, regular and irregular stars, H-shaped and pom-pom polyethylene,[51] and star polyisoprene.[42,52] In Fig. 3, the behavior of zero-shear viscosity vs. molecular weight for a series of H-shaped polystyrenes is shown. At low molecular weights and hence smaller branch lengths, there is a viscosity reduction, while at higher molecular weights, there is a viscosity enhancement.

To understand this viscosity enhancement, it is easier to start with the theory for linear polymers. The behavior of linear polymers can be described by the reptation model.[53,54] For a linear polymer of high molecular weight in the melt, chains can be modeled as a confined tube where the diffusion of the chain is restricted along the tube contour. Entanglements are formed between chains where the reptation of a chain along its contour becomes the dominant mode of movement. The addition of a branch point prevents reptation and other forms of movement must occur for the chain to change its configuration. In the case

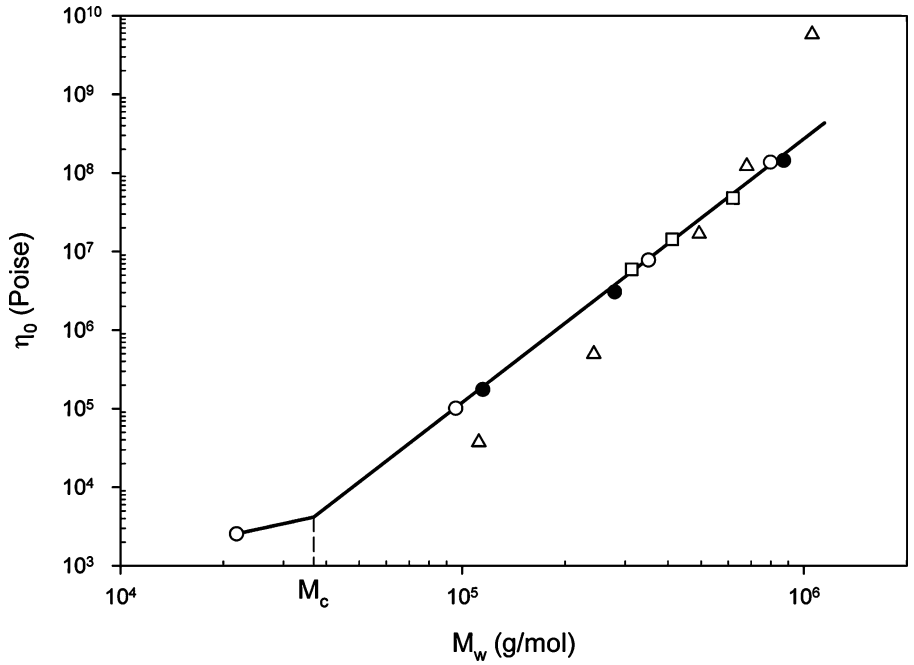

Fig. 3 Zero-shear viscosity at 169.5°C as a function of weight-averaged molecular weight for polystyrene melts. Open and closed circles and squares, linear; triangles, H-polymers. (From Ref.[39].)

of a star polymer, the arms retract partway down its contour tube and then move outward along a different trajectory.[54] This process is slow relative to that of linear polymers and is influenced by the branching length. For longer branches, there are a higher number of entanglements per branch, leading to a higher zero-shear viscosity. In the case of star polymers, it has been found that the viscosity increases exponentially with arm molecular weight and that the effect of functionality is no longer significant for $f > 4$ (i.e., total star molecular weight does not influence viscosity; only arm molecular weight does).[52] For star polymers, the exponential dependence of zero-shear viscosity on the number of entanglements per arm is given by:

$$\eta_o \propto \left(\frac{M_a}{M_e}\right)^{1/2} \exp\left(v' \frac{M_a}{M_e}\right) \tag{26}$$

where M_a is the arm molecular weight, M_e the molecular weight between entanglements, and ν' a constant. To properly describe the dynamics of branched melts, other effects aside from arm retraction that were not included in the original treatment of linear polymers, such as contour length fluctuations and dynamic tube dilation are important.[55] In the case of comb and H-shaped polymers, the length of branches is not the only factor as it has been found that the length between branch points is a significant variable.[43]

The zero-shear recovery compliance is another viscoelastic property of polymers that is noticeably influenced by the presence of branching, and similar to viscosity, the effect of branching is dependent upon several factors including polymer concentration and molecular weight. In dilute solutions, J_e^o is expected to decrease with branching according to:[40]

$$J_e^o = \frac{2g_2M}{5cRT} \tag{27}$$

where c is the concentration of polymer and g_2 is defined as follows:

$$g_2 = \left.\frac{\left[\frac{\langle s^4\rangle - \langle s^2\rangle^2}{\langle s^2\rangle^2}\right]_{br}}{\left[\frac{\langle s^4\rangle - \langle s^2\rangle^2}{\langle s^2\rangle^2}\right]_{l}}\right|_M \tag{28}$$

Similar to other branching factors, g_2 is unity for linear polymers and less than 1 for branched polymers. Equations for the determination of g_2 for certain branching structures have been determined including those for uniform stars and combs.[56] This reduction in J_e^o has been observed for low molecular weight star polymers at low and high concentrations and for high molecular weight stars at low concentrations.[42] However, in most instances, J_e^o is much larger for branched polymers compared to a linear polymer of the same molecular weight[39,42,44–47,57] and Eq. (27) does not accurately predict the behavior of a branched polymer. Based on the theory used to derive Eq. (26), a similar relationship for the zero-shear compliance and molecular

weight of star polymers is expressed as follows:

$$J_e^o = v' \frac{M_a}{M_e} \frac{1}{G_N^o} \quad (29)$$

where G_N^o is the plateau modulus which has been found to be independent of branching.[57] As well, the enhancement of η_0 and J_e^o does not necessarily coincide at the same polymer concentration and some polymers (e.g., polystyrene) are less prone to enhancement than others.[11]

DETECTION OF LONG-CHAIN BRANCHING

For the most part, detection of long-chain branching relies upon indirect methods that compare the properties of a branched polymer to the corresponding linear polymer. However, spectroscopic or chemical methods can quantitatively determine the number of branches or end groups without needing a linear reference. The results from different methods typically do not agree as each technique has a different criterion as to how long a branch must be so as to be considered ''long.'' Long-chain branches are usually defined as being comparable in length to the main chain. Using polyethylene as an example, it has been found that size exclusion chromatography (SEC) can detect a minimum length for a straight chain alkane branch greater than six and less than twelve carbons.[35] It is generally accepted that six carbons or longer can be detected by ^{13}C-nuclear magnetic resonance (NMR) spectroscopy.[58] In the case of rheology, a definite length is not completely established. It has been proposed that the length of an LCB corresponds to the critical entanglement molecular weight.[59] For polyethylene, this equates to 270 carbon atoms or greater (reported values of M_c vary from 2100 to 5200[12]). Other sources have found that branches longer than twice the molecular weight between entanglements are considered long in rheological terms.[60] In the case of polyethylene, this corresponds to 180 carbon atoms in length. Because of this variability in the methods of detecting LCB, agreement between techniques can be considered fortuitous.

Spectroscopic Methods

Spectroscopic methods rely on the chemical difference between end groups or branch points in a polymer. In the case of polyethylene, the most common spectroscopic technique for determining long-chain branching has been nuclear magnetic resonance spectroscopy. Using ^{13}C-NMR, branches of one to five carbon atoms can be distinguished, while a six-carbon-atom branch produces the same spectral pattern as any subsequent branch of greater length.[58] Peak assignments for various chemical shifts in polyethylene have been well documented.[61] Fig. 4 is a typical ^{13}C-NMR spectrum of polyethylene showing the various peak assignments).[62] Recent studies employing NMR have reported long-chain branching as low as 0.2 branches per 10,000 carbon atoms in polyethylene.[62] Although NMR is seen as an absolute technique for determining LCB in polyethylene, studies have found limitations when compared to methods utilizing rheological measurements. A series of commercial high-density polyethylenes (HDPE) with similar molecular weight and

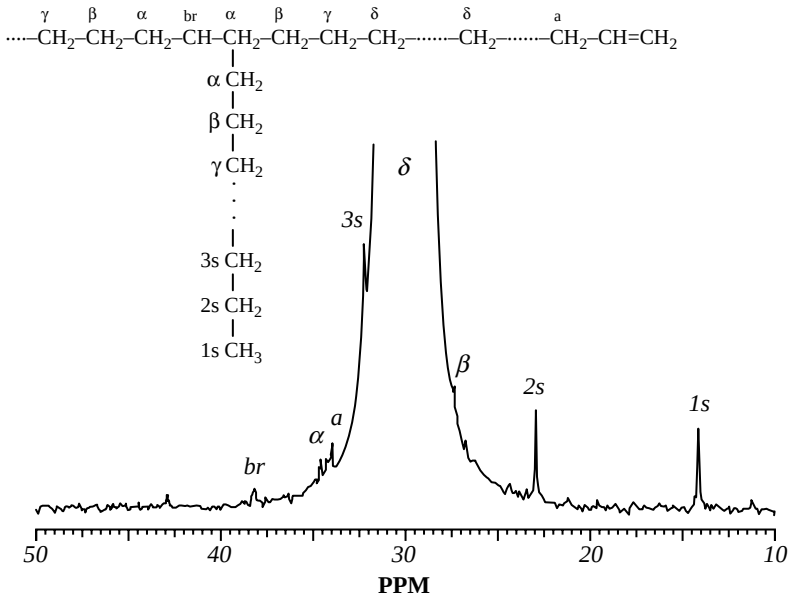

Fig. 4 ^{13}C-NMR spectrum of polyethylene sample measured at 120 °C using deuterium *o*-dichlorobenzene and 1,2,4-trichlorobenzene as solvents. (From Ref.[62].)

molecular weight distributions were found to have large and systematic increases in zero-shear viscosity, which were attributed to long-chain branching.[59] However, the number of branches determined with NMR showed random scatter. In the same study, it was found that NMR could not detect the presence of long-chain branching in peroxide modified high-density polyethylene, nor could it identify LCB in multiple pass extruded HDPE. In both cases, samples showed large changes in their rheological behavior relative to the unmodified samples.

Chromatographic Methods

Grubisic et al. proposed that SEC separates polymer molecules, regardless of chemical composition and large-scale structure, but according to a hydrodynamic volume, V_H.[63] They found this hydrodynamic volume to be proportional to the product of intrinsic viscosity and molecular weight:

$$V_H \propto [\eta]M \tag{30}$$

The excellent correlation between hydrodynamic volume and ($[\eta]M$) has become the basis of the universal calibration curve (UCC) for polymers. Although other size parameters, namely those dependent on R_g, have been suggested, the applicability of UCC has recently been verified for a variety of polymers including those with a high chemical and molecular weight asymmetry (e.g., miktoarm stars where arms are of different composition).[64]

Methods for determining long-chain branching in polymers through the use of SEC depend upon the type of detectors employed, and thus the type of information collected. For conventional SEC equipped with only a concentration detector, a calibration curve is constructed where molecular weight is a function of elution volume. For a linear and branched macromolecule of the same molecular weight, it is known that the branched macromolecule will have a smaller intrinsic viscosity ($[\eta]_{br} < [\eta]_l$) and as a result, it will elute later than the linear macromolecule. Because of this, SEC with only a concentration detector will underpredict the molecular weight of branched polymers. Using the KMHS relation for the linear polymer, two branching ratios can be defined for SEC:[65]

$$g'_{[\eta]} = \left(\frac{[\eta]_{br}}{[\eta]^*}\right)^{\alpha+1} \tag{31}$$

$$g'_M = \left(\frac{M^*}{M_{br}}\right)^{\alpha+1} \tag{32}$$

where $[\eta]^*$ and M^* are the intrinsic viscosities and molecular weight of linear molecules leaving the column at the same elution volume as the branched molecules having intrinsic viscosity and molecular weight of $[\eta]_{br}$ and M_{br}. Several workers have applied an iterative method to derive the branching density (λ) based on SEC chromatograms.[66–68] Assuming a value of λ, the number of branches is calculated as a function of molecular weight ($n = \lambda M$) and using the appropriate equation, g can be determined for each molecular weight (see Table 1). Then assuming a value for ε, g' and then $[\eta]_{br}$ can be calculated for each elution volume. The total intrinsic viscosity can be determined as a weighted sum of the individual elution volumes. This total intrinsic viscosity calculated from SEC data can be compared to the measured value. The process is repeated by changing λ until the two values agree. Problems with this method arise from the various assumptions made, including constant values of λ and ε. Several studies have found that the branching density varies with molecular weight for a particular sample and a constant value of ε cannot be assumed.[29,33,37] Another problem lies in the fact that theoretical equations for g are for chains in an unperturbed state, best represented by a θ solvent and temperature. Typically, SEC measurements are made in good solvents. For these reasons, values of the branching density based on this method are only valid for relative comparisons.

Most SEC studies of branching employ at least one other detector aside from a concentration detector. In the past, the most common additional detector for measuring long-chain branching was an online viscometer. By using UCC and a viscometer, both molecular weight and intrinsic viscosity distributions can be determined for a polymer sample. Low-angle light scattering detectors with UCC have also been employed for the determination of molecular weight and intrinsic viscosity distributions, and in turn, the detection of long-chain branching. However, the use of a viscometer has been found to be more appropriate for studying branched polymers. If a branched sample has a distribution in the extent or type of branching, the fractionation with SEC will not be complete. It is possible for two polymer molecules, one more branched than the other, to have the same hydrodynamic volume ($[\eta]M$) and coelute. The more highly branched chain will have a smaller intrinsic viscosity, but it may also have a higher molecular weight. In this case, the detector cells do not contain monodisperse fractions, and the results from the detectors at each elution volume are average results. Light scattering is known to provide a weight-average molecular weight estimate and from the work of Hamielec and Ouano,[69] it was determined that UCC provides the number-average molecular weight for

polymer molecules of the same hydrodynamic volume but differing molecular weight.

With the intrinsic viscosity distributions obtained from either a viscometer or light scattering detector, previous studies have attempted to quantitatively determine the amount of long-chain branching. First, g' was related to g using an assumed value of ε, and the appropriate equation from Table 1 was used to calculate the number of branches per molecule. However, because of the assumptions involved, it is more appropriate to determine the level of branching in a more qualitative manner. From the molecular weight and intrinsic viscosity data collected, a KMHS plot can be constructed for each polymer sample and comparisons can be made to the linear polymer. In Fig. 5, an example of a KMHS plot for branched polystyrene compared to a linear sample obtained using SEC is shown. As the level of branching increases, the $[\eta] - M$ relationship can no longer be expressed as a linear relation in a log–log plot. Therefore, deviations

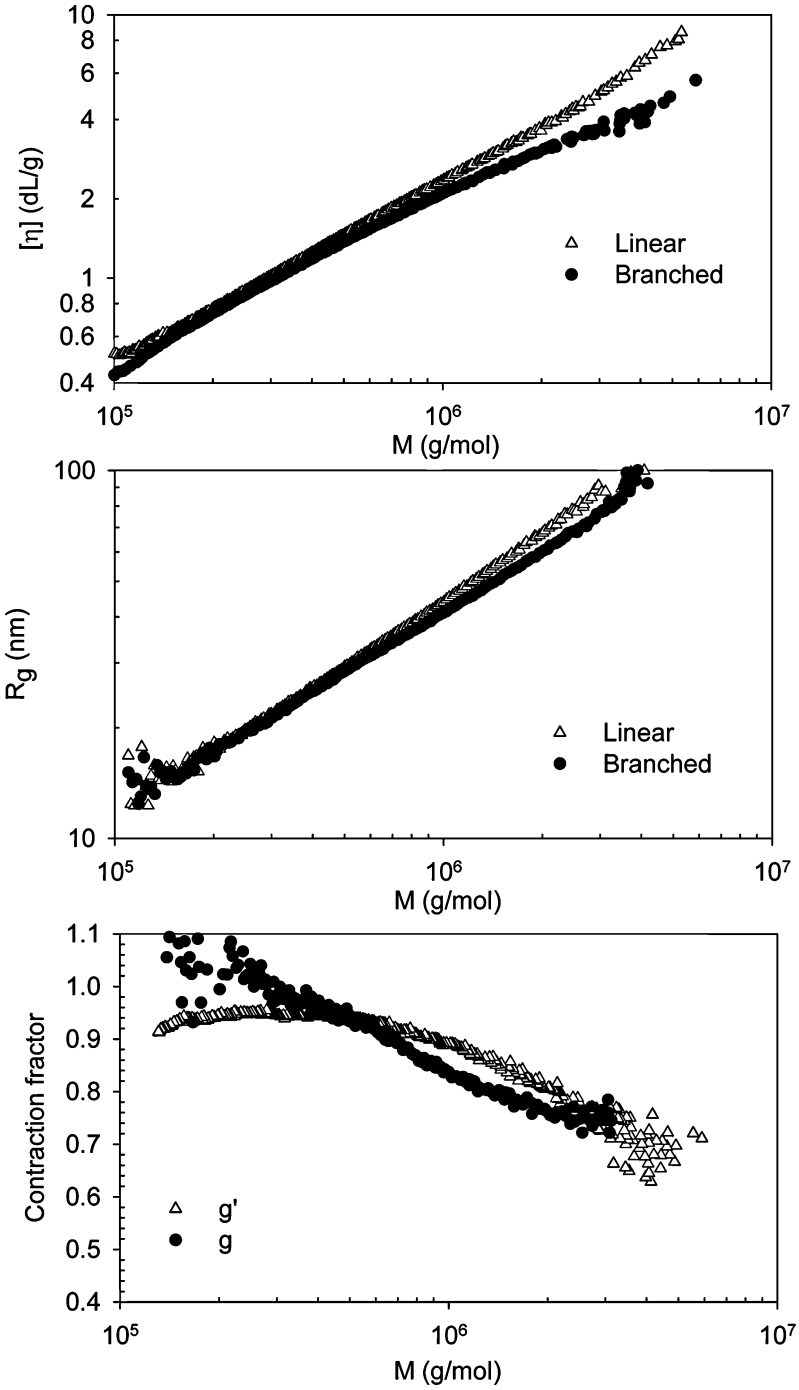

Fig. 5 Intrinsic viscosity, radius of gyration, and contraction factors as a function of molecular weight for polystyrene (SEC at 30°C with 1.0 ml/min of tetrahydrofuran). (From Ref.[74].)

from the KMHS plot for a linear sample are an indication of branching, with more curvature being an indication of higher levels of branching.

The introduction of commercial low angle laser light scattering (LALLS) detectors for SEC in the 1970s was followed by multiangle laser light scattering (MALLS) detectors in the 1980s. Coupled with SEC, a MALLS detector allows for the determination of the radius of gyration as a function of molecular weight for a polymer sample. In plots of $R_g - M$, the presence of branching is detected by lower trends for branched polymers compared to a linear sample (see Fig. 5). The use of MALLS also allows for the determination of g directly and the branching density can be determined from a suitable equation from Table 1. Most studies now involve the combination of three detectors in the analysis of branched polymers (concentration, light scattering, and viscosity detectors). Mourey et al. have reported on a unique method to analyze branched polymers with triple detector SEC.[70–73] Because light scattering reports a weight-average molecular weight, and viscometry with UCC provides an estimate of the number-average molecular weight, it is possible to determine the local polydispersity for each elution volume. However, significant molecular weight heterogeneity is needed between the types of branched macromolecules to detect any local polydispersity.[73]

Rheological Methods

The most common rheological method is to compare the zero-shear viscosity of the branched polymer to that of the linear. It is well established that for linear polymers above the critical molecular weight for entanglement, zero-shear viscosity scales with molecular weight to a power of 3.4. For the most part, η_0 is independent of the molecular weight distribution as long as there is no significant fraction of low molecular weight material below the entanglement threshold.[75,76] Thus, deviation from the power law for linear samples implies the presence of branching. Whether there is a reduction or enhancement of zero-shear viscosity depends upon polymer molecular weight and branching characteristics (number, length, and architecture). Gabriel and Münstedt completed a study on the long-chain branching in polyethylene where reduction or enhancement was observed in various samples.[76] For highly branched low-density polyethylene (LDPE), a reduction in zero-shear viscosity was observed as high branching densities (i.e., a high number of branches of relatively short length) led to a lower radius of gyration and fewer entanglements. However, for metallocene-catalyzed polyethylenes with very low levels of long-chain branching, a significant increase in η_0 was observed and attributed to a higher number of entanglements from longer branches.

Recently, a model has been proposed for the relationship between zero-shear viscosity and weight-average molecular weight to also account for the effect of branching.[77] Although the model has limitations and uncertainties in some parameters, it was found to predict the reduction and enhancement in the $\eta_0 - M$ behavior of branched polyesters and branched polyethylenes. The authors attribute an increase in η_0 to cases where the molecular weight between branch points is much larger than the entanglement molecular weight, while decreases in η_0 are found in polymers with high branching densities where the molecular weight between branch points is small. The main limitation of the model is to account for varying types of branching within a polymer sample. In Fig. 6, it is illustrated how the number of branches per chain can influence the zero-shear viscosity based upon this model.

Unlike the zero-shear viscosity, the zero-shear compliance is significantly influenced by the molecular weight distribution, particularly the high molecular weight fractions. For linear polymers, increases in polydispersity correspond to an increase in elasticity (increase in J_e^o). In the case of branched polymers, the zero-shear compliance can experience a reduction or enhancement depending on a number of factors including molecular weight, number, length and type of branching, and molecular weight between branch points. Fewer studies rely on the detection of long-chain branching from zero-shear compliance estimates.[76] This is most likely because of the difficulties in separating the effects of polydispersity and LCB.

Shroff and Mavridis have completed a number of studies on the determination of branching in polyethylene.[59,78,79] The authors have reviewed and proposed several indices relying on rheological data to quantify the amount of long-chain branching including what they have termed as the long-chain branching index (LCBI):[78]

$$\text{LCBI} = \frac{\eta_0^{1/a_3}}{[\eta]_{\text{br}}} \frac{1}{K_3^{1/a_3}} - 1 \tag{33}$$

where k_3 and a_3 are the constants for a linear polymer in a $\eta_0 - [\eta]$ power law equation as follows:

$$\eta_0 = K_3[\eta]^{a_3} \tag{34}$$

The LCBI is zero for linear polymers with larger numbers denoting higher levels of long-chain branching. A significant advantage of this index is that it is independent of molecular weight and molecular weight distribution. The LCBI has been developed for essentially linear polymers, and its derivation relies upon

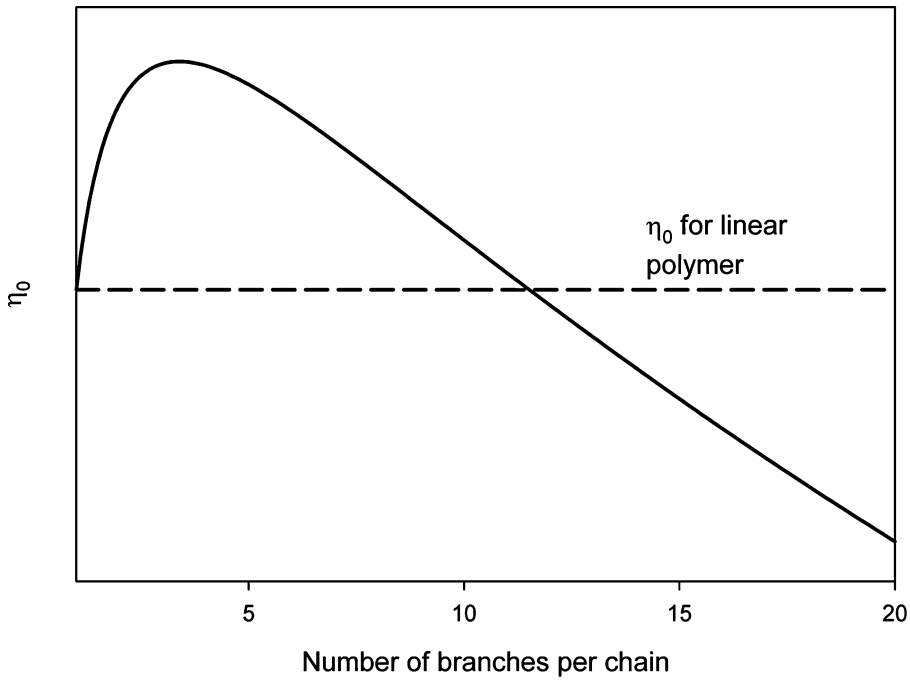

Fig. 6 Zero-shear viscosity as a function of the number of branches per chain for polyethylene. (Based on Ref.[77].)

the assumption that $g \approx g' \approx 1$. In other words, the LCBI is only valid for low levels of long-chain branching not detected by solution methods. A modification of Eq. (33) has been proposed to accommodate those polymers where $g' < 1$. However, this method relies on assuming a value for ε, and as previously noted, this parameter is found to vary with long-chain branching and molecular weight. As Shroff and Mavridis show a series of low-density polyethylenes where branching was detected with solution methods, the expected trend of samples with increasing LCB is only found at $\varepsilon = 0.5$ and not for other values of ε reported for polyethylene in the literature.[78] Shroff and Mavridis have also reviewed and extended a list of rheological polydispersity indices.[79] It was found that the presence of even small amounts of long-chain branching significantly alters most of the measures of rheological polydispersity, while no changes were observed in the MWD obtained from SEC. One such measure proposed by the authors is E_R, which is independent of molecular weight but influenced by molecular weight distribution and long-chain branching:[79]

$$E_R = C_1 G'|_{\text{at } G''_{\text{ref}}} \tag{35}$$

where G''_{ref} is a reference low modulus value corresponding to low frequencies and C_1 is a constant. For polyolefin melts, the authors have suggested $G''_{\text{ref}} = 5000\,\text{dyn/cm}^2$ and $C_1 = 1.781 \times 10^{-3}\,\text{cm}^2/\text{dyn}$. In Fig. 7, an example of a $\eta_0 - M_w$ plot for various polyethylene samples where very small amounts of LCB produced an increase in the zero-shear viscosity but were not detected with SEC is provided. The samples categorized as having lower E_R values do not display as much viscosity enhancement as the samples with much higher values of E_R.

Another index developed to detect long-chain branching is the Dow rheology index (DRI).[80] It was specifically derived for polyethylenes with similar, narrow molecular weight distributions ($M_w/M_n \sim 2$) and is not able to distinguish between the effects of polydispersity and branching.

$$\text{DRI} = 3.65 \times 10^5 \frac{\tau_0}{\eta_0} - 0.1 \tag{36}$$

where τ_0 is a characteristic time determined from the Cross equation.

Another technique to calculate the amount of LCB in polymers was developed by Wood-Adams and Dealy.[81] The procedure involves transforming the complex viscosity data as a function of frequency into a molecular weight distribution. This distribution is then compared to that obtained from SEC and the difference in the location of peaks is correlated to a level of branching.

Although providing only a qualitative determination of the level of branching, comparing the linear viscoelastic data of samples from dynamic rheology measurements is a common technique. Plots of the loss angle, δ, as a function of frequency are altered because of branching:

$$\delta = \tan^{-1}\left(\frac{G''(\omega)}{G'(\omega)}\right) \tag{37}$$

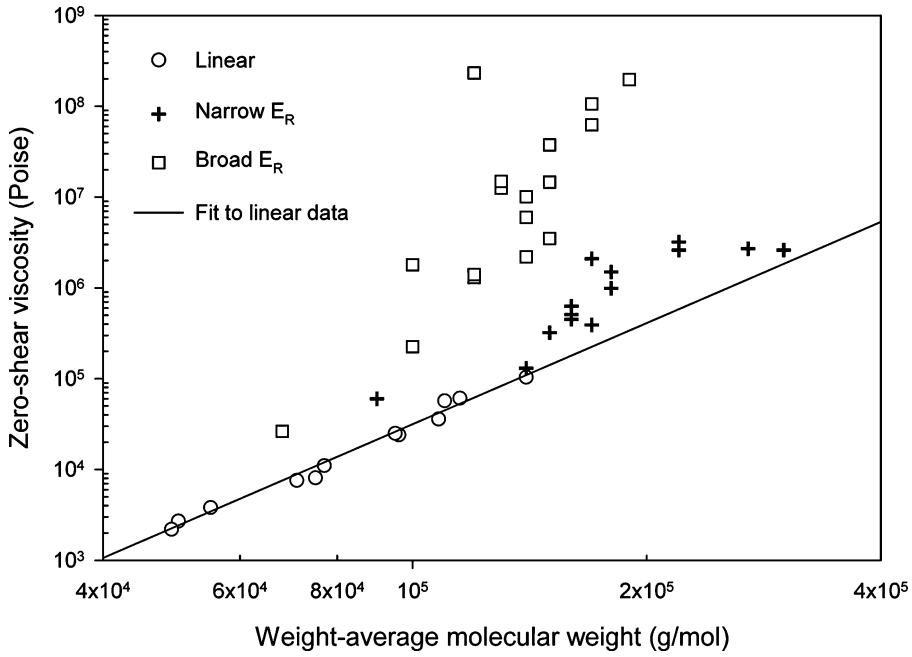

Fig. 7 Zero-shear viscosity as a function of weight-averaged molecular weight for various polyethylene samples at 190°C. (Circles) Fairly narrow MWD ($M_w/M_n \sim 2$–6) linear samples; (crosses) broad to very broad MWD ($M_w/M_n \sim 6.6$–30) branched samples but with narrow rheological polydispersity ($E_R \sim 1.7$–3.7); (squares) broad MWD ($M_w/M_n \sim 6.0$–14) branched samples with large rheological polydispersity ($E_R \sim 6.0$–14). (From Ref.[78].)

where $G''(\omega)$ and $G'(\omega)$ are the loss and storage moduli and ω is the angular frequency. For a perfectly elastic solid, the loss modulus is zero and so also is the loss angle. For a perfectly viscous fluid, the storage modulus is zero and the loss angle is 90°. In Fig. 8, a plot of the loss angle as a function of frequency for high-density polyethylenes from metallocene catalysts is provided. In general, the presence of branching causes a plateau in the loss angle with the magnitude and breadth of the plateau depending on the degree of LCB.[82] A variation of this technique is known as the reduced van Gurp–Palmen plot where the loss angle is plotted as a function of the ratio of the complex modulus and plateau modulus ($G_{red} = |G^*|/G^o_N$).[83,84] The plot is found to be temperature invariant and because a reduced modulus is used, the curves are not influenced by polymer composition. In Fig. 9, an example of a reduced van Gurp–Palmen plot is provided. For a linear polymer, the loss angle starts as a plateau at 90° for low G_{red}. As the reduced modulus increases, the loss angle decreases past an inflection point toward a minimum at $G_{red} = 1$ and then increases

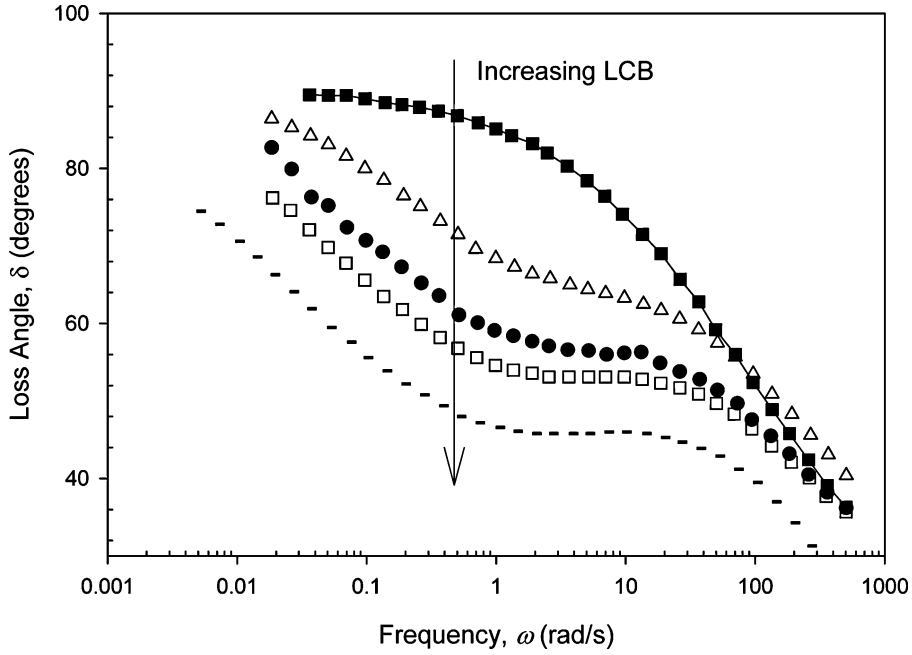

Fig. 8 Loss angle as a function of frequency at 150°C obtained for high-density, metallocene catalyzed polyethylene samples of increasing long-chain branching. (From Ref.[82].)

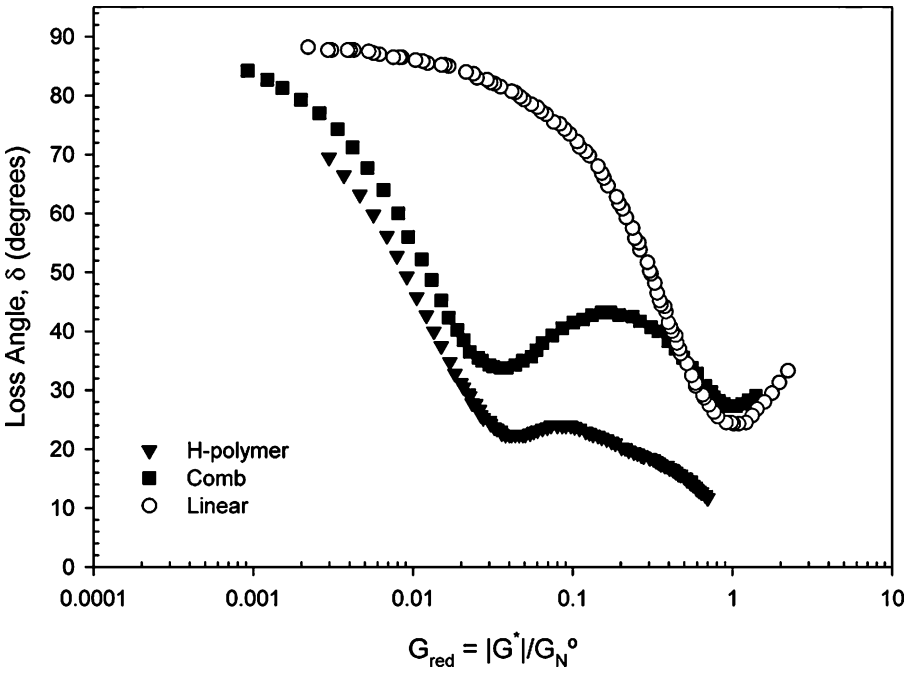

Fig. 9 Loss angle as a function of the reduced modulus (ratio of complex modulus and plateau modulus) for polystyrene samples. (From Ref.[84].)

again. The effect of molecular weight is to lower the value of the loss angle at the minimum, while a broader molecular weight distribution tends to cause a less steep drop in δ toward the minimum (i.e., δ begins to decrease from 90° at much lower values of G_{red}). The impact of branching is to produce a plateau or even a second minimum at the inflection point of $G_{red} < 1$. This presence of a second minimum has also been found for blends of linear high and low molecular weight materials.[83]

CONCLUSIONS

The task of quantifying branching in polymers is complicated by their very nature. Typical branched macromolecules are extremely heterogeneous in terms of the number, type, and length of branches, molecular weight variations, and in most instances, the presence of linear or cross-linked fractions. Spectroscopic methods such as NMR are some of the best methods for quantitatively determining the level of branching. Chromatographic techniques can provide more information such as molecular weight and branching distributions depending upon the detectors employed. Yet both spectroscopic and chromatographic methods are not sensitive enough to be able to detect the very low levels of branching that can still significantly alter a polymer's flow behavior. In such instances, rheological characterization becomes the only solution. However, the rheology of branched polymers is still not fully understood and the techniques typically provide a qualitative view on branching.

Bubble Cap Tray

Stanley Marple
Chemical Engineering Department, University of Houston, Houston, Texas, U.S.A.

INTRODUCTION

Bubble cap trays are commonly used to provide mass or heat transfer between liquid and vapor streams. Its advantages include minimum liquid leakage, wide range of operating rates, reasonable cost, and usefulness at very low liquid rates.

Sieve and valve trays have replaced bubble cap trays in many new construction projects because of lower cost. Yet bubble cap trays are still often used for the superior characteristics mentioned earlier.

This entry summarizes the technology of bubble cap trays. Industrial-scale data contributed by Fractionation Research, Inc. (FRI) are included. More detailed technical material is available in Ludwig[1] and in Refs.[2–5]

GENERAL DESCRIPTION

Bubble cap trays are commonly used to provide mass or heat transfer between liquid and vapor streams. The most common installation is the multiplate column containing two to several hundred trays at vertical spacing of 6–36 in. (Fig. 1).

Fig. 2 shows an assembled tray with 3 in. caps. A closer view of the caps is seen in Fig. 3. Fig. 4 displays the dimensions of 3 in. caps used by FRI in their experimental studies (Fractionation Research, Tulsa, Oklahoma, U.S.A., private communication).

Caps may be 2–8 in. in diameter or larger, but there is a performance advantage for the smaller 3 or 4 in. caps. The vapor slots are typically 0.25–0.50 in. wide, with total slot area perhaps 10% of the tower cross-sectional area. The vapor risers (Fig. 4) prevent liquid from flowing down through the openings in the tray.

Caps are sometimes tack-welded into place for long-term durability, or they may be fastened with double lock-nuts or hold-down bars installed parallel to the liquid flow.

Liquid flow may be directed onto the tray across a low entrance weir to even out the flow, or the downcomer skirt clearance alone may be relied upon for this function. The liquid is agitated into a frothy mix as it flows across to the outlet weir. The outlet weir is normally 1–4 in. high to provide a liquid seal and leads to a downcomer that occupies about 8–20% of the tower cross-sectional area.

The overflow weir should be at least 0.50 in. higher than the downcomer skirt clearance to prevent vapor from passing up the downcomer, thus escaping vapor–liquid contact on the tray above.

Sometimes for large liquid rates, the downcomer skirt clearance is increased by recessing the bottom end of the downcomer into a sump built into the tray floor. Such a sump increases tray cost and may trap debris.

Weep Holes and Tray Leakage

During shutdown, it is necessary to drain the trays and seal pans of unevaporated liquid and steam condensate. At least two drain holes are needed for each tray or seal pan, at 0.50 in. minimum diameter and preferably 0.75 in. to avoid plugging. As a rule of thumb, a 0.75 in. hole will deliver about 2 gpm of liquid during tower drainage.

If tray leakage during operation is found to be harmful, gasketing or seal welding may be employed.

Sequential Start-up

It may be necessary to establish liquid flow before introducing vapor flow through the tray, especially with small downcomers. However, large ones usually do not require this measure.

Direction of Liquid Flow

The most common flow arrangement (Fig. 1) has liquid alternating direction as it passes down the tower. Lewis studied three different flow arrangements[6] and found that the most efficient method is to have the liquid flowing in the same direction in plug flow on each tray. The reversing arrangement is, however, mechanically expedient.

Hanging Downcomers

It is a common practice, as shown in Fig. 1, to slope the downcomer wall inward so that the bottom of the

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120008098

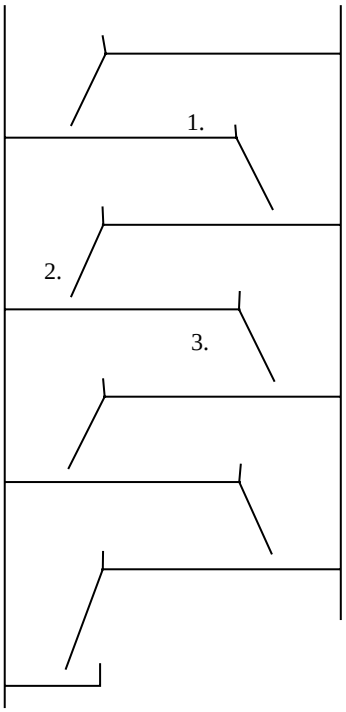

Fig. 1 Schematic arrangement of bubble cap trays: 1) capped trays; 2) liquid downcomers; and 3) disengagement zones.

downcomer occupies less tray area than the top. Active area is thus increased, and the downcomer is equally effective because froth settling gives lower downward velocity in the lower part of the downcomer.

In recent years, downcomer area encroachment on the active area has been further reduced by a concept called "hanging downcomer." The resulting lower slot velocities allow more vapor-handling capacity. One such arrangement is the UOP (originally the Union Carbide) MD Tray (Fig. 5).[7] A restricting slot in the bottom of the downcomer box causes liquid to back up, providing a seal to prevent vapor passage up the downcomer.

The capacity advantage provided by the hanging downcomer depends on how much additional area is provided. For example, if the inflow downcomer for a conventional tray covers 15% of the tray area, the capacity improvement for a hanging downcomer might be 10% or 12%.

Trays with Centrifugal Action

At least two manufacturers offer trays that depend on centrifugal action to separate vapor and liquid streams. Each tray is an array of centrifugal contacting and separating devices, which brings the streams together

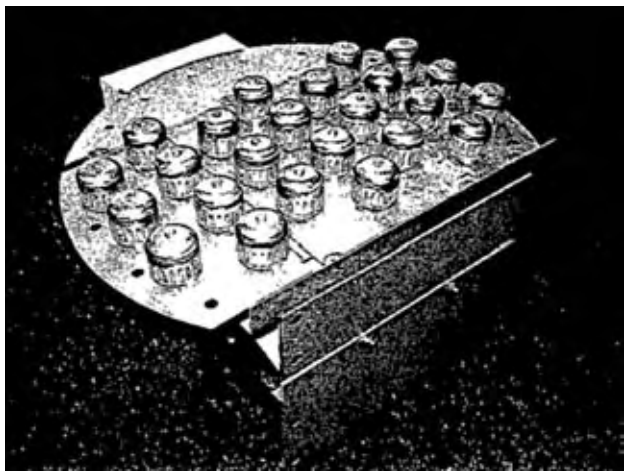

Fig. 2 Bubble cap tray assembly. (Photograph courtesy of ACS Industries, Inc.)

and then separates them in a swirl within each device. Because the separating force can be much greater than gravity, the towers can operate with very high vapor velocities. The capital cost of these centrifugal trays is high at present.

Manning at Shell Research was one of the first to experiment with centrifugal separation on an industrial scale.[8]

PREDICTING SYSTEM PERFORMANCE WITH BUBBLE CAP TRAYS

Correlations of data for either capacity or separating power cover a wide range of hardware and distilling

Fig. 3 Side view of 3 in. bubble caps as installed. (Photograph courtesy of ACS Industries, Inc.)

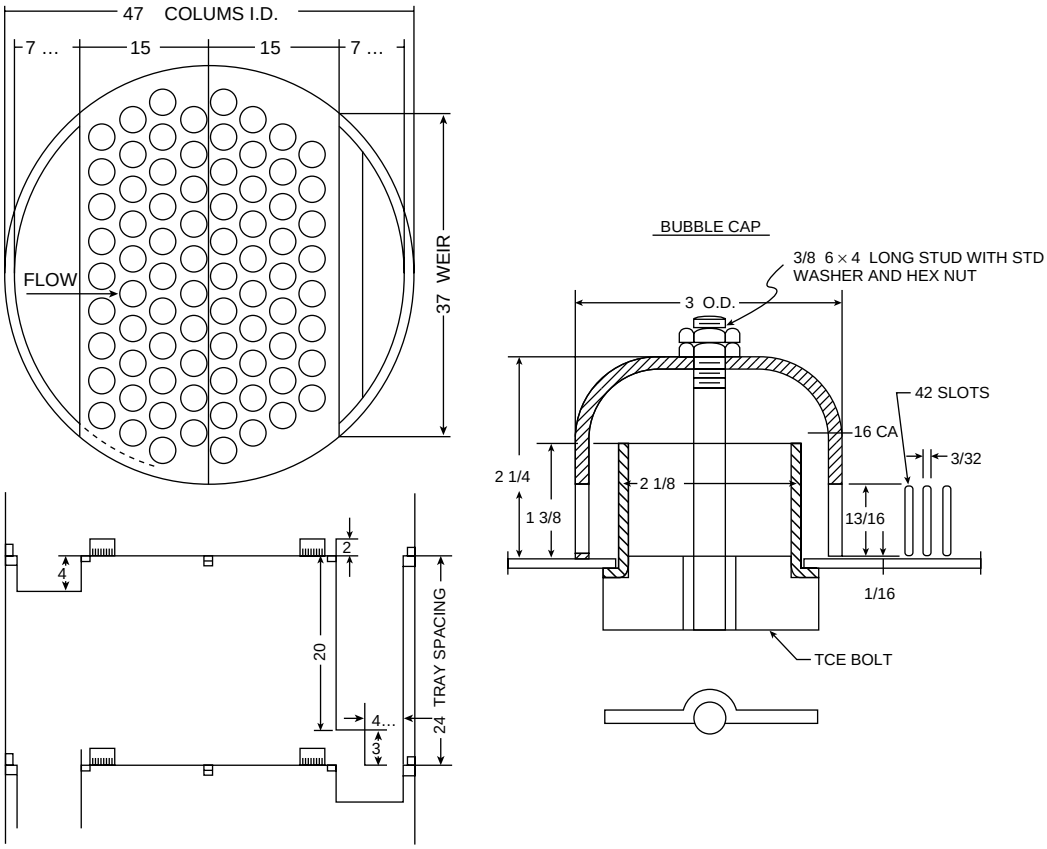

Fig. 4 Mechanical details of 3 in. cap installation at FRI. (Drawing courtesy of Fractionation Research, Inc.)

systems. The most dependable predictions for a new system are therefore based on operating data for similar equipment and distilling systems. To this end, pertinent data obtained by FRI are given in the following material (Fractionation Research, Tulsa, Oklahoma, U.S.A., private communication, 2003).

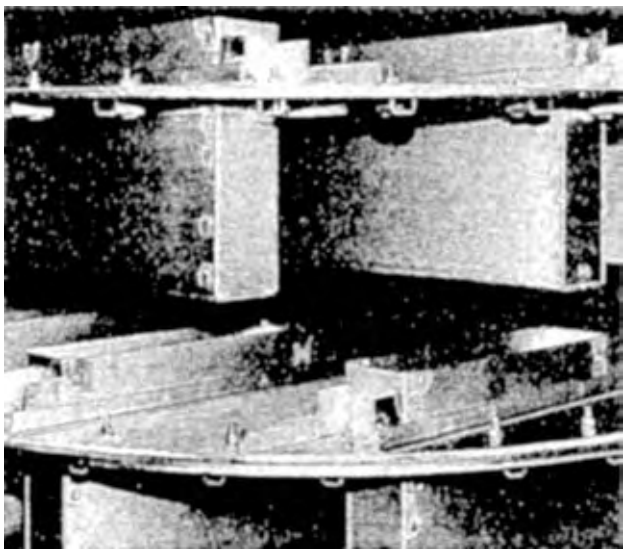

Fig. 5 Side view of MD trays. (Courtesy of UOP.)

Vapor-Limited Capacity

Operation of bubble cap trays at high vapor rate in effect may be limited by massive entrainment of a liquid into the vapor stream. This causes high-pressure drop for vapor flow, which in turn prevents liquid from flowing down the tower. Thus, while the term ''vapor flood'' is often applied to conditions of high entrainment, it is also true that flooding refers to a failure to handle liquid flow.

Fig. 6 includes full-scale capacity data for 3, 4, and 6 in. caps at low pressure obtained by FRI and by Shell for 6 in. caps only (Fractionation Research, Tulsa, Oklahoma, U.S.A., private communication).[9] Both sets of data for 6 in. caps show a capacity deficit compared to the smaller caps; however, the Shell data show approximately 80% of the capacity found by FRI. The difference may be caused by system properties or by the more conservative definition of flood point used by Shell. Data at higher pressure with the butane–isobutane system at the 4 ft diameter were also obtained by FRI (Fig. 8).

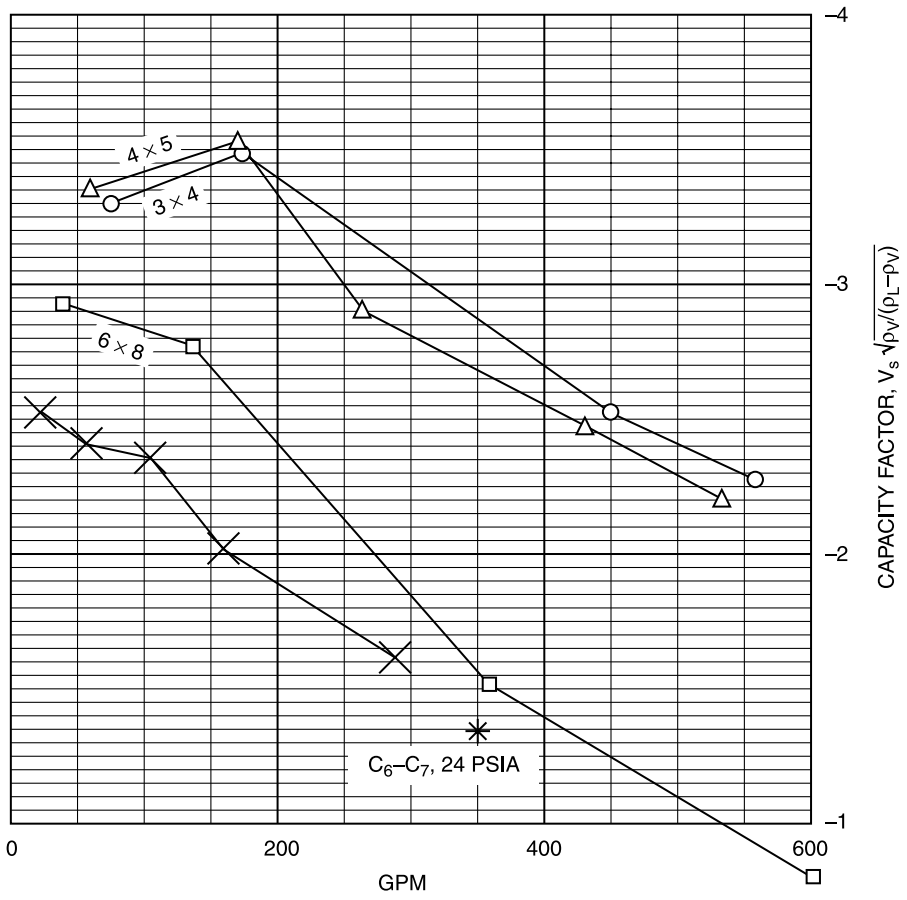

Fig. 6 Capacity of bubble cap trays, low-pressure systems. V_s, superficial vapor velocity (ft/sec); ρ_v, vapor density (any units); ρ_l, liquid density (same units as vapor); ○, data supplied by FRI for 3 in. caps and on 4 in. triangular pitch; Δ, FRI data, 4 in. caps on 5 in. triangular pitch; □, FRI data, 6 in. caps on 8 in. triangular pitch; ×, Shell data, 6 in. caps on 8.5 in. triangular pitch, 2,2,4-trimethyl pentane/toluene system, 19.7 psia; ∗, except Shell data. (From Ref.[9].)

Effect of Foaming Tendency

Systems of low-foaming tendency tend to conform to a standard capacity prediction as defined by liquid and vapor densities. Systems of higher molecular weight also have higher boiling points. Thus, at a given operating pressure, higher distilling temperatures for heavier materials cause foaming tendencies to be similar to those for distilling lighter materials. There is, however, no guarantee that a new system may not have unusual foaming tendency.

The degree of foaming tendency may be checked by laboratory foaming tests, but it is difficult to predict what effect a given degree of foaming may have on tray capacity.

At least four types of foaming systems have been recognized in the distilling industry. They are:

1. The ''soapy'' foam in which bubbles are stabilized by surface-adsorbed components. These foams cover a wide range of system factors. Sometimes chemical foam-breaking additives are used.
2. A second type of foam is found in which the liquids have high viscosity so that the liquid film forming the bubbles drains slowly. An example of this type is encountered when stripping small amounts of volatile solvents from heavy hydrocarbon lubricating oils.
3. Another type of foam has been observed when a multicomponent liquid has a composition close to a separation into two liquid phases. Surface tension drops to a very low value, allowing easy formation of bubbles. An example is found in solvent recovery from lubricating-oil extraction processes. This type of foam has been referred to as ''Ross'' foam,[10] named after an investigator of these foams.
4. The fourth type, Maragoni foam,[11] so called after Maragoni's observation of liquid film stabilization on evaporation, has been described by Zuiderweg and Harmens.[12] This foam occurs in a complex system when surface tension increases as evaporation proceeds, thus strengthening the bubbles. It is usually weak, thus often felt to have little industrial significance. On the other hand, there appears to be no other way to

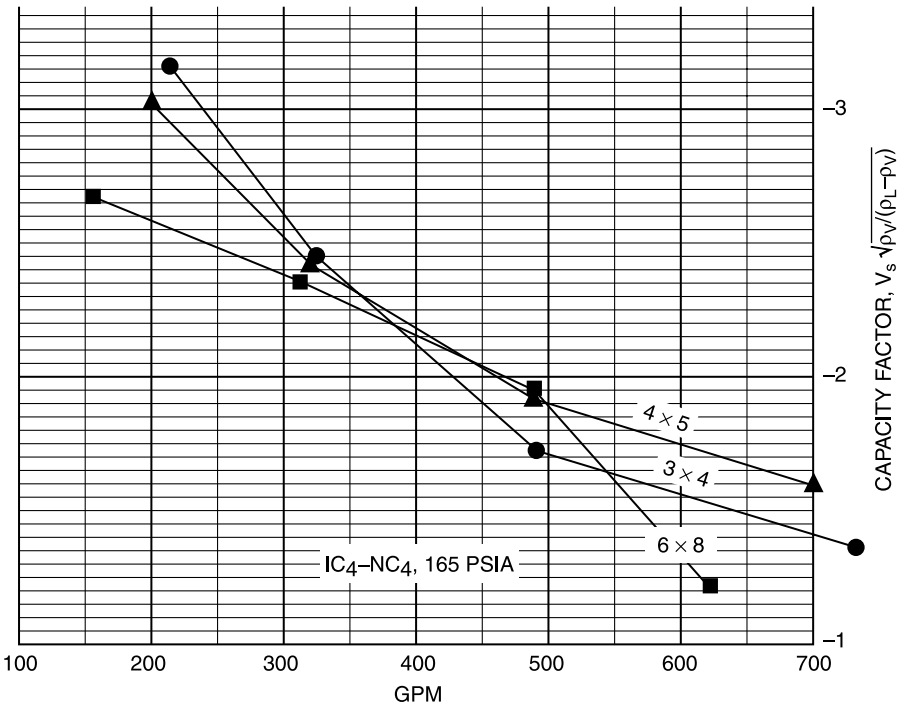

Fig. 7 Capacity of bubble cap trays, butane–isobutane system (FRI 4 ft. I.D. Tower). •, 3 in. caps on 4 in. triangular pitch; ▲, 4 in. caps on 5 in. centers, triangular pitch; and ■, 6 in. caps on 8 in. centers, triangular pitch. (Data courtesy of Fractionation Research, Inc.)

explain the strong capacity decrease observed in the upper trays of absorption plant stripping towers in the petroleum refining industry. Of course, slurries of fine particles are a special case of foaming.

The observed system capacity factors have been reported by Glitsch in Table 1.

Predicting Vapor-Limited Capacity

The most conservative definition of vapor flooding capacity is the load for which tower pressure drop exhibits a sharp increase, signifying liquid buildup at some tray. It is, however, possible to operate the tower at somewhat higher load, perhaps 10% more. As the load is increased, reboiler pressure rises, allowing a semistable operation, albeit with reduced separating efficiency. Fractionation research with others is understood to use a higher limiting load, i.e., the load at which the tower becomes inoperable.

When flooded zones expand, they move upward in the tower. The limiting tray can often be identified from pressure measurements.

Souders and Brown introduced the relationship $U_{\max} = KV\sqrt{D_v/(D_l - D_v)}$, a modified kinetic energy ratio to correlate limiting entrainment rates for various systems.[13] In this relationship V is the vapor velocity; D_v is the vapor density; and D_l is the liquid density.

Fair has published a refinement of the Souders–Brown correlation for bubble cap tray capacity,[3] while Glitsch has provided a vapor flooding relationship for valve trays, which also seems to represent bubble cap tray capacity for 3 or 4 in. bubble caps at low pressure.[14] In the latter, originally developed for valve trays and called ''equation (13)'' by Glitsch, the effect of hydraulic liquid head gradient is expressed as an equivalent added vapor load:

$$\frac{\%\ \text{Flood}}{100} = \frac{V_{\text{load}} + \text{gpm} \times \text{FPL} \div 13{,}000}{\text{AA} \times \text{CAF}}$$

In this relationship, V_{load} is the vapor rate, cfs $\times \sqrt{D_v/(D_l - D_v)}$; FPL is the flow path length across the tray (in.); gpm is the liquid flow rate (gal/min); AA is the active tray area (ft^2); and CAF is the Glitsch capacity factor (Fig. 9).

Table 1 System factors for capacity estimation

Nonfoaming regular systems	1.0
Fluorine systems, e.g., BF_3, Freon	0.9
Moderate foaming, e.g., oil absorbers, amine, and glycol regenerators	0.85
Heavy foaming, e.g., amine and glycol absorbers	0.73
Severe foaming, e.g., MEK units	0.60
Foam-stable systems, e.g., caustic regenerators	0.30

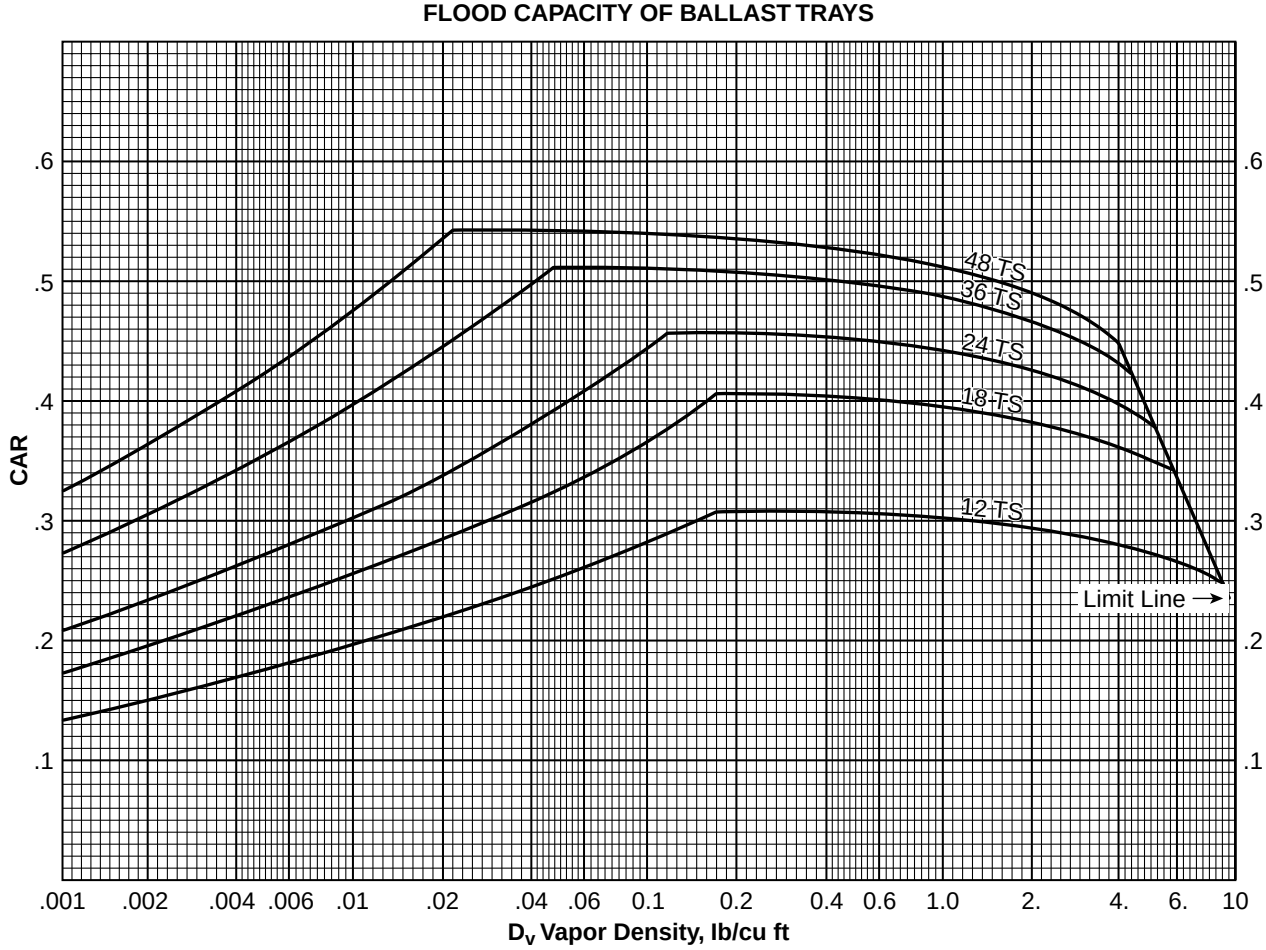

Fig. 8 Glitsch capacity factors for valve trays or bubble cap trays with small caps. TS, tray spacing. (Courtesy of Koch–Glitsch, Inc.)

A conservative design would be to take 90% of the Glitsch value as the flooding load with 3 in. bubble caps, and 70% of the valve-tray flooding load for a tray with 6 in. caps (Fractionation Research, Tulsa, Oklahoma, U.S.A., private communication).

Liquid Rate Flooding

Flooding is much more sensitive to vapor rate than to liquid rate. Trays can, however, definitely be flooded by high liquid rates. Prediction of maximum liquid capacity is based on hydraulic calculation of liquid backup in the downcomers. For low-foaming systems, it is often assumed that liquid backup cannot be more than half of the downcomer height, calculated as clear liquid. For high vapor density, e.g., 3.0 lb/ft^3, the limiting backup is even less.

Above the limiting liquid load, the vapor is entrained downward in the downcomer, the tray liquid level builds up, and the liquid becomes entrained into the vapor stream. The tower floods with the liquid, separation degrades, and eventually the liquid carries overhead just as in vapor-initiated flooding.

Predicting Liquid-Limited Capacity

The backup of the liquid in the downcomer is the liquid depth on the tray plus the equivalent tray pressure drop and the head loss under the downcomer skirt. The latter can be somewhat decreased by using a shaped downcomer skirt edge, but this measure is often found to be inconvenient.

The dry tray head loss for vapor passing through the caps has been measured by a number of investigators.[2,15] In general, we add the head loss through the riser, the slots, and the reversal area to give very roughly three times the velocity head ($U_{\text{riser}} \times D_{\text{vapor}}$) (in ft) of the fluid handled. To this dry tray drop, we add the submergence at the bottom of the slot opening, calculated from the weir height and the weir crest, plus half of the liquid-head gradient on the tray, to get the wet tray pressure drop. Bolles and Dauphine, as

summarized by Ludwig, give a detailed exposition that is too lengthy to include here.[1,2,15]

The downcomer liquid backup, then, is:

$$H_d = h_w + h_{ow} + \Delta + h_d + h_t$$

where H_d is the downcomer backup (in. of liquid); h_w is the weir height (in.); h_{ow} is the weir crest (in. of liquid); Δ is the hydraulic gradient across the tray (in.); h_d is head loss under the downcomer skirt (in. of liquid), and h_t is the total wet tray pressure drop (in. of liquid).

The wet tray pressure drop is obtained by calculating the dry tray drop, then adding the slot submergence, including the weir crest and half of the average hydraulic gradient.

The weir crest is obtained from the Francis weir formula as $h_{ow} = 0.4(\text{gpm}/L_{wi})^{2/3}$, in which L_{wi} is the effective weir length in inches.

The slot opening is easily obtained from the volumetric vapor flow at the tray pressure and temperature, and the slot geometry.

It is also required to size the downcomer for adequate phase separation. One method often employed for setting downcomer design velocity is laid out in the Glitsch design manual for valve trays.[13] Here, the downcomer design velocity is correlated from the difference between liquid and vapor densities and the system factor as described above. For many low-pressure liquids, downcomer area at the top might allow 200–250 gpm/ft^2 at 24 in. tray spacing.

Hydraulic Gradient

Large liquid head gradients reduce tray capacity and may damage separation by causing maldistribution of vapor flow across the tray. In fact, an extremely large head gradient can cause some caps to dump the liquid to the tray below.

Bolles gives helpful guides to predict the hydraulic gradient and are also reproduced in Ludwig.[1,2]

On the other hand, Shell research staff found only a small measured hydraulic gradient on a well-designed low-pressure tower at 5 ft diameter with a liquid load of 121 gpm/ft of weir length.[9]

Trays for High Liquid Loads

Liquid-handling capacity can be improved by splitting the flow between two paths, usually called ''passes'' (Fig. 9). It is frequently possible to use four or more passes per tray, but it is difficult to distribute liquid evenly in a cylindrical tower if more than two passes are used. Another method of handling large liquid flow is to split each flow path into two or more levels with the liquid flowing over a weir at each level.

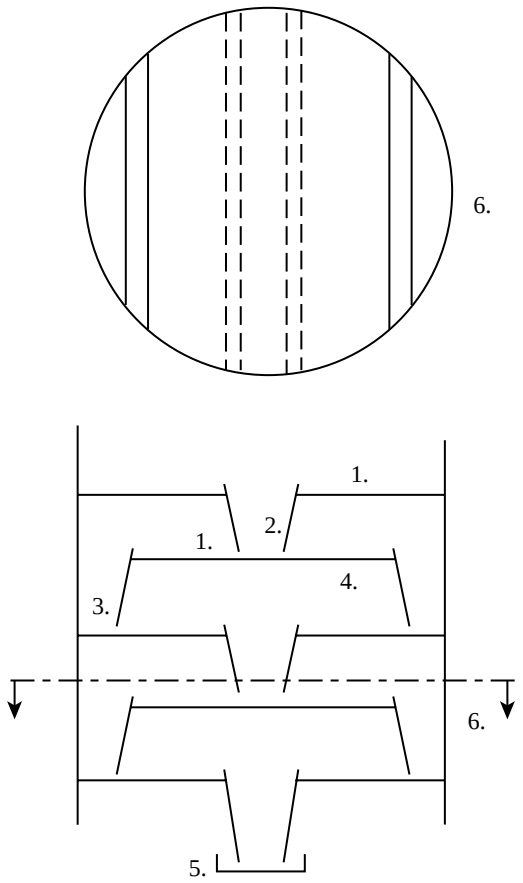

Fig. 9 Two-pass trays: 1) capped areas; 2) center liquid downcomers; 3) side liquid downcomers; 4) disengagement zones; 5) seal pan; and 6) cross-sectional view.

A swept-back weir is often used to increase weir length for high liquid rates. Caps with directional vapor flow may also be used to push liquid across the tray.

''Hanging downcomers'' as in the UOP MD tray (Fig. 5) are useful for high liquid loads, but there is efficiency loss because of the short flow path lengths. This problem may be countered by using more trays at reduced spacing.

Tray Separating Efficiency

Quantification of separating efficiency is useful in: 1) design and 2) rating performance of operating or experimental equipment.

The most commonly used definition of efficiency is the overall efficiency, defined as the number of theoretical trays required for a separation divided by the number of actual trays. A theoretical tray is defined as a contacting stage for which the vapor and the liquid streams leaving would be in thermodynamic equilibrium. The overall efficiency is inexact because separation

within one tower will vary with species properties and tray hydraulics. Practically speaking, it is usually constant in one section of the tower within 10% and is often a basis for design.

For an individual tray, the concept of efficiency often used is the Murphree vapor efficiency, defined as the ratio of the composition change in the vapor stream to the composition change if the vapor leaving the tray were in thermodynamic equilibrium with the liquid leaving. Thus,

$$e_{\mathrm{mv}} = \frac{y_n - y_{n-1}}{y_n^* - y_{n-1}}$$

where y_n is the vapor mole fraction of the light key. The subscript identifies the tray number. y_n^* is the vapor composition in equilibrium with the liquid leaving the tray.

Tray efficiencies are usually assumed to have the same value for each component in the separation. However, actual separating efficiency for several components may vary because of differing molecular properties, such as diffusivity.

In research and development work, a concept called point efficiency is useful. Considering a local element of tray contacting area, the point vapor efficiency is defined as the composition change in the vapor stream passing through the element, divided by the composition change that would be obtained if the vapor leaving the element were in equilibrium with the liquid leaving it.

$$e_{\mathrm{l}} = \frac{y_{\mathrm{l},n} - y_{\mathrm{l},n-1}}{y_{\mathrm{l},n}^* - y_{\mathrm{l},n-1}}$$

where e_{l} is the point vapor efficiency; $y_{\mathrm{l},n}$ is the composition of the vapor leaving the tray element; $y_{\mathrm{l},n-1}$ is the composition of the vapor entering the tray element from the tray below; and $y_{\mathrm{l},n}^*$ is the vapor composition that would be in equilibrium with the liquid leaving the tray element.

Point efficiency is difficult to measure directly because it is hard to get a vapor sample experimentally that does not contain entrained liquid droplets.

It would be possible to do design work integrating local efficiencies for each tray through the entire tower, though calculating the detailed work required would be a lengthy procedure.

A related design concept would be to use a film diffusion model to predict composition changes for each element of tray area, integrating over the entire tower. This ''rate based'' concept has attraction in special cases and is of course the normal method of design for packed distilling towers, as contrasted to plate towers.

For design purposes, it would be accurate to use the Murphree efficiency that is applied to each tray and integrated for the entire tower. Some day it may be feasible to do that. The amount of calculation required for a complete Murphree efficiency approach would be large, and often the overall efficiency is close to the Murphree tray efficiency.

Prediction of Separating Efficiency

An important reference often used for design is O'Connell's correlation of tray efficiencies.[16] This work is an improvement of an earlier publication by Drickamer and Bradford.[17] In O'Connell's correlation (Fig. 10), it is assumed that mass and heat transfer depend on diffusivities and liquid viscosity, and that both effects can be correlated by using the liquid viscosity and the component relative volatility for the separation.

The next step in predicting tray efficiency for design would be to take into account the effects of 1) tray and tower configuration and 2) hydraulic conditions on the tray. For the effects of the former, one can refer to a comprehensive treatise by W. K. Lewis, Jr.[6] In this somewhat idealized study, the advantage of plug flow of liquid across the tray and its flow direction for the liquid on each tray is shown. Such an arrangement can produce Murphree tray efficiencies as high as 150% from a point efficiency of 80%.

A few towers with very low liquid flow rates have been set up with pipe downcomers arranged for liquid flow in the same direction on successive trays. On the other hand, it is much simpler mechanically to provide reversed flow of liquid on adjacent trays.

If the liquid flow is reversed on successive trays, the cross-flow enhancement of efficiency is greatly reduced, but still present. Thus, tray efficiencies of 110% or more are sometimes observed for low-viscosity systems, such as depropanizers or butane–isobutane splitters.

The effects of tray leakage and liquid entrainment in the vapor stream may need to be taken into account. For bubble cap trays, tray leakage is normally of no significance. Entrainment, on the other hand, can decrease separation markedly. Quantitative prediction of entrainment is sometimes possible; however, the effect of entrainment is usually combined with the effect of vapor velocity on local efficiency, using the results of experimental full-scale studies, such as those performed by FRI.

Optimization of Tray Efficiency

It is tempting to reduce capital cost by designing distilling towers that operate at a high percentage of maximum load, say 85% or more, though the optimum design may be at lower loads; for example, see Fig. 11.

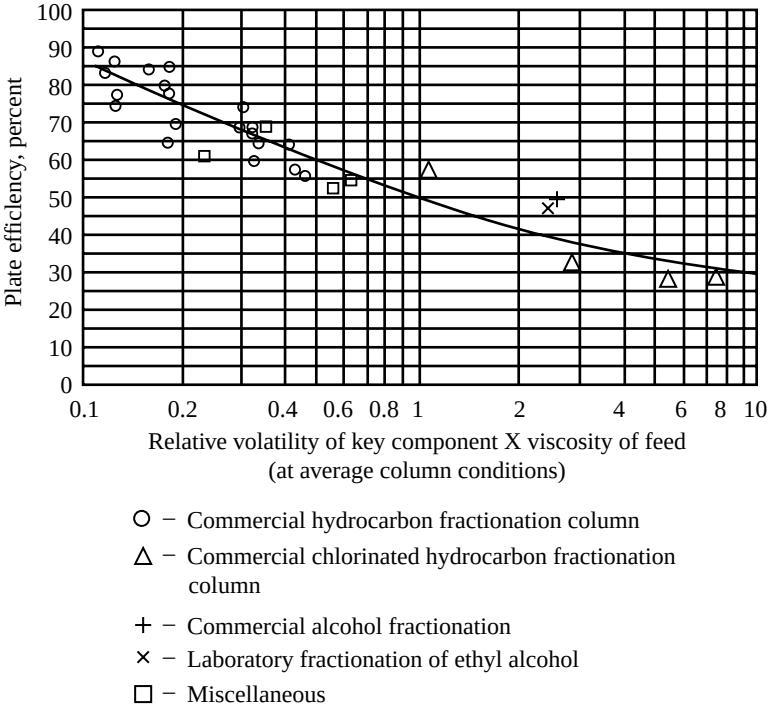

Fig. 10 O'Connell correlation of tray efficiencies. (From Ref.[16].)

The maximum efficiency is frequently found at approximately 60% of the maximum vapor load. At higher loads, vapor contact time is decreased and entrainment may significantly reduce tray efficiency.

It has been confirmed that the effect of vapor rate on entrainment has a higher exponent for dense vapors as in high-pressure distillation.[18] Thus, the effect of entrainment on efficiency is less marked for high-pressure distillation, because as soon as entrainment sets in with increasing vapor rate, the column is overcome by the massive entrainment rate. This effect may mean that it is reasonable to design for a somewhat higher fraction of flooding vapor load in a high-pressure system than in a low-pressure system. See Fig. 12 for FRI data on the effect of vapor rate on efficiency at high pressures.

It is rare to encounter a satisfactory long-term operation at more than about 92% of vapor capacity. Above about 95% of maximum load, small surges in feed rate or reboil rate may cause temporary local flooding, which interferes with good separation.

The effect of entrainment on separating efficiency depends on each case. In general, entrainment is more harmful in rectifying sections than in stripping sections, because it carries less volatile components toward the draw point for the volatile product. It is, in fact, possible to estimate the reduction in tray efficiency caused by a given amount of entrainment. The amount can be estimated roughly by the method of Simkin, Strand, and Olney.[18]

Tray Spacing, Hydraulic Regime, and Entrainment

Direct observations of operating distilling towers have established that the liquid/vapor mixed phase on a bubble cap tray usually exists in three zones. On the bottom there is a thin layer, a few millimeters thick, of dense liquid. Above this is a somewhat foamy layer containing a lot of vapor, but essentially liquid-continuous. This layer extends roughly to the top of the caps or, perhaps, a few centimeters higher. Then the upper part of the tray space contains a spray zone, varying in density so that relatively little liquid is carried to the tray above.

As pointed out by Bennett and Novak,[19] at low liquid rates the liquid-continuous foamy layer may practically disappear and mass transfer takes place in a vapor-continuous spray regime.[19] Operation in the spray regime is less effective for mass transfer and should be avoided when possible.

When the vapor rate is increased as much as possible, the region of higher spray density expands upward and an exponential increase in liquid tray-to-tray entrainment takes place.

Larger tray spacings reduce entrainment markedly. The optimum spacing will vary with the system. For example, systems that leave corrosion products behind must be maintained more frequently. It may then be necessary to have 2 ft. tray spacings to allow convenient access. The optimum spacing for clean systems will be less, perhaps 15 or 18 in.

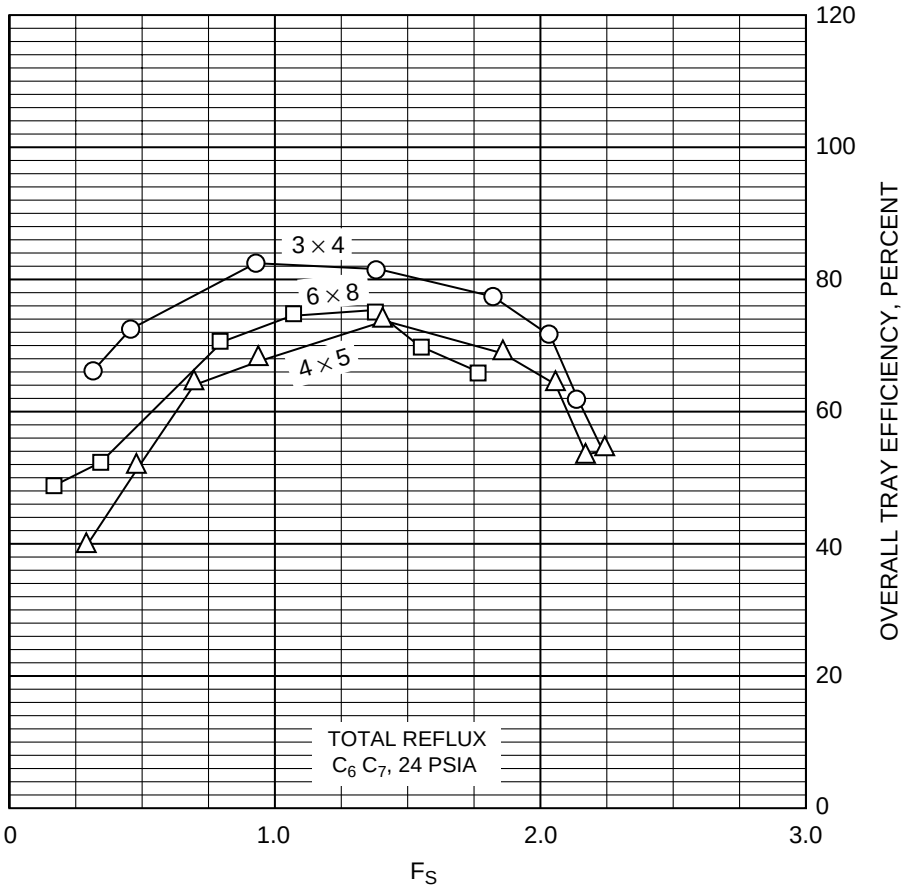

Fig. 11 Data on efficiency of bubble cap trays at low pressure. $F_s = V_s P_v^{1/2}$ (for legend see Fig. 6). (Data courtesy of Fractionation Research, Inc.)

Large-diameter towers require more spacing to provide heavy tray supports.

Effect of Liquid Leakage

The effect of liquid leakage from the tray is more important for stripping trays than for rectifying trays. For stripping trays, liquid leakage carries more volatile components toward the draw point for the less volatile product, thus reducing the effectiveness of the stripper. Fortunately, for most bubble cap trays, there is no tray leakage of consequence.

VACUUM TOWERS

Bubble cap trays are often used in vacuum towers with absolute top pressures of 50–120 mm mercury (Torr.). For lower top pressures or large numbers of theoretical trays, structured packing may be preferred because of its lower pressure drop per theoretical stage. If practicable, the bubble cap trays have the advantage of lower installed cost and easier cleanup in fouling service.

The importance of tray pressure drop in vacuum columns might be illustrated by the following example: Take a limiting case with 50 mm mercury (Torr) top tower pressure. If tray pressure drop is at best 2 mm mercury/tray and 20 actual trays are needed (assume 10 theoretical stages), then the bottom pressure would be at least 90 mm mercury. The reboil pressure would need to be higher, perhaps 120 mm mercury absolute. In a typical situation, the bottom oil product might tolerate 800°F for a short time. The maximum equivalent atmospheric initial boiling point for the bottom product oil would be about 750°F. This boiling point would be too low for most lubricating oils; but if a large flow of steam is introduced into the tower, the reduction in oil partial pressure might allow an equivalent atmospheric boiling point of the bottom product as high as 950°F, or 510°C. This initial boiling point is in the range of industrial and automotive lubricating oils.

There are many cases in which deeper distillation cuts are needed. For such cases, the packed towers can go somewhat deeper. Furthermore, heat-sensitive materials may require lower bottom tower temperatures. A more expensive device, such as the spinning band column, can go to very low pressures because

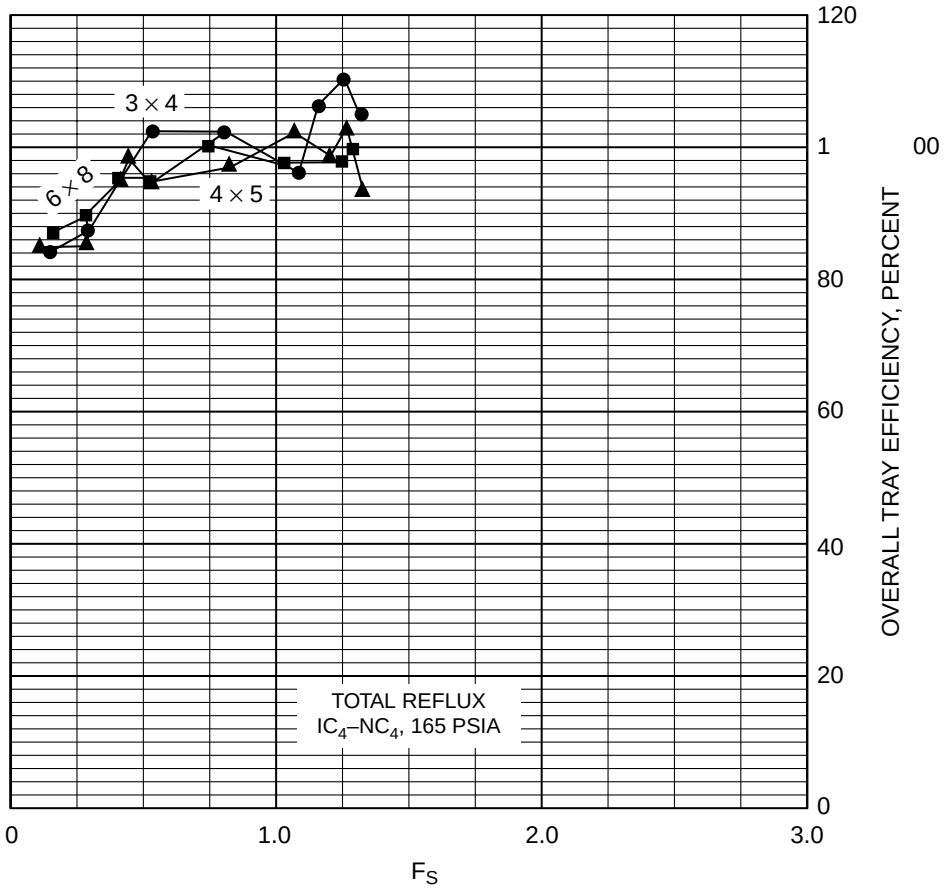

Fig. 12 Tray efficiency of bubble cap trays at high pressure. In FRI 4 ft tower. $F_s = V_s P_v^{1/2}$ (for legend see Fig. 7). (Data courtesy of Fractionation Research, Inc.)

the contacting dispersion is supplied by an external source of energy.

Another advantage of bubble cap trays for vacuum distillation is that there is no tray leakage. At the low liquid rates used in vacuum distillation, tray leakage, if present, would have a large effect on separation.

Bubble cap trays in vacuum service normally have a large number of small caps, say 3 in. diameter. Slot submergence is reduced by using a small exit weir height. The slot submergence is often only 0.25 in. or so to reduce tray pressure drop. Maintaining liquid seal on the tray can be made more certain by recessing the bottom end of the downcomers below the tray deck level. Recessed seal pans have an advantage by allowing larger skirt clearance for any kind of service. As pointed out earlier, there are also disadvantages in the use of recessed downcomer bottoms.

Blowing at Low Liquid Loads

Vacuum towers have high vapor velocities because of low vapor density; they also have correspondingly low liquid loads. The liquid/vapor flow parameter, $F_{lv} = L/G\sqrt{D_v/D_l}$ dimensionless, in which L is the liquid rate (weight units); G is the vapor rate (weight units); D_v is the vapor density; D_l is the liquid density (same units as vapor density); if below about 0.005, is considered to be on the low side. It is possible under such conditions for the high cap-slot velocities to pick up a major fraction of the liquid on the tray and blow it into the exit downcomer, thus bypassing good contact in the active zone of the tray.

Two methods are used to prevent tray liquid blowing. The simplest is probably the picket-fence exit weir (see Fig. 13). In this arrangement, a high exit weir interrupts the trajectory of flying liquid droplets. The slots control liquid depth on the tray.

The second antiblowing technique is to install a vertical baffle upstream of the exit weir. Substantial clearance above and below the baffle allows normal tray function (Fig. 14).

FEEDING ARRANGEMENTS

Feed streams are often introduced by means of a perforated pipe distributor (Fig. 15), which directs the

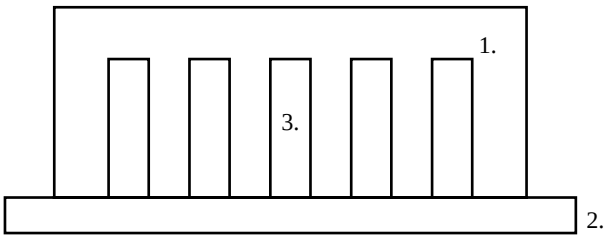

Fig. 13 Picket-fence exit weir: 1) spray-catching baffle, 12 in. or higher; 2) nominal exit weir height; 3) and open slots to allow liquid passage.

flow against the wall of the downcomer from the tray above the feed tray. Often the liquid introduced may not reach equilibrium with the tower internal liquid stream before it reaches the exit weir. To prevent capacity limitation by boiling the liquid in the downcomer, it is a good practice to provide extra spacing for the tray below the feed tray as well as on itself.

Similarly, cold condensate reflux may not be completely heated to top tray temperature by passage over one tray. Providing extra tray spacing below the top tray may prevent hydraulic disturbance at the top tray.

Superheated feeds from chemical reactors or petroleum cracking units are a special case, often requiring a baffle-tray desuperheating section in the tower.

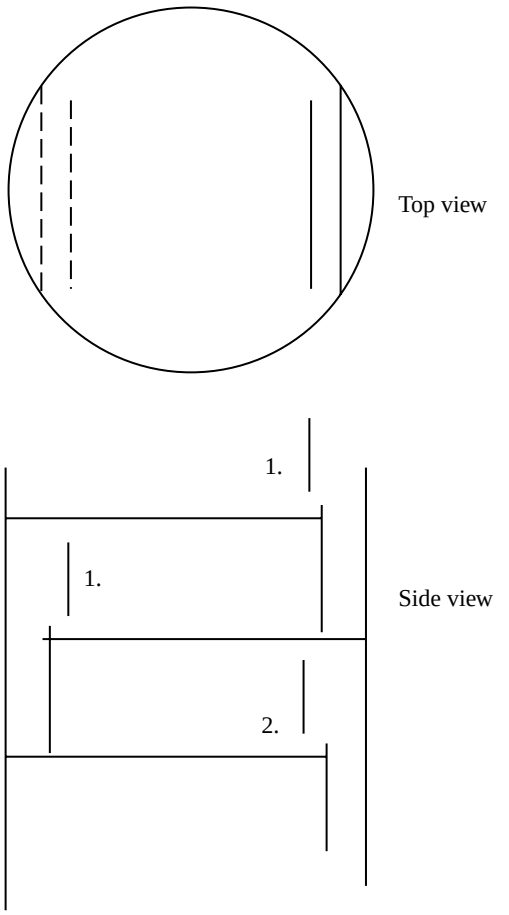

Fig. 14 Antiblowing baffle arrangement: 1) antiblowing baffle and 2) clearance for liquid passage.

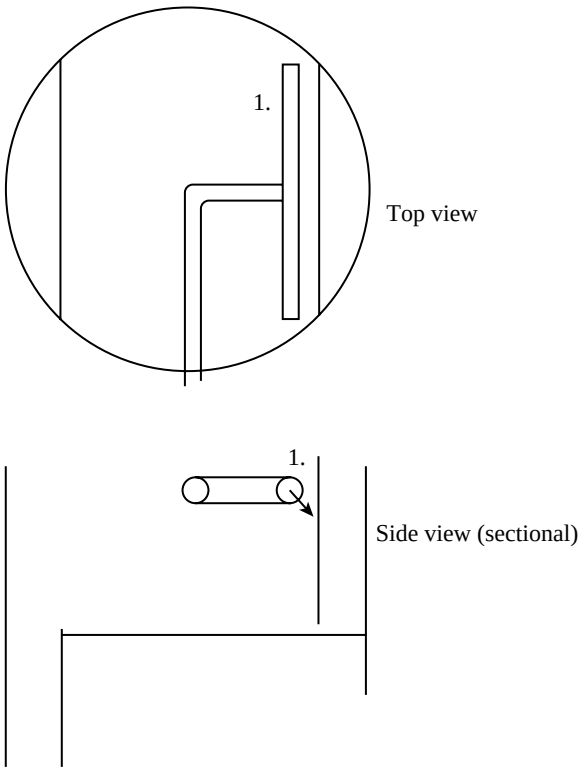

Fig. 15 Slotted feed manifold, showing stream entry. 1) Slotted feed delivery pipe.

SIDE-DRAW PRODUCTS

Partial Draws

If the draw is markedly less in rate than the internal liquid flow, it can be drawn under flow control from an internal or external sump, and arranged so that the tower internal reflux flows through the sump. It is a good idea, nonetheless, to have a seal baffle or a seal pan set up so that if the side draw rate is set higher than the internal reflux flow, the downcomer will not become unsealed.

Total Draw Streams

If the draw stream rate is to be at or near the total internal liquid flow rate, it is best to provide an internal or external sump, with the draw rate controlled by the liquid level. The residual internal reflux can be a controlled flow to the tray below the draw.

Vapor Side Draws

Vapor side draws are rarely used. Usually, extra tray space is provided with a demister mat placed to exclude liquid droplets.

CONCLUSIONS

Bubble cap trays are used in thousands of distilling, absorption, and stripping towers to provide mass and heat transfer between liquid and vapor streams. In new construction projects, valve trays and sieve trays are used more often because of lower capital cost. However, bubble cap trays continue to be preferred when tray leakage must be prevented as, for example, if liquid flow rate is unusually low. They are also superior in effective range of throughputs. It has been found that the best capacity and efficiency are obtained with small (3 or 4 in. diameter) round caps. Those with such caps have a capacity advantage of 10–25% over trays with larger caps, such as those with 6 in. diameter. Apparently, the larger caps have more resistance to liquid flow, causing the liquid to accumulate on the tray, thus leading to more entrainment and downcomer backup.

For pressures near atmospheric, bubble cap trays with the smaller caps are approximately equivalent in hydraulic capacity and separating efficiency to valve or sieve trays.

Modern tray designs often increase hydraulic capacity by modifying the liquid downcomers to increase bubbling area. For example, some trays use hanging downcomers, in which no active tray area is sacrificed for liquid delivery.

Bulk Molding and Sheet Molding Compounds

Sanjeev N. Rao
Krishnan Jayaraman
University of Auckland, Auckland, New Zealand

INTRODUCTION

Both bulk molding compound (BMC) and sheet molding compound (SMC) are precompounded reinforcements intended for fast processing by compression, transfer, and injection molding. As its name implies, SMC is supplied in sheet form, while BMC, though similar in constitution, is supplied in bulk form, usually as a thick rope or a log. The compounds consist of reinforcing fibers (almost always random discontinuous E-glass), fillers, and resin [which is usually either unsaturated polyesters (UPE) or vinyl ester]. The SMC has a leathery consistency and may be cut with shears or blanked into shapes, whereas BMC is in the form of dough generally extruded as a log or a rope that is weighed and consolidated by hand first. The charge is then placed in the mold. This entry discusses some general aspects of BMC and SMC, their variants, molding technology, reuse, and applications.

BACKGROUND

Polymer composites are widely used in the automobile, electrical, and building industries because of their properties. Earlier, conventional methods (where the fibers and resin were combined and wetted out within the process) were used in the manufacturing of composite parts, but as technology advanced, there have been innovations in the field of formulation, compounding methods, and molding techniques.

These improvements have made it possible to develop compounds with excellent and varied performance characteristics at low compound cost by the choice and regulation of the proportions of the compound ingredients.

BMCs and SMCs are based on unsaturated polyesters and short glass fiber reinforcements. They have found wide applications, particularly in automotive and electrical industries, in parts such as automobile bumpers, light housings, and reflectors because of their low price and easy processing. The earliest BMC was manufactured as early as the 1950s, employing a process that impregnated the glass fibers with resins, fillers, and other additives. Today BMC and SMC are mostly accepted as high-performance thermoset molding compounds used extensively in the manufacture of electrical and automobile components. This entry deals with an overview of BMC and SMC, their manufacturing techniques, compositions, properties, and applications.

BULK MOLDING COMPOUNDS AND SHEET MOLDING COMPOUNDS

BMCs and SMCs are polyester-based thermosetting composite materials that are a premix of fiber reinforcements, fillers, and additives that cure under heat and pressure. Unlike conventional manufacture of composites, BMCs and SMCs are fully compounded products that are readily available to mold. The constituents of both compounds are similar but differ in proportions; BMCs generally have high filler and low fiber content, making it flow easily and improving its moldability. The properties vary according to their area of application;[1] however, they are typically materials having high rigidity and heat resistance, good electrical insulation, shrinkage, and good dimensional stability. BMC is also termed dough molding compound because of its appearance, and it is usually extruded as a long rope or a log, while SMC is usually in the form of sheets that appear in the form of continuous rolls. Typical SMC sheets are 1–2 m wide and around 5 mm thick.

FORMULATIONS

The main constituents of BMC and SMC are thermosetting resin, fiber reinforcements, and some fillers. Table 1 gives the formulations of BMC, SMC, and their variants.

Resins

The polymer component, which is a thermosetting resin, forms cross-linked bonds between chains of molecules, which enhances the characteristic of the product. Unsaturated polyesters and vinyl esters are primarily used as resin systems. Epoxies are also used in some cases, but the cure cycle is longer. Phenolic resins have gained importance these days because of their inherent properties, especially in applications that require lower flammability, reduced smoke generation, and higher thermal stability. New resin systems such as

a hybrid of unsaturated polyester and urethane are also becoming popular.[2]

Fiber Reinforcement

Glass fibers used for reinforcement have the obvious effect of strengthening the material. The length of the glass fibers varies between 3 and 25 mm depending on the type of mold and the molding conditions. E-glass is most commonly used as reinforcement in the composites; other fibers used include carbon, amarid (Kevlar), and S-glass. The glass fiber loading is normally around 30% by weight in compression-molded composites, but can vary from 18% to 65%.[2] Table 2 shows typical fibers used in polymer composites.

Natural fibers have gained importance because of their biodegradable nature. While natural fibers offer properties similar to synthetic ones, their moisture absorption characteristic undermines their efficient use in composite manufacturing.[3] The use of natural fibers goes way back to 1950s when sisal fibers were used as reinforcements for producing automobile heater housings.[2]

Fillers

Both BMC and SMC can accept relatively large filler loadings; most of the fillers used are inorganic and are of mineral type.[4] The fillers used usually produce the following effects:

1. Increase in viscosity of the liquid resin system.
2. Reduction of shrinkage during curing.
3. Act as a heat sink by decreasing the peaking exothermic reaction on cure.
4. Increase in specific gravity of the resin (by using denser fillers).
5. Acceleration or retardation of gel time during cure.
6. Reduction in cost of the composite as compared to pure raw material.

Table 2 Common fibers used in BMC and SMC

Fiber	Specific gravity	Tensile strength (GPa)	Tensile modulus (GPa)	Tensile failure strain (%)	Coefficient of thermal expansion ($\times 10^{-6}$/°C)
E-glass	2.54	3.45	72.2	4.8	5
S-glass	2.48	4.30	86.9	5.0	2.9
Carbon (graphite)	1.76–2.15	1.5–5.6	220–690	0.3–1.2	10.1–1.2 (longitudinal), 7–12 (radial)
Kevlar 49	1.45	3.62	131	2.8	−2 (longitudinal), 59 (radial)

(From Ref.[2].)

The fillers are normally added after thorough dispersion of catalyst in the resin and other additives such as internal mold release, pigments, wetting agents. But the addition may precede the dispersion of catalyst if it is a shrink control filler. Table 3 gives some examples of the fillers used.

Calcium Carbonate Fillers

Calcium carbonate fillers are either of ground limestone type or precipitated chalk type. They are inexpensive and have low oil–absorption, which allows considerable freedom in filler levels while keeping the viscosity under control. Relatively coarse particle size fillers ranging from 30 to 100 mesh are used to incorporate high loadings.

Clay Type Fillers

Clay fillers are used to improve electrical properties of the compound and enhance flow in molding. They are also chemically inert when compared to carbonate fillers, which enhances their chemical resistance.

Alumina Trihydrate Fillers

Alumina trihydrate fillers (ATH) are largely used for imparting flame retardation property to the compound. This property conferred is because of the energy absorption that occurs as three water molecules are liberated from each molecule of ATH at combustion temperatures. Both SMC and BMC employ filler loading levels from 150 to over 200 parts of ATH filler per 100 parts of resin.

Pigments and Colorants

Inorganic pigments such as titanium oxides, and organic pigments such as the phthalocyanine pigments are used as dyes. Care must be taken when using colorants in polyester pigments so that they do not interfere with the proper cure of the resin. With peroxide catalyzed systems, the colorants must also be able to resist the oxidizing action of peroxide.

Thickeners

Thickening agents are integral parts of BMC and SMC. They are used to thicken the molding compounds and make them easy to handle. The most common thickening agents are metal oxides and hydroxides of magnesium and calcium.

Internal Mold Release Agent

Internal mold release agents are added to facilitate part ejection from the mold. The most common types of agents include metal stearates, fatty acids, fatty acid amides, and hydrocarbon waxes. Zinc stearate and calcium stearate are the widely used mold release agents in SMC and BMC.

Low Profile Additives

Low profile plastics are added to reduce shrinkage during cure. They are normally thermoplastics that include polyvinyl acetates, polymethyl methacrylate, and copolymers with other acrylate, vinyl chloride–vinyl acetate copolymers, polyurethane, polystyrene, polycaprolactone, cellulose acetate butyrate, saturated polyester, and styrene butadiene copolymers. More details about the low profile additive (LPA) mechanism are published in the literature.[5]

Table 3 Additive families developed for shrinkage control properties

Category	Examples
First generation. Nonpolar polymer additives that are noncompatible with the resin system	Polystyrene Polyethylene
Second generation. Systems with reduced or no molding shrinkage developed for automotive and other commercial applications	Polyvinyl acetates Polymethylmethacrylate and copolymers Polyvinyl chloride–vinyl acetate copolymers Styrene–butadine copolymers Cellulose acetate butyrate Modified polyvinyl acetates
Third generation. Highest levels of shrinkage control. Accuracy of mold reproduction and surface smoothness	Dual thickening systems containing isocyanate prepolymers Saturated polyesters Saturated polyester blends with polyvinyl chloride Polyurethanes

(From Ref.[1].)

Initiators and Inhibitors

Initiators are used to initiate the curing reaction at elevated temperatures. Cross-linking or polymerization occurs by a free radical mechanism in which the double bond of the polyester chain reacts with the vinyl monomer that is usually styrene, and this reaction provides a three-dimensional network that converts the viscous resin to a hard thermoset solid. The initiators added decompose at elevated temperatures thus providing free radicals to initiate the cross-linking. Peroxyesters and peroxyketals are the most common classes of peroxides used as initiators.

Inhibitors are added in small quantities to increase the shelf life of the compounds. They also help in modifying the cure rate and the magnitude of the exotherm to prevent cracking in thick sections of the molded components. Substituted phenolic derivatives and the quaternary ammonium salts, like hydroquinone and *p*-benzoquinone, are two general classes of inhibitors usually used. More information about initiator chemistry is available in the literature.[5]

MANUFACTURE OF BMC/SMC

Standard SMC consists of chopped strand E-glass blended with resin and fillers supplied in continuous rolls. The schematic of the manufacturing process is shown in Fig. 1. Two sheets of polyethylene films are brought together from different levels and are coated with a resin that has been mixed with fillers, initiators, inhibitors, and thickening agents. The glass fibers are deposited over the coated film and are consolidated to homogeneous sheets. On exit from the machine, the sheets are coiled into rolls and stored in a maturation room.

BMCs are manufactured in a large hopper where all the ingredients are mixed with Z-blades for a set time.

VARIANTS OF BMC/SMC

Z Molding Compounds

Z molding compound (ZMC) was first prepared in France in 1979.[2] This compound needs a special type of injection machine—a combination of plunger and screw—and was indigenously developed by *Billion* in France. The machine uses a screw to homogenize and measure the shot. The injection is made like a plunger by the displacement of the screw and inner barrel inside the main barrel. Compared to SMC, ZMC parts have lower mechanical properties, but higher performance when compared to conventional injection molded BMC.

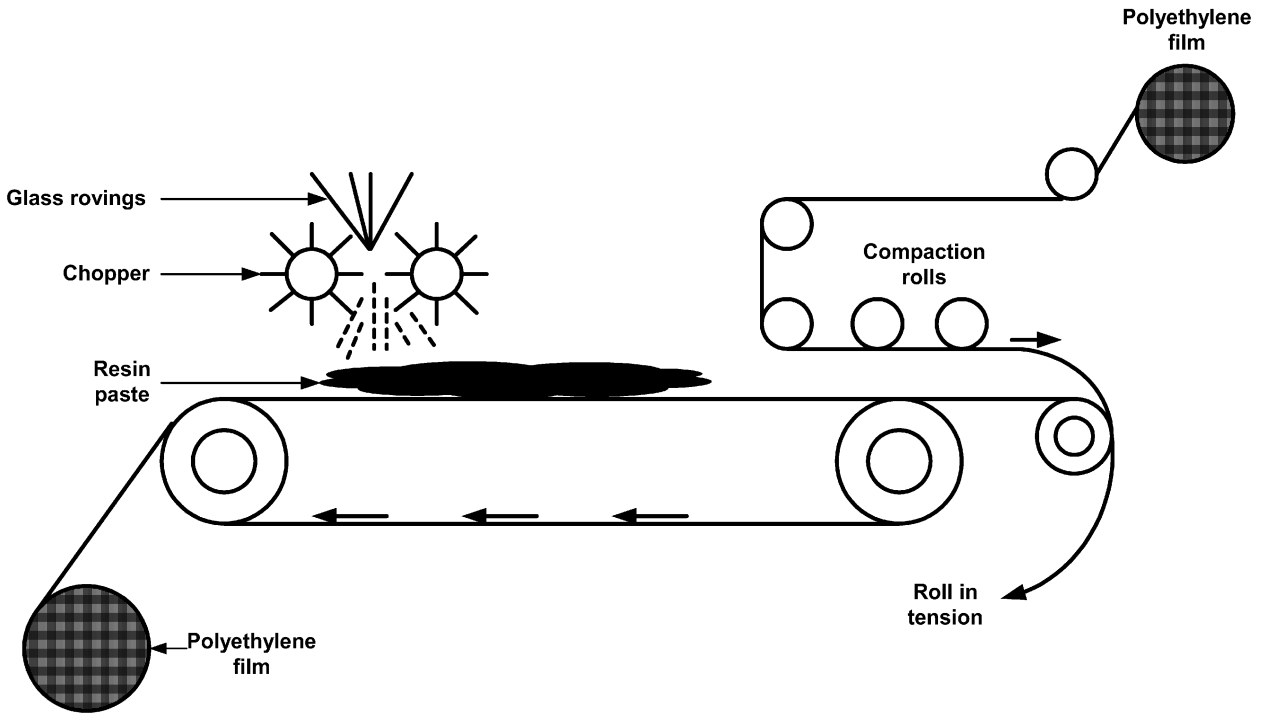

Fig. 1 Manufacture of SMC.

Thick Molding Compounds and Continuous Impregnated Compounds

Thick molding compounds (TMCs) (Fig. 2) and continuous impregnated compounds (CICs) (Fig. 3) are rather recent developments in the manufacture of polyester compounds.[1] They are manufactured by a continuous mixing process that enables high filler and glass loadings. The compounding and equipment used are similar for both the compounds. The resin premix is distributed on two large mixing rolls and then the chopped glass fibers are distributed onto the rolls, and efficient mixing and impregnation takes place as the resin–glass compound passes between the rollers. In TMC, the compound is sandwiched between polyethylene films and passed through impregnation rolls. But in CIC, the compound is removed from the mixing rolls by doctor blades and transported by a screw or plunger into boxes or drums to give the material the physical characteristic of BMC. Modified CIC is also known as kneaded molding compound (KMC).[2]

Low Pressure Molding Compound

Low pressure molding compound (LPMC) is an SMC kind of material. LMPC is made by replacing the chemical thickening mechanism with a physical thickening mechanism using crystic polyester. The material is first heated to melt crystic polyester, and then the other additives are added and run on a modified SMC machine at elevated temperatures. By using cooling rolls, the cooling process can be paced and thus the material could be molded right off the SMC machine without having to wait for 24–48 hr, which is the standard thickening time for SMCs.[2] The shelf life of LMPC is much longer than that of SMC, and the physical properties comparable. LPMC allows the use of lower tonnage presses to mold larger parts, thus reducing the tooling costs.

Glass-Mat Reinforced Thermoplastic

Glass-mat reinforced thermoplastic (GMT) is similar to SMC and is available in sheet form, reinforced with random oriented fibers that may be continuous or discontinuous. It is manufactured on a double belt press where the glass fiber mats are sandwiched between layers of extruded molten polymer before it enters the press. The thermoplastic is usually about a few millimeters thick and thus stiff, and hence stored as flat sheets. Another method involves deposition of a molten mixture of resin, chopped fibers, and additives over a moving belt where the water is driven off. The fiber volume fraction in this compound is usually 0.1–0.3 and fiber lengths are in the range of 10–30 mm, unless the reinforcement is continuous.

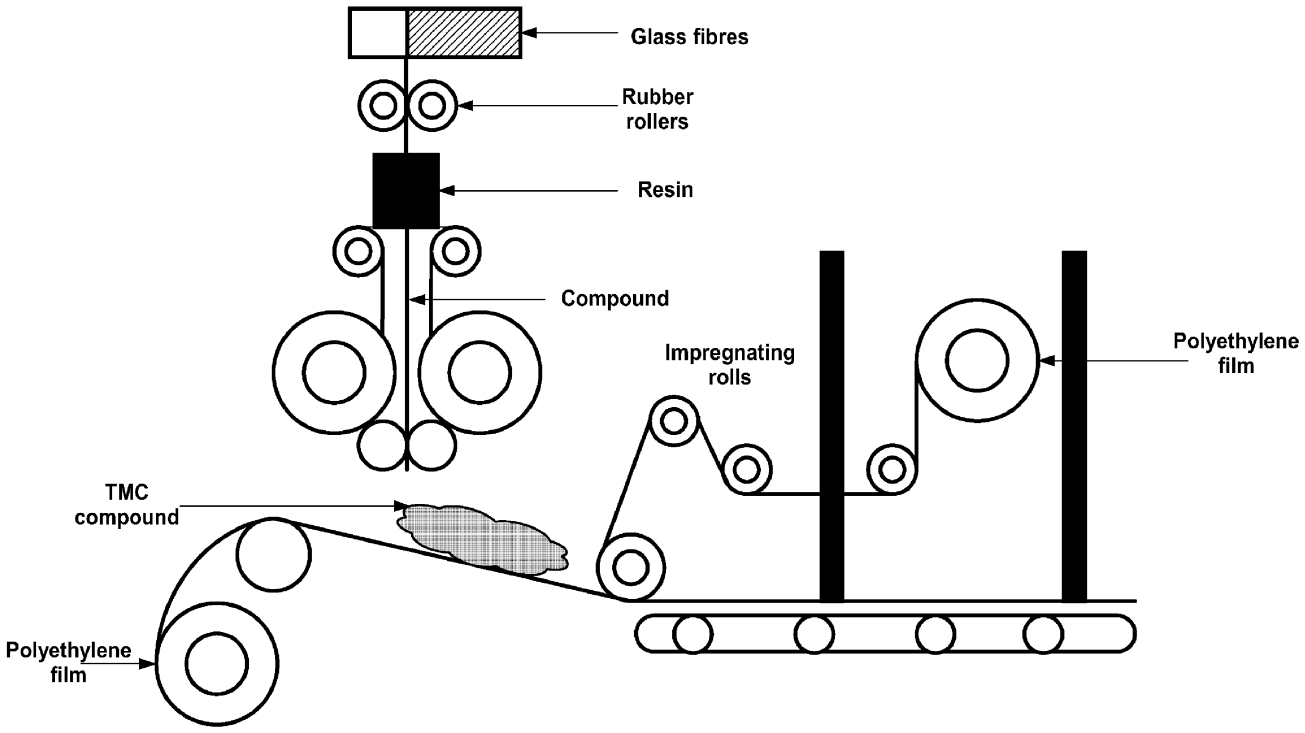

Fig. 2 Manufacture of TMC.

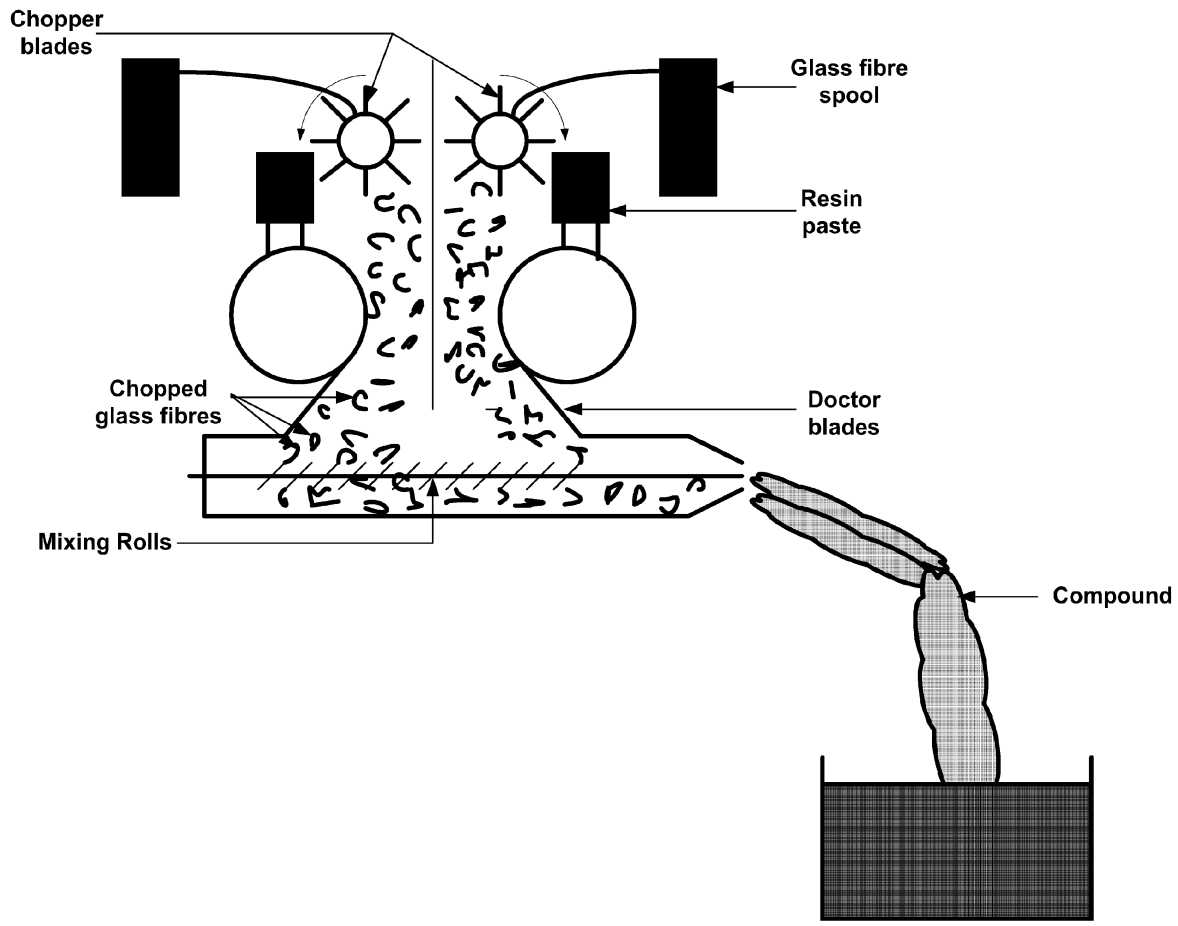

Fig. 3 Manufacture of CIC.

MOLDING OF BMC/SMC

Compression Molding

Matched metal compression molding is one of the oldest manufacturing techniques in the plastics/composites industry. Compression molding (Fig. 4) involves placing a charge into a heated mold and using the closing action of the mold to form the required shape, with cure taking place within the mold. The general technique of the molding process is the same for both SMC and BMC, but the parameters such as pressure and temperature may vary. The pressure applied is low for BMC (35 bar is sufficient for most moldings) and considerably high (70 bar) for SMC to make them flow in the mold. Operating temperature is around 135°C for SMC while it is 120°C for BMC, owing to the fact that BMC flows easily at room temperature. Compression molding is a complex process, and it may result in some surface imperfections that can be controlled by proper material selection, part design, and molding techniques. Compression molding involves four distinct steps.[2]

Charge preparation and placement

The sheets of SMC are cut into a desirable shape (charge is weighed in case of BMC) and stacked on the lower half of the mold, and the movable upper half is brought down to close the mold. BMC material is normally consolidated by hand before they are placed in the mold; in most cases the charge is placed centrally in the mold. The placement determines the quality of the part as it influences the length of the flow in the mold, fiber orientation, flow line, and other surface defects.

Mold closing and filling

Once the charge is properly placed in the mold, it is closed quickly to contact the top surface of the charge. Mold closure is a critical factor: delay in closure time may cause some precure owing to the gelation of the top surface, occurring before the part is molded, and faster closure rates trap air, which induces surface imperfections, which is undesirable. A 10-sec closure time has been suggested as optimum to avoid any precure.[1]

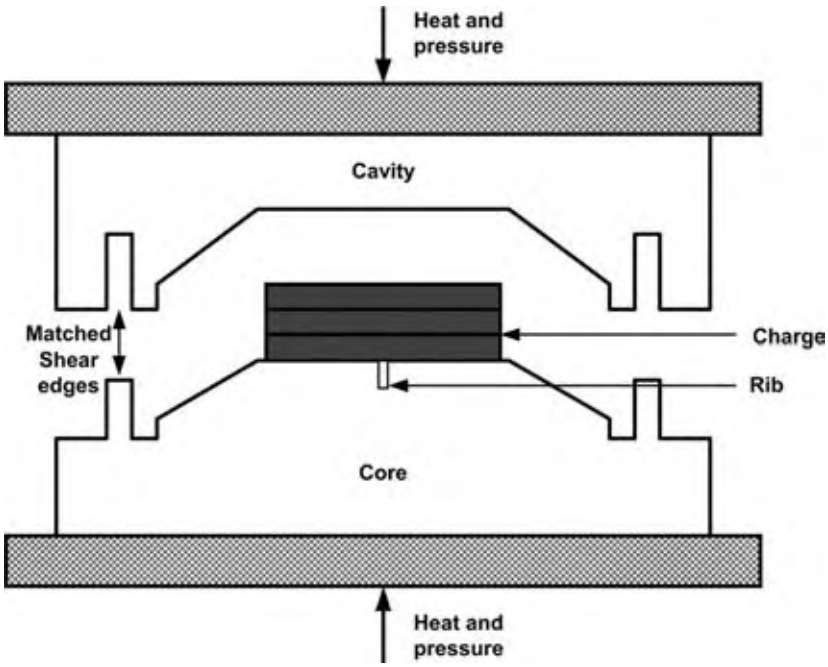

Fig. 4 Compression molding technique.

Curing

After filling, the charge remains in the hot mold for the cross-linking reaction to be completed and solidify. The curing time depends on several factors such as resin–initiator–inhibitor reactivity, part thickness, and mold temperature. More about curing is explained in the cure section.

Part ejection and post cure

At the end of the molding cycle, the mold is opened and the part is ejected from the core. The part is allowed to cure under ambient temperature, during which shrinkage may occur because of the residual stresses developed owing to differential cooling at variable sections of the part.

Transfer Molding

Transfer molding process (Fig. 5) is another alternative process for compression molding so as to accommodate multi-impression molding of the same material. This process is mainly used in molding parts that involve a lot of insertions into the part. Integral type transfer molding is commonly used, but where auxiliary ram type is used, the pot is maintained at lower temperature than that of the mold, thus maintaining the BMC at higher viscosity and rendering the flow control easier. It is often seen that the strengths of the transfer molded components are lower compared to compression molded ones, which is because of some damage caused to the glass fibers when the compound passes through the runner and the gate system. However, this could be minimized by designing larger gate and runner sizes. An important factor to be considered while designing a mold is the fiber orientation, which depends on the size and shape of the mold cavity and the point where the material enters first. The operating temperatures and curing rates are more or less the same as in compression molding. The main advantage of this process is high production volumes because of the facility of feeding multiple cavities from one charge of BMC in the transfer pot.

Injection Molding

Injection molding is a completely automated process, providing economic benefits over other processes. It consists of an injection screw and a barrel, with the screw having constant pitch to accommodate constant feed rate. Fig. 6 shows a schematic of a simple force feed hopper system consisting of a pressurized ram and a cylinder that forces the BMC to the start of the screw. The jacket provided is used to heat the barrel and the charge passing through it. The flight of the rotating screw causes the material to move through a heated ''extruder'' barrel, where it softens (being made fluid) and so it can be fed into the shot chamber (front of screw). This motion generates a pressure that causes the screw to retract, and when the preset limit is reached and the shot size met, the screw stops rotating. At a preset time, the screw acts as a ram to push the melt into the mold.

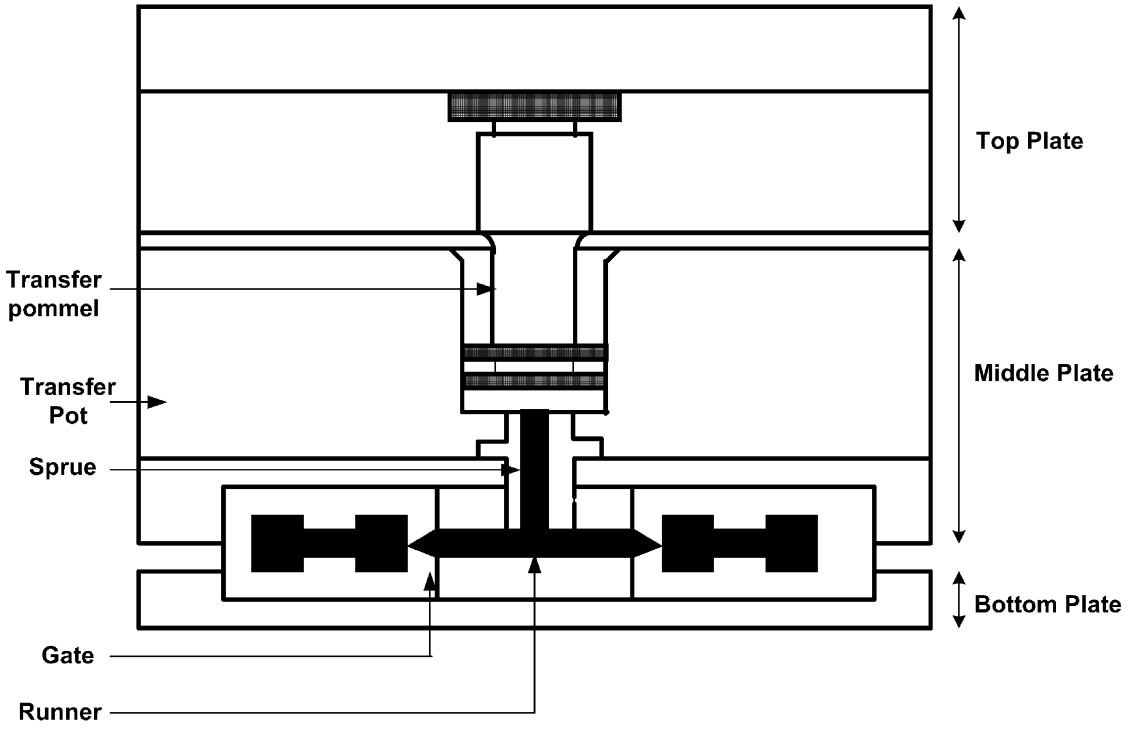

Fig. 5 Transfer molding technique.

Factors influencing injection molding

Time, temperature, and pressure are the primary factors influencing the surface finish of the molded part. Time factors include rate of injection, duration of ram pressure, time of cooling, cross-linking time, and rotation of the screw (RPM). Pressure factors are applied pressure (high or low), back pressure on the extruder screw, and pressure loss before the charge enters the cavity, which can be caused by a variety of restrictions in the mold cavity. Temperature factors are mold (cavity and core), barrel, and nozzle temperatures, as well as the melt temperature because of back pressure, screw speed, and frictional heat.

GENERAL MOLD DESIGN CONSIDERATIONS

All mold components contacted by the molding compound—runners, gates, and cavities—should be made of hardened steel, hardened to 65–68 on Rockwell scale, highly polished, and hard chrome plated.

The ejector pins should have an adequate cross-sectional area to minimize the possibility of distorting or puncturing the molded plastic at the time of ejection from cavities, as most of the thermoset compounds are slightly soft during that time.

In automatic molds, it is vital to ensure that the undercuts, hold down pins, and the molded part remain in the desired half of the mold, so that when the parts of the runner system are ejected, they do not get dislocated with that movement.

Flash removal at the end of each cycle is important for successful automatic molding.

The molds should have the ability to maintain constant temperature despite continual heat removal by the relatively cooler molding compounds; this can be monitored by placing temperature sensors and heat cartridges to provide uniform temperature. Insulating blankets may prove beneficial in minimizing mold heat losses and variations caused by local air currents around the molds and presses. A cut out should be provided, which will cut off the power to the heat cartridges as and when it senses a few degree rise than the desired temperature.

COMPARISON OF MOLDING PROCESSES

BMC can be molded by compression-, transfer-, or injection molding processes. Compression molding is the oldest and most commonly used process. It consists of forming the material between the heated metal punch and die. This process is the most economic one; however there are a few components that cannot be compression molded owing to their intricate shapes. Another drawback of compression molding process involves weighing of the charge before it is laid out

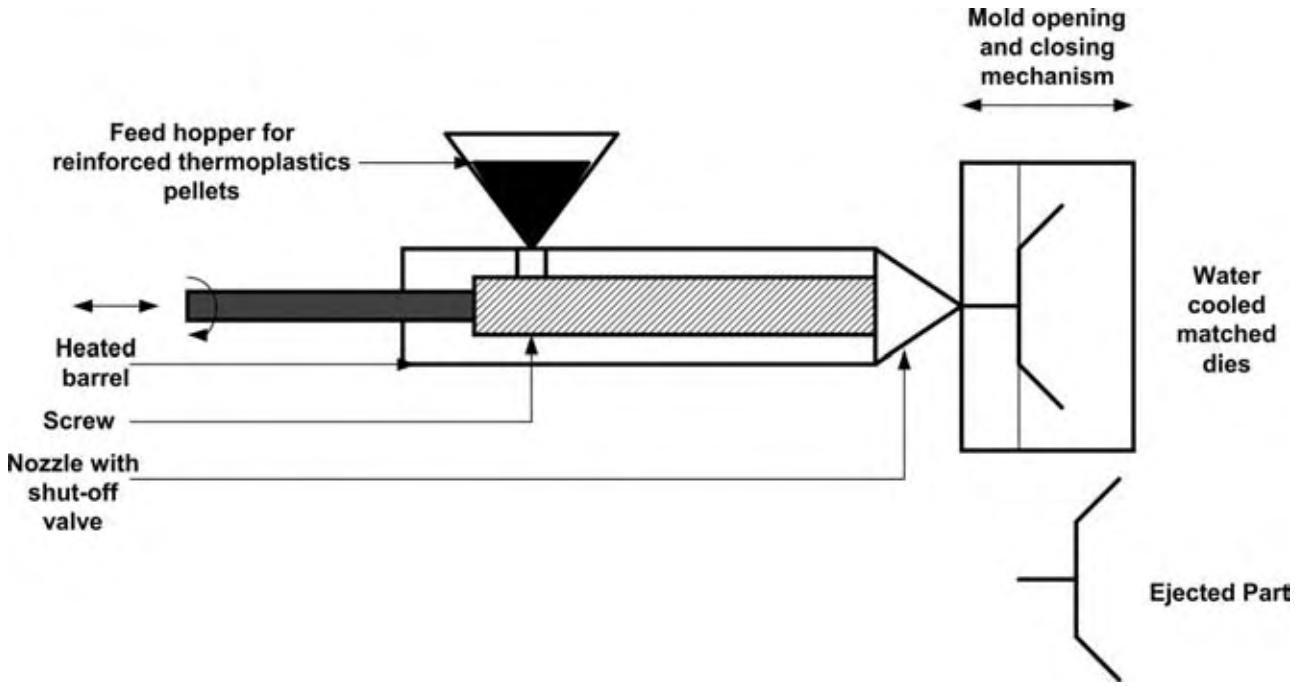

Fig. 6 Injection molding process.

in the mold cavity, which would make it tedious for the molder. Transfer molding or injection molding processes are preferred to avoid this difficulty and reduce production cycle time and labor costs. Transfer molding again involves weighing out and dispensing of one quantity of charge per production cycle, which is still a manual operation, but injection molding process provides its own means of weight calculation, no matter whether it is a single or a multi-impression mold.

The production cycle is delayed in compression- and transfer molding as it takes time to bring the charge to the mold temperature where the cross-linking reaction initiates, thereby increasing cure time. This is avoided in injection molding as the charge is preheated in the barrel of the injection unit, and moreover because of the frictional heating as the material passes through the runner system and the gate. As a consequence, the charge enters the mold at a higher temperature and the cross-linking reaction starts as soon as the charge enters the mold, thus reducing the cure time.

Cure time for compression molding is influenced by the molding thickness, and very thick moldings may require more time than thin ones. Compared to this, injection molding is much less influenced by the molding thickness, and very thick moldings may require a little more cure time that thin ones.

Another difference between the processes is the flash formation and its removal. As it is reinforced with fibers, it becomes difficult to remove the flash formed. As compression molding uses semipositive molds, there would be some material loss in the form of flash, and deflashing is normally done by hand. This process would make it more expensive and less satisfactory, because the finish line is visible and this may be objectionable. Injection molding would prove to be advantageous as the flash formed is less, because the mold is already closed and the two halves fit close to each other (Table 4).

As BMC and SMC are fiber reinforced, fiber orientation is very important. During compression molding, the central loading of the mold may lead to radial orientation of the fiber as the material flows out to the extremities of the cavity. Transfer- and injection molding are likely to give stronger orientational effects because the filling of the cavity is from one fixed point, which is the gate. The location of the gate depends on the mold designer and many other parameters that are beyond the scope of this entry.

Comparison of the molded parts yields a conclusion that injection- and transfer molding would be advantageous in mass production as the production cycle time is much shorter compared to compression molding. However, compression molded parts are much stronger compared to injection- and transfer molded parts, which is because of the damage done to the fibers when the material flows through the runner system and the gate of the mold. Another aspect of quality of the product is surface finish, which is not consistent and attractive in the compression molded parts, as the handling of material may transfer some dirt from the hand to the working surfaces. As BMCs are fast curing, some amount of precure is inevitable before the

Table 4 Comparison of typical production rates for different processes

	Small molding[a]			Large molding[b]		
Cycle element	**Compression**	**Transfer**	**Injection**	**Compression**	**Transfer**	**Injection**
Cure time (sec)	30	30	25	45	40	30
Press open time (sec)	50	15	10	15	15	10
Total cycle time (sec)	80	45	35	60	55	40
Saving as a % of compression cycle time	—	44	56	—	8	33

[a]Thin section/10 g weight, 12-impression mold.
[b]Thick section/1000 g weight, single impression mold.
(From Ref.[1].)

mold is closed. Injection molding differs significantly as the material is transferred very rapidly from the barrel of the machine to the cavity, and thus any precure can be avoided; being an automated process, it involves less material handling.

CURE OF BMC/SMC

Thermosets are widely used for their cost effectiveness and outstanding mechanical properties, especially at high temperatures. Unfortunately, they run the risk of being over- or undercured, which plays a substantial role in determining the product quality. The term ''cure'' refers to the monomeric liquid resin becoming a cross-linked rigid solid, which produces a tightly bound three-dimensional network.

As the quality of the product predominantly depends on the curing reaction, monitoring the cure reaction is most important. Infrared spectroscopy, nuclear magnetic resonance spectroscopy, and chromatography are typical methods in research and development. However, for practical reasons, these methods are difficult to incorporate into the production process. The macroscopic attributes that change during cure are mechanical and electrical material parameters. Typical mechanical parameters are complex elastic or shear modulus, and viscosity. These quantities can be measured by dynamic mechanical analysis (DMA), ultrasound propagation, and viscosimetry.[6] Table 5 shows the sensors incorporated in the molds for monitoring and their relative costs.

Computer simulation software are commonly used as cure monitoring tools basically in visualizing the flow front of the charge inside the mold. They reduce time and cost of the cure monitoring. The basis for the models developed for simulation is the analysis of the flow behavior taking into account the thermoset cure. The flow analysis would involve calculation of elementary viscosity, pressure distribution as the flow front expands, correcting at all times for elementary cure level. Temperature calculation is based on the equation that accounts for convection, conduction, viscous heating, and cure reaction. The elemental cure time can be calculated from the material database developed, which stores data files on curing behavior of the compound such as viscosity, gel time, and heat of reaction. The development of these simulation programs depends on the need to standardize material tests necessary to provide reliable data for computation.

PROPERTIES OF BMC/SMC

Properties of a thermoset can be varied by using different formulations such as fiber content, filler content, etc.; this uniqueness makes it difficult to generalize the definition of properties of the material. Its characteristics are used as guidelines in part design and material selection to understand the effect of the change in formulation on mechanical properties. Table 6 shows static and impact properties of SMC, BMC, LPMC, and ZMC. Tensile and flexural properties are routinely

Table 5 Sensors incorporated in the molds for monitoring and their relative costs

	Configuration of use	**Monitored value**	**Cost**	**Use in operation**
Fiber-optic sensors	Embed	Chemical constitution refractive index, strain, temperature	High	Good

Piezoelectric sensors	Embed	Impedance	Intermediate	Good
Ultrasonic sensors	Attach to die	Sound velocity, attenuation	Low	No

(From Ref.[6].)

Table 6 Static and impact properties of SMC, BMC, LPMC, and ZMC

	Tensile strength (MPa)	Tensile modulus (GPa)	Flexural strength (MPa)	Flexural modulus (GPa)	IZOD impact (un-notched)	Specific gravity	Coefficient of thermal expansion ($\times 10^{-6}/^{\circ}C$)
SMC	65–100	9.5–14	130–200	8–14	600–1200	1.3–2.0	8–14
BMC	30–70	8–12	50–150	9–17	100–700	1.7–2.1	15–20
ZMC	30–70	8.5–12.5	50–150	7–12	200–500	1.8–2.0	11–27
LPMC	65–100	9.5–14	120–200	8–14	600–1200	1.8–2.0	7–10

(From Ref.[2].)

measured in general; compression and shear for special purposes. The static properties are highly dependent on the fiber length, loading, and its orientation. Tensile strength increases rapidly with the increase in fiber content and fiber length, but the modulus is affected moderately. The type of fiber being used as reinforcement plays an important part (E-glass, S-glass) in both tensile strength and modulus during low fiber loading.

Several other tests are used to correlate properties with the working conditions. The dynamic mechanical analyzer (DMA) is used to measure modulus and viscoelastic properties related to ductility. By using the DMA test method, the degradation in modulus could be understood and applied to the end use application. The effect of the environmental conditions is also tested; the esthetic durability in heated environments is not restricted to warp and relaxation attributed to creep. Creep and stress relaxation tests are also done on SMC/BMC for their structural applications. The retention of color is critical for a heated appliance application. BMC/SMC can be formulated to offer excellent color stability when exposed to high temperatures.

RECYCLING OF BMC/SMC

Thermoset polymers are considered to be nonrecyclable plastic materials. Once they are formed into a shape and cross-linked, they cannot be remolded or melted. When they are used as matrix materials for composites, the recycling problem becomes more difficult because of the multiphase nature of the composite. Some methods of recycling[7] are explained in the following sections. Table 7 gives the property of BMC reinforced with recycled glass reinforced SMC.

Mechanical Degradation

Mechanical recycling methods are based on the use of SMC scrap directly without altering its chemical properties. The SMC scrap is shredded or ground using mechanical hammers into a form that can be used as fillers. The entire SMC could be ground into fine powder (including glass fiber). The other method is to mill the SMC in such a way that some glass fibers could be recovered, and later separated and reused as reinforcement. Recovery of some glass is very important from the cost effectiveness point of view as the fibers have more value as reinforcement. Moreover, it requires more energy to grind all the fiber into powder.

Pyrolysis

Pyrolysis can be considered as a nonconventional method of recycling plastic materials and is especially

Table 7 Property of BMC reinforced with recycled glass reinforced SMC

		Tensile			Flexural		Izod impact	
Sample	SMC added (%)	Strength (MPa)	Modulus (MPa)	Elongation (%)	Strength (MPa)	Modulus (MPa)	Notched (J/m)	Un-notched (J/m)
BMC control	0	27.9	13,099	0.44	96.7	10,548	270	361
Standard BMC + SMC	6	16.1	9,858	0.68	68.6	9,789	270	278
Standard BMC + SMC	12	17.3	12,685	0.22	71.4	10,203	209	274
BMC resin + SMC	70	25.8	7,859	0.36	55.4	6,411	89	114

(From Ref.[7].)

appropriate for thermoset composites that cannot be remolded. In the pyrolysis process (heating without oxygen), the organic part of the material is decomposed to gases and liquids, which can be useful as fuels or sources of chemicals. Inorganic components such as glass fibers and calcium carbonate filler ($CaCo_3$), which are left relatively unmodified, could be reused as a whole or individual components in other composite materials.

Chemical Degradation

This process involves reversing chemical reaction where the organic polymer is converted back to more basic chemical building blocks. Among these processes, hydrolysis, glycolysis, methanolysis, and aminolysis are well known. This depolymerization process will also free the glass fiber reinforcement, which is an added value.

Heat Cleaning

This process involves completely volatizing the resin and freeing the glass fibers. The SMC is passed through a furnace maintained at a set temperature where the compound becomes completely volatile and frees the glass fibers that can be recovered. The gases liberated during the process are also potentially useful by-products.

GENERAL APPLICATIONS

BMC provides cost advantages particularly for high load and temperature bearing products, thus finding application in electrical and mechanical industries. The BMC/SMC are tested for short circuiting where heaviest current loads are applied, which produces an electric arc inside the switch and raises the temperature to several thousands of degrees in a short period of time. BMC is used for household appliances, circuit breaker housings, heat shields for electric irons and headlamp reflectors. BMC/SMC provide economic solutions for electrical equipment because of its electrical insulation, thermal resistance, and freedom of design of properties. BMC has become a choice for low and high voltage applications such as switches and arc barriers. They provide efficient power distribution and protect the end user from dangerous effects of short circuiting.

As SMC is transparent to electromagnetic waves and offers additional benefits such as low cost compared to metals, dimensional stability, stiffness, low weight, and high temperature resistance, DaimlerChrysler is considering using class A SMC to manufacture body parts in one of their coupe models.[8]

CONCLUSIONS

The compounds, both SMC and BMC are pre-compounded reinforcements designed for fast processing by compression-, transfer-, and injection molding. Unlike conventional methods of composite manufacturing where the fibers and resin were combined and wetted out within the process (which was also time consuming), BMC/SMC offer the advantage of being ready to mold mix, which saves a lot of time and hence production volumes. Injection molding and transfer molding processes are used for mass production, and by optimizing mold design, high volume products with superior surface finish can be obtained. As BMC/SMC can be tailored accordingly, products with high mechanical strengths, and electrical and thermal properties can be obtained. Recyclability and reuse of SMC/BMC parts add to its advantage. Hence, the compounds find a wide range of applications in mechanical and electrical industries.

Capsule Pipeline

Henry Liu
Freight Pipeline Company, Columbia, Missouri, U.S.A.

INTRODUCTION

The use of various types of capsule pipelines for materials transport or conveying in industry is described. They include small pneumatic capsule pipeline (PCP) systems with nonwheeled capsules for dispatch of materials and documents over short distances, often within a building complex or between neighboring buildings; large PCPs with wheeled capsules for bulk materials transport for longer distances in lieu of using trucks or conveyor belt; short as well as long hydraulic capsule pipeline (HCP) systems for transporting grain, minerals, construction materials, and solid wastes; and product capsule pipeline (PRCP) systems for transporting coal, petroleum coke, and certain minerals. Also included is a brief discussion of the economic, safety, and environmental benefits of capsule pipelines.

This entry focuses on the application of capsule pipelines, including: 1) selection of the appropriate types of capsule pipeline for any given application; 2) understanding of the underlying theory and basic equations needed for design; 3) special design considerations; and (d) key operational properties of capsule pipelines for specific applications. It provides important information to engineers for planning and preliminary design of an appropriate capsule pipeline system for any given application. Reference materials are also provided to enable the reader to find more detailed information on the subject.

TYPES OF CAPSULE PIPELINE

Capsule pipeline is the transport of solids by using capsules (cargo-carrying vessels or vehicles) moving through pipelines. The capsules are generally cylindrical in shape, having a diameter slightly (about 10%) smaller than the pipe diameter, and a length two to five times the capsule diameter. They are suspended and/or propelled by the fluid moving through the pipe. The fluid can be any liquid or gas. When a gas is used as the fluid to propel capsules, the system is called PCP, whereas when a liquid is used as the fluid, the system is called HCP. Air is usually the most practical gas for use in PCP, whereas water is the most practical for HCP. Both PCP and HCP are discussed separately.

Pneumatic Capsule Pipeline

Because the density of the gas used in PCP is 100–1000 times smaller than that of the liquid used in HCP, both the buoyancy and the lift forces on capsules are much smaller for PCP than for HCP. They are insufficient to overcome the weight of the capsules and cannot suspend the capsules in the pipe. Thus, PCP capsules slide along the bottom of the pipe and generate large contact friction. This causes large energy loss and wear of capsules and pipe. To avoid such undesirable effects, PCP capsules, especially those that are large and/or carry heavy cargoes, have wheels. Fig. 1 shows two types of wheeled PCP capsules: those for use in circular pipes and those for use in rectangular or square pipes. Both types have been utilized successfully in Japan.[1] Note that while the square and rectangular PCPs use bottom wheels mounted on the capsule bottom frame, the round (circular) PCPs use gimbals-type wheel assemblies mounted on the centerline of both ends of each capsule—compare (A) with (B) in Fig. 1. The gimbals-type wheel assemblies in circular pipes allow the wheels to rotate freely around the pipe's inside circumference, thereby keeping capsule bodies stable in the pipe. Without the gimbals arrangement, the capsule body would be unstable and would rotate in the pipe, causing spillage of cargoes and other problems. An example of a round PCP used in Japan has a one-way length of 3.2 km using a 1 m-diameter pipe.[2] The pipeline transports 2 million tons of limestone per year from a mine to a cement plant. This pipeline was built in 1983, and it has operated very successfully ever since, having compiled an availability record exceeding 98%. A square-type PCP was also used successfully in Japan.[3] This was a temporary pipeline used in the construction of a long and large tunnel for bullet trains to cross a mountain. The capsules in this pipeline carried ready-mixed concrete and other construction materials into the tunnel, and on their return trip carried the excavated soil and rocks. As the tunnel construction progressed, the square-section

pipeline was extended into the tunnel by adding new sections to its front end. The pipe was assembled from panels made of lightweight concrete. The pipeline was dismantled and discarded (used for landfill) upon completion of the tunnel. In addition, the former Soviet Union also used 1 m-diameter round PCPs for transporting rocks.[4]

During the first half of the 20th century, non-wheeled PCPs of 300 mm or less were used extensively around the world for transporting light cargoes such as mail, telegrams, cash, and receipts.[5] Six major cities in the United States, New York, Washington, DC, Boston, Philadelphia, Chicago, and St. Louis, used them for transporting mail (including small parcels) between these cities' central post office and branch offices. By 1950, they were all replaced by automobiles.[6] Today, continued use of such small PCPs, called "tube transport," exists in the United States at large hospitals, airport terminals, drive-in banks, large factories, etc. Fig. 2 shows a system used at a large hospital. All current PCP systems, large or small, are highly automated and computerized. It is a far cry from the old tube transport systems of the past.

Hydraulic Capsule Pipeline

The liquid used in HCP has a large density, which enables the development of a large-buoyancy force on the capsules in HCP, and a significant lift force even at relatively low velocity. For this reason, HCP capsules need no wheels, and they can be operated at relatively low velocity to conserve energy. The energy intensiveness (EI) of HCP, which is the energy consumed by HCP for transporting a unit weight of freight over a unit distance, is much smaller for HCP than for PCP. The conventional unit of EI used in the United States is Btu/TM (British thermal unit of energy consumed per ton of cargo transported per mile of distance). According to Liu, the values of EI for HCP and PCP are approximately 700 and 1800 Btu/TM, respectively, whereas for train and truck they are approximately 680 and 2300 Btu/TM, respectively.[7] This shows the advantage of HCP from the energy conservation standpoint, making the system attractive for long-distance transportation of bulk materials. Proper operation of HCP requires that the capsules be lifted off the pipe floor (by both buoyancy and lift), which minimizes not only the contact friction but also the wear and tear. Because of the lack of contact friction in HCP, there is no need for capsules to have wheels. This in turn reduces the cost of capsules and maintenance needed. How HCP capsules are suspended by the flow is an interesting topic to be discussed in "Theory and Equations."

The capsules in HCP may use either rigid containers or flexible containers. Fig. 3 shows a 7 in.-diameter steel capsule tested for grain transport in an 8 in. steel pipe at the University of Missouri–Columbia (UMC). With rigid containers, a second pipeline is needed to return the empty capsules, as is the case with PCP. If flexible containers made of plastic film are used to hold

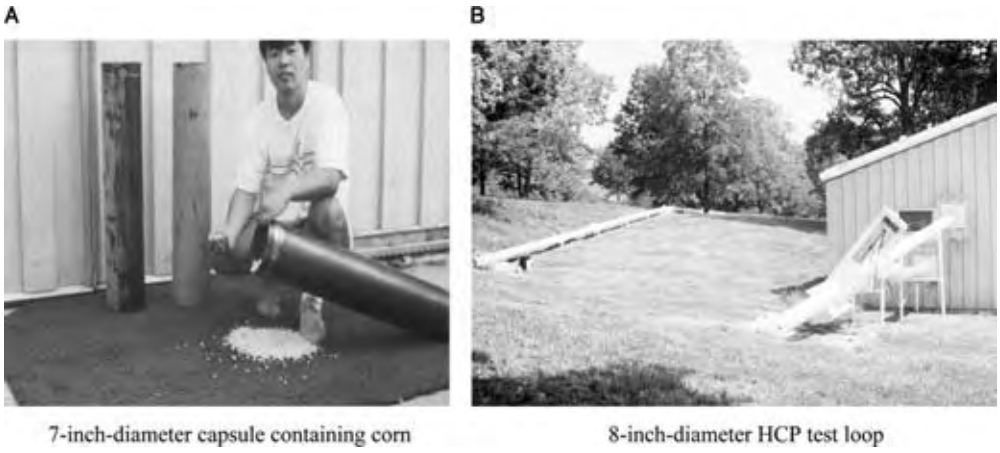

Fig. 3 Grain capsules tested at University of Missouri–Columbia. *(View this art in color at www.dekker.com.)*

the cargo, the plastic film can be recycled for other uses at the pipeline outlet, and the second pipeline is avoided, which reduces the overall cost, especially if the transportation distance is long. In the early 1980s, the W.R. Grace Company proposed to build such a pipeline from western Colorado to the coast of California for transporting powdered coal for export. However, the project was unable to attract financiers because of the lack of research to prove that the plastic film of the coal capsules can endure the long-distance transport without breakage.

A third type of HCP is PRCP, in which the capsule is made of the product (goods) to be transported, and no capsule shell or container is needed at all. This alleviates the need for both containers and the return pipeline. This type of HCP has been developed for transporting coal—the coal log pipeline (CLP). The CLP technology was studied extensively for 10 yr (1991–2000) at the Capsule Pipeline Research Center of the UMC. The Center was a State/Industry University Cooperative Research Center of the National Science Foundation. Both binder and binderless methods were developed to produce strong and wear-resistant coal logs for hydrotransport through pipe.[8,9] Fig. 4 shows the 5.4 in.-diameter coal logs produced by a hydraulic press tested in a 6 in.-diameter pipe test loop.[10] The 5.4 in. logs were also tested in a commercial pipeline in Kansas over a distance of 5 mi.[11] Coal logs of 1.9 in. diameter were tested extensively in a 2 in.-diameter pipe recirculating test loop at UMC, and the best logs tested were able to travel over 200 mi in the pipe with only 5% weight loss because of wear.[12] In addition to coal, petroleum coke (pet-coke) has been tested for compaction into logs for hydrotransport, and the result is promising. At about 50°C, pet-coke can be compacted without binder

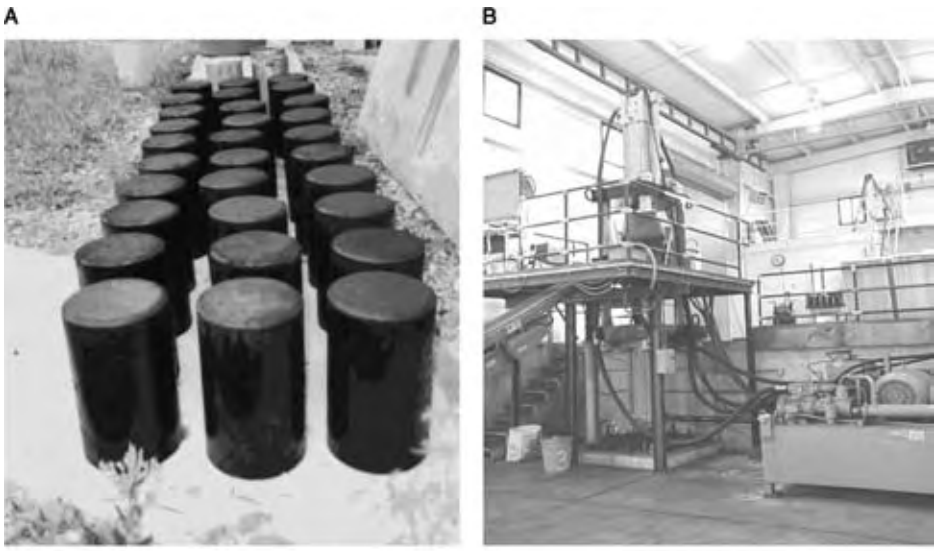

Fig. 4 Coal logs of 5.4 in. diameter and the press to produce such logs at University of Missouri–Columbia. *(View this art in color at www.dekker.com.)*

to produce strong and water-resistant logs for hydrotransport by pipe. At much higher temperatures, such as those experienced when the pet-coke is first produced before quenching with water, it can be cast into logs for hydrotransport. Another type of PRCP involves cans; the cans themselves are the capsules. It would be relatively simple to transport cans for short distances in a pipe of a diameter approximately 90% the can diameter. Whenever applicable, PRCP appears to be the most economically attractive type of HCP.

A fourth type of HCP is slurry capsule pipeline (SCP), which uses slurry instead of pure liquid (water) for transporting capsules through pipe. This is especially advantageous for long-distance transport of minerals. The mineral in the slurry of SCP may be either the same or different from that transported by the capsules in the pipe, depending on the situation and need. Using slurry instead of water for transporting capsules has three advantages: 1) more solids (minerals) can be transported by the pipe; 2) less water is used for the transport; and 3) the density of the slurry is significantly higher than that of water, and this increases the buoyancy and the lift on capsules, which in turn reduces contact friction between capsules and pipe, and hence reduces energy loss and wear. The last advantage is especially important when heavy minerals such as iron ore are to be transported by HCP. A dense slurry can be used in such a case, which greatly facilitates capsule transports. The concept of SCP has been proven in a laboratory study.[13]

Comparison Between PCP and HCP

A comparison of HCP with PCP is provided in Table 1. It is important to keep the different factors listed in Table 1 in mind when determining whether HCP or PCP is more suitable for a given application. For instance, for transporting cargoes that require speed, PCP is likely to be a better choice. On the other hand, when energy consumption is substantial and when cargo transport speed is immaterial, HCP is likely to be a better choice. All other key factors must be considered as well to make a wise selection between HCP and PCP. In addition, a comparison of the costs of the two systems for any given application should also be conducted using the life-cycle cost analysis to be discussed later.

Table 1 Comparison between HCP and PCP

Items for comparison	HCP	PCP
Fluid used	Liquid (water)	Gas (air)
Buoyancy and lift	Substantial	Negligible
Contact friction encountered	Low	High
Need for wheels	No	Yes
Capsule speed	Low (<3 m/sec)	High (>8 m/sec)
EI	Low (about 700 Btu/TM)	High (about 1800 Btu/TM)

ADVANTAGES OF CAPSULE PIPELINES

Use of capsule pipelines instead of trucks for freight transport reduces the number of trucks on highways, streets, and in and around industrial plants, thereby reducing traffic jams, accidents, air and noise pollution, and security problems caused by trucks. Also, trucks being mobile can be used by terrorists as bombs to attack selected targets. Capsule pipelines being fixed to the ground have much fewer security problems. From the security standpoint, it is especially important to use capsules pipelines instead of trucks to transport hazardous materials and explosives. When compared with conveyor belt systems, capsule pipelines have the advantage of being enclosed and are hence much safer to people, and less likely to pollute the air. Furthermore, because capsule pipeline is mostly underground, it is better from the land-use standpoint, and is unaffected by the weather.

THEORY AND EQUATIONS

Pneumatic Capsule Pipeline

The motion of capsules in a PCP is driven by the pressure drop across each capsule, Δp_c, generated by the air movement through the pipe. The faster the air flows through the pipe, the greater the pressure drop that develops across each capsule, and the faster the capsule moves. However, even at high air velocity, V, the capsule velocity V_c still trails the air velocity. The velocity difference, $V - V_c$, is related to the pressure drop Δp_c as follows:

$$\Delta p_c = C_D \frac{\rho(V - V_c)^2}{2} \quad (1)$$

where C_D is the drag coefficient of the capsule, and ρ is the air density at the capsule location in the pipe.

As shown in Fig. 5, most PCP capsules have two plates attached to the two flat ends of each capsule, called ''seal plates,'' or two rings around the capsule body near the two ends, called ''seal rings.'' Their purposes are the same: to seal the ends of the capsule so that little air passes through the seal and around the capsule. This generates a large drag coefficient

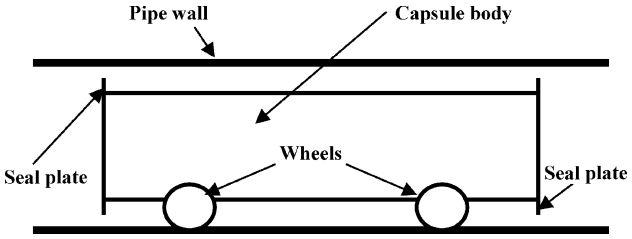

Fig. 5 Basic configuration of a capsule in a PCP of rectangular cross section.

C_D, which from Eq. (1) causes the slip velocity, $V_d = V - V_c$, to diminish for a given capsule pressure difference Δp_c, which means little slip between the capsule and the air. The value of C_D for a capsule with two seal plates or end rings can be calculated from the following equation derived by Kosugi:[14]

$$C_D = \frac{4k_s^4}{(1 - k_s^2)^2} = \frac{4k_A^2}{(1 - k_A)^2} \tag{2}$$

In the above equation, k_s is the seal plate diameter ratio, which is the seal plate diameter, D_s, divided by the inner diameter of the pipe, D. For PCP of rectangular or square cross-section, the seal plate area ratio k_A should be used, namely, $k_A = A_s/A = k_s^2$, where A_s is the seal plate area and A is the pipe cross-sectional area. For a capsule with only one seal pate, the factor 4 in Eq. (2) should be changed to 2. Note that in commercial PCPs, while the seal plate diameter D_s is usually greater than 97% of the pipe diameter D, the capsule body diameter is usually much smaller—about 90% of D. The smaller body diameter is needed to allow capsules to pass through PCPs having bends of reasonable curvature. With $k_s = 0.97$, Eq. (2) yields a drag coefficient of 1014. Most commercial PCPs have a drag coefficient greater than 1000.

From Eq. (1), the drag force F_D on the capsule is

$$F_D = A\Delta p_c = AC_D \frac{\rho(V - V_c)^2}{2} \tag{3}$$

For air moving at a constant speed V through a PCP having an upward slope of angle θ, the capsule velocity can be obtained from the Newton's second law, which yields

$$V_c = V - V_d$$
$$\text{where } V_d = \sqrt{\frac{2W_c(\eta \cos\theta + \sin\theta)}{C_D A\rho}} \tag{4}$$

In Eq. (4), V_d is the slip velocity, which is the difference between the air velocity V and the capsule velocity V_c; W_c is the capsule weight; and η is the contact friction coefficient between the capsule and the pipe (i.e., the rolling friction or wheel friction). When the pipe is horizontal, the slip velocity in Eq. (4) becomes $V_d = \sqrt{2\eta W_c/(C_D A\rho)}$.

Although Eq. (4) was derived for a PCP with an upward slope, it is also applicable to the downward slope if θ is taken to be negative, as long as the slope angle θ is less than $\tan^{-1}\eta$. When θ is greater than $\tan^{-1}\eta$ on a downslope, the capsule velocity now exceeds the air velocity V, and the capsule speed becomes

$$V_c = V + V_d$$
$$\text{where } V_d = \sqrt{\frac{2W_c(\sin\theta - \eta\cos\theta)}{C_D A\rho}} \tag{5}$$

The pressure drop along a PCP can be calculated by separately calculating the pressure drop across each capsule in the pipe, that across each capsule-free space between neighboring capsules, that between the blower outlet and the first capsule in the pipe, and that between the last capsule in the pipe and the pipe outlet. Summing all these pressure drops yields the total pressure drop along the PCP. The pressure drop across each capsule can be determined from Eq. (1) using the local values of ρ, V, and V_c. To calculate the pressure drop along the pipe in the capsule-free regions, equations in fluid mechanics can be used. The Darcy–Weisbach or Fanning equation can be used if the flow is assumed incompressible. The incompressible flow assumption is good if the total pressure drop along the entire length of the pipe is no more than a few pounds per square inch. For a higher total pressure drop along the pipe, the flow must be treated as compressible, and the following formula for compressible isothermal flow can be used:

$$\frac{fL}{D} = \frac{1}{\gamma M_1^2}\left[1 - \frac{p_2^2}{p_1^2}\right] + 2\ln\frac{p_2}{p_1} \tag{6}$$

In the above equation, L is the length over which the pressure drop $p_1 - p_2$ is to be calculated; p_1 is the absolute pressure of the flow at an upstream point 1, and p_2 is the absolute pressure of the flow at a downstream point 2; f is the Darcy–Weisbach friction factor that can be determined from the Moody Diagram; γ is the adiabatic exponent (equal to 1.4 for air); and M_1 is the Mach number of the flow at the upstream point 1. In addition to the pressure equations, the following equation of state of ideal gas is also needed:

$$\frac{p_2}{p_1} = \left(\frac{\rho_2}{\rho_1}\right)^{\gamma} \tag{7}$$

Using Eqs. (1), (2), (4) [or (5)], (6), and (7) for various reaches along the pipe, and using the boundary

condition $p = p_a$ (atmospheric pressure) at both ends of the pipe, and the pressure across the blower, p_b, the equations can be solved simultaneously to determine the variation of p, ρ, V, and V_c along the PCP. This in a nutshell explains how the pressure, air density, air velocity, and capsule velocity along a PCP can be calculated by assuming compressible flow. More details of such computations with illustrative examples are given in Liu and in York.[15,16]

Hydraulic Capsule Pipeline

Because of the fact that the capsules in HCP have no wheels and are strongly affected by the buoyancy and hydrodynamic lift, the fluid mechanics of HCP is far more complicated than that of PCP. However, extensive research has been conducted in HCP since 1960 by more than 30 researchers in about 10 nations to understand the basic nature of HCP flow and to derive the necessary equations for the design of HCP. In what follows, only the most pertinent theories and equations needed for the design of commercial HCPs are discussed. Readers interested in knowing more about the theory of HCP should read the vast body of papers and reports published; they total well over 100.

It is permissible to assume that all steady flows in HCP are incompressible. By using the one-dimensional continuity equation for incompressible flow, the following holds:

$$VA = V_c A_c + V_a(A - A_c) \quad \text{or} \quad V_a = \frac{V - k^2 V_c}{1 - k^2} \tag{8}$$

In Eq. (8), A, A_c, and $(A - A_c)$ are the cross-sectional areas of the pipe, the capsule, and the capsule–pipe annulus, respectively; V_a is the mean velocity of the fluid in the annulus; and k is the diameter ratio D_c/D. From Eq. (8), one can conclude the following:

- If $V > V_c$, then $V_a > V$ or $V_a > V > V_c$.
- If $V < V_c$, then $V_a < V$ or $V_c > V > V_a$.
- If $V = V_c$, then $V_a = V$ or $V_a = V = V_c$.

Perhaps the most important progress made in the last decade in understanding HCP flow is the four-regime theory. The theory was developed by Henry Liu and verified by experiments conducted by several of his graduate students at the Capsule Pipeline Research Center, UMC. The theory is briefly described as follows.

Consider a cylindrical capsule immersed in water in a pipe, with the capsule being denser than the water. Assume that initially the water is at rest. In this case, the capsule sinks to rest on the floor of the pipe. Later, if the water is allowed to flow slowly through the pipe at low velocity, there is insufficient drag generated on the capsule to cause it to move, and the capsule remains at rest in the pipe despite the fluid motion. This is Regime 1, in which the capsule velocity is 0 and $V > V_c = 0$. Fig. 6A depicts Regime 1. If the water velocity in the pipe is increased sufficiently, a point will be reached when the capsule will start to slide. The water velocity at this point is called the ''incipient velocity,'' designated by V_i. The capsule starts to slide at V_i because the drag on the capsule by the flow has exceeded the resistance caused by contact friction. If the water velocity V is increased to beyond V_i, the flow is in Regime 2, in which the capsule slides on the pipe floor, and the water velocity is higher than the capsule velocity ($V > V_c$). The situation is depicted in Fig. 6B. As the velocity of the fluid increases in Regime 2, more and more lift is generated on the capsule to reduce contact friction and to increase capsule speed. A point is reached where the capsule velocity

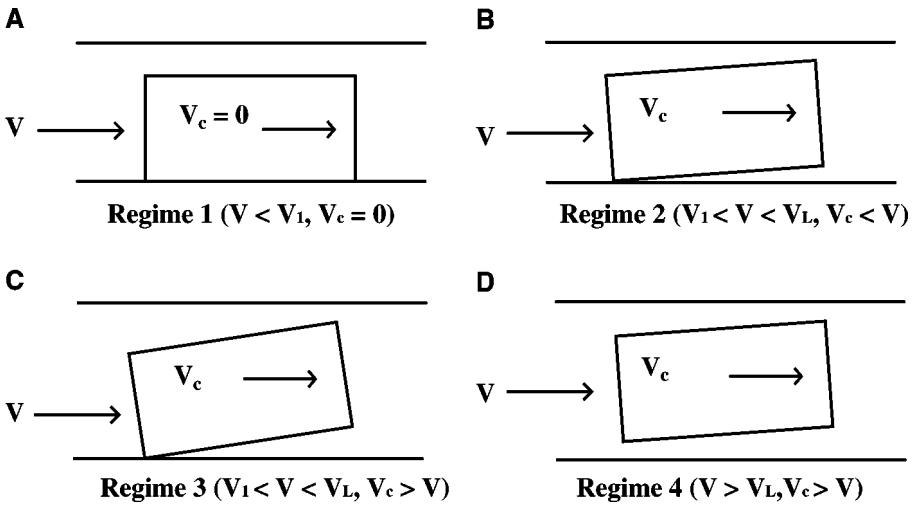

Fig. 6 The four regimes of capsule flow in pipe.

becomes equal to the fluid velocity. This velocity, marking the end of Regime 2 and the beginning of Regime 3, is called the critical velocity, V_0.

If the water velocity is increased to beyond the critical velocity, the drag (owing to pressure gradient across the two ends of the capsule) and the lift (because of pressure differential between the bottom and the top of the capsule) continue to increase, whereas the contact friction continues to decrease. This makes the capsule move faster than the fluid ($V_c > V > V_0$), and the flow is said to be in Regime 3 (see Fig. 6C). As the water velocity continues to increase in Regime 3, the drag and lift on the capsule further increase, and the contact friction continues to decrease. There comes a point when the combined upward force on the capsule because of buoyancy and lift equals the downward force on the capsule owing to capsule weight. When this happens, the capsule is completely lifted off the pipe floor, in a nose-up position as shown in Fig. 6D. The fluid velocity at the end of Regime 3 is called the ''lift-off velocity,'' designated as V_L. If the fluid velocity continues to increase beyond the lift-off, the capsule is completely suspended by the flow, and the flow is in Regime 4. In this regime, $V_c > V > V_L$, and the capsule velocity is about 15% greater than the fluid velocity (namely, $V_c \cong 1.15V$). This is not a desirable situation because a turbulent wake is generated behind the capsule, causing violent vibration of the capsule in the pipe, which in turn causes the capsule to impact the pipe wall. Such random impacts result in high energy loss and severe abrasion of the capsules and the pipe. The most desirable operational condition for HCP is when the fluid velocity is slightly (say 10%) less than the lift-off velocity (namely, $V \cong 0.9V_L$). Under such a condition, the capsules in the pipe start to lift off but are not yet completely lifted off. They move in a stable nose-up position with the front being lifted up and the tail touching the pipe gently. Both headloss and abrasion are minimized under such a condition.

To determine the flow regime of an HCP flow, the three characteristic velocities that mark the boundaries between regimes (i.e., V_i, V_0, and V_L) must be known. They can be calculated as described in Ref.[15]. Once these three characteristic velocities are found for any given HCP flow, the flow regime becomes known. With the flow regime known, one can then use the equations derived for this regime to calculate the capsule speed and pressure gradient along the pipe, as discussed in Gao.[17] More about the fluid mechanics of capsule pipeline together with illustrative examples is given in Ref.[15]. Note that the four-regime theory, discussed above conveniently in terms of water, is actually applicable to any fluid—both liquid and gas. Thus, the theory is applicable to both HCP and PCP involving any fluid. However, in the case of PCP, the buoyancy and lift caused by air (or another gas) are usually so small that they have little effect on capsule motion. Consequently, all horizontal PCPs operate only in Regimes 1 and 2, with capsules either resting on the pipe floor or rolling in the pipe at a velocity less than the fluid velocity. Only in rare cases does a PCP operate in Regime 3.

SYSTEM COMPONENTS AND OPERATION

System Description

All capsule pipeline systems include a pipe, many capsules, an injection system to inject capsules into the pipe, a pumping system to pump the fluid and capsules through the pipe, an ejection system to eject the capsules from the pipe, an instrumentation system to monitor the flow rate, pressure, temperature, and the passage of capsules at key locations, and an automatic control system that uses programmable logic controllers and an SCADA (Supervisory Control and Data Acquisition).

Capsule Design

Different types of capsule pipelines require different capsule designs. Information on designing capsules for PCP can be found in Refs.[1–3] and from the vendors of PCP; for HCP it can be found in Ref.[18]. Usually, several PCP capsules are linked together to form a train, and there are usually more than one train moving through the pipe at any time. In contrast, HCP capsules are not linked—they operate better without being linked because collision between capsules is not a problem for HCP.

Pipe Types

The types of pipe required differ with the types and applications of capsule pipelines. Generally, for PCP of circular cross section, steel pipes of sufficient rigidity (thickness) are used. Pressure concrete cylinder pipes may also be used if the pipe joints are smooth, and if the capsules use rubber wheels, which do not abrade the concrete. For PCPs of rectangular or square cross section, the pipe (rectangular conduit) may be made of steel or concrete. The square PCP used in Japan for constructing the long tunnel for bullet trains was made of precast concrete plates linked together to form the rectangular conduit.[7] Other arrangements are also possible. Note that the pressure in PCP is not high (normally not more than 1 or 2 atm), and the pipe

can tolerate a small amount of leakage without serious consequence.

Loading/Unloading at Inlet/Outlet

The PCP in Japan for transporting limestone uses a rotary loader, which automatically loads each capsule of a train successively.[6] Upon reaching the destination, each capsule dumps its load by opening the bottom door without having to stop. An alternate unloading system has also been developed, which rotates the capsules 180° (upside down) so that the cargo can be dumped through the same opening from which it enters the capsules. The foregoing system used in Japan for loading/unloading has proved rather reliable. It is an in-line system because the capsules are loaded and unloaded when they are moving in-line. Capsules never leave the line except for occasional cleanup and maintenance. The capsule trains in the pipe are recirculated through the dual pipe. A review of different types of injection and ejection systems for HCP is given in Liu.[19] The most practical type of capsule injector for HCP is the multilock launcher described in Ref.[20]. The system can achieve over 90% of linefill (% total length of pipe occupied by the capsules), which is essential for cost-effective use of HCP. Loading/unloading cargo for the system is done off-line.

Pumps/Blowers

All current commercial systems of PCPs use blowers to blow air through the pipe, and the air in turn drives the capsules through the pipe. Because capsules cannot pass through the blowers, a swinging pipe segment is used to cause each capsule train to bypass the blower. This greatly impedes capsule traffic, causing the PCP to have a very low linefill rate, usually less than 5%. It also makes the use of booster pumps difficult, thereby limiting the distance of PCP to only a few miles. Research has been done in recent years to solve this problem by using electromagnetic capsule pumps, which allow the capsules to pass through the pumps unimpeded.[21,22] The electromagnetic capsule pump can increase the linefill of PCP to 20%, and it makes the use of booster pumps a simple matter. For HCP, the multilock injection system causes capsules to enter the pipe without having to go through the pump. It can pump high (90%) linefill through the pipe until the capsules arrive at the first booster station. Then, a special pump-bypass is used for adding energy to the flow and causing the capsules to move to the next booster station and so forth. Information on the design of such booster stations can be found in Refs.[20,23]. Electromagnetic capsule pumps have also been developed for use as booster pumps in HCP.[24]

Operational Considerations

An important consideration in the operation of HCP is the weight of the capsules. Whenever possible, each capsule should be filled to a weight corresponding to a specific gravity between 1.00 and 1.05, which will optimize operation—minimize energy loss and abrasion (wear). While this may not be a problem for capsules loaded with cargo, it becomes a problem for empty capsules that must be returned via a return pipeline. Those returning capsules must be filled either with another cargo or water, so that they can have a specific gravity in the 1.00–1.05 range. With the returning capsules carrying water, there will be an excess of water at the pipeline intake reservoir, which is the same as the outlet reservoir of the return pipeline. This problem can be solved easily by running the cargo delivery pipeline at a velocity faster than the return pipeline, so that the water flow rate will be the same in the two pipelines. To keep the number of capsules delivered per second the same for the two pipelines of different velocities, the delivery line should have a linefill rate of capsules lower than that of the return line, which has little consequence other than a small reduction of capacity. The linefill rate can be controlled by the rate of capsule injection into the pipe at the inlet.

COST ANALYSIS

The cost-effectiveness of any capsule pipeline system can be determined by comparing the unit freight transportation cost (i.e.,"unit cost" in short), in dollars per ton of the cargo transported through the pipeline, to the unit cost or tariff (also in $/ton) for the same distance charged by competing modes of freight transport including truck, railroad (if there is a rail link), conveyor belts, etc. Rigorous determination of the unit cost of capsule pipeline requires the use of the life-cycle cost analysis. The life-cycle cost includes not only capital cost but also operation and maintenance costs, which in turn include energy, fuel, salaries, corporate income tax, insurance, etc. A reasonable annual profit (return on investment), such as 15%, should also be included so that the unit "cost" obtained for the pipeline can be readily compared to the tariffs of other modes. From the life-cycle cost and from the annual cargo throughput of the pipeline, one can calculate the unit cost as explained in detail in Ref.[25]. All future projects of capsule pipelines should conduct such an analysis before the project is approved or authorized.

CONCLUSIONS

Extensive R&D has been conducted on various types of capsule pipelines in the last 50 years to warrant their commercial use for transporting solids, at least for short and intermediate distances. In considering a capsule pipeline for a given project, the first matter to be determined is which type of capsule pipeline is best suited for the specific application. The information provided in this entry, together with other practical considerations, will lead to the selection of an appropriate type. Once the type of capsule pipeline is determined, a preliminary system can be designed using the information provided in this entry, including details provided in the listed references, and using standard knowledge of fluid mechanics and pipeline design. The design parameters obtained will include the pipe diameter, fluid speed, capsule speed, linefill, total pressure drop along the pipe, total power needed, distance between booster stations, pump head for each booster station, horsepower of each pump (or blower), etc. Using such a preliminary design, one can determine the cost of each individual item, and calculate the life-cycle cost and the unit cost. By comparing the profit-included unit cost of the selected capsule pipeline system with the tariffs charged by competing modes of freight transport, the designer can determine whether the capsule pipeline considered is the most cost-effective way to transport the solids for the given project. Other factors, such as convenience, environment, safety, and security, should also be compared with other modes to determine whether the capsule pipeline system considered should be the choice.

In passing, it may be of interest to point out that in 2004, the New York state government sponsored a study to determine the technical and economic feasibility of using large PCP systems for underground freight transport in New York City.[26] The study found that all of the six applications investigated are technically feasible, and five of them are also cost-effective.

INTRODUCTION

Fossil fuels provide a large, affordable source of energy that is limited by environmental impacts rather than resource constraints. A major concern in using fossil fuels is the emission of CO_2 to the atmosphere. CO_2 is a potent greenhouse gas and the dominant contributor to anthropogenic climate change. It is also an acid gas that changes the chemistry of the surface ocean, which is in equilibrium with the atmosphere. Since CO_2 is physiologically active, in plants as well as animals, a change in CO_2 concentrations is likely to have widespread ecological effects even without climate change. In order to stabilize the level of CO_2 in the air, emissions have to be reduced by a factor of three or more. In what follows, the options for the capture of CO_2 and its subsequent disposal are outlined. Together, these technologies are known as carbon sequestration.

BACKGROUND

The atmospheric concentration of CO_2 rose from 280 ppm in 1800 to 370 ppm in 2000, mainly due to the consumption of fossil fuels.[1] This increase in CO_2 concentration is expected to have various environmental and ecological effects. For example, doubling of the CO_2 concentration in the atmosphere reduces the rate of calcium carbonate deposition in coral reefs by 30–40%.[2] Most of this rise has occurred over the last few decades, and, unless action is taken, the projected growth over the 21st century could lead to a doubling or tripling of the preindustrial level of CO_2.[3] Unlike for SO_2 emission, the total accumulation of CO_2 matters rather than the rate of CO_2 emission. Oceanic uptake of CO_2 can compensate for some emissions,[4] but this uptake will collapse once CO_2 concentrations in the air are held constant. Oceanic uptake depends on a concentration gradient in the surface ocean maintained by the currently rising CO_2 concentration in air. At an increased CO_2 level in air, the ocean uptake rate will decrease and, with it, the world's annual emission allowance. In order to stabilize the atmospheric CO_2 level, emissions have to be reduced by several factors. As a result, the world's per capita emission would have to be a factor of 10–30 smaller than current per capita levels in industrial countries.[5] Stabilization of CO_2 concentrations in the atmosphere either requires abandoning fossil energy or capturing and storing most, if not all, CO_2 produced.

The term ''sequestration'' refers to ''putting aside and locking up'' carbon that is freed in the extraction of fossil fuels. Among some researchers, the term sequestration has become synonymous with biological sequestration, i.e., the cultivation of biomass to capture and store CO_2.[6] Here, the term is used more broadly: Sequestration refers to any storage scheme that can keep CO_2 out of the atmosphere. Carbon sequestration schemes can be ranked by capacity and permanence of storage, by environmental consequences, and by cost of implementation.

Carbon sequestration involves three steps—capture, transport, and disposal. The current estimated cost of capture and compression of CO_2 to pipeline pressure (110 bar) is approximately US$ 30–50 per ton of CO_2. Transport of CO_2 adds US$ 1–3 per ton per 100 km.[7] Disposal costs vary, but in some cases, they are quite low, e.g., US$ 4 per ton of CO_2 for some forms of underground injection.

Since CO_2 sequestration raises the cost of energy, it is unlikely that sequestration will be introduced without regulatory pressure. The trade-off between ignoring the risk of climate change and paying for a carbon-neutral energy infrastructure is easier if the cost of the carbon management can be held low.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007689

Sequestration will only be considered if it is cheaper than the alternatives for reducing CO_2 emissions. Alternative forms of energy, including wind and nuclear energy, limit the acceptable price of CO_2 sequestration.

The enabling technologies for sequestration fall into four categories:

- CO_2 capture from large industrial sources, such as power plants, refineries, cement plants, steel mills, or hydrogen production facilities.
- Capture of carbon from natural and short-lived carbon reservoirs, including the capture of CO_2 directly from the air.
- CO_2 transport from the point of capture to the point of disposal.
- CO_2 disposal in locations that allow for long-term storage of large quantities of CO_2.

CO_2 CAPTURE AT CONCENTRATED SOURCES

CO_2 sequestration requires economically competitive capture of CO_2 at industrial sources. This involves its separation from other gaseous constituents in plants' effluents and its preparation for transport and disposal. Fossil fuel burning power plants are among the largest sources of CO_2 emission worldwide (30%); other large sources include cement plants (6%), steel mills (6%), and hydrogen production facilities (1%). Capture strategies need to be tailored to each specific case. Most research has concentrated on power plants, for which a number of strategies have been developed. They differ in the location in the process where CO_2 is removed from the material flow stream.

Upstream Capture or Decarbonizing of Fuel

Carbon capture occurs upstream of the power plant while creating an intermediate carbon-free fuel from a carbonaceous energy resource such as coal. Capture is combined with fuel preparation and refining, and thus, the energy conversion itself does not involve emission of CO_2. In this case, the carbon capture becomes more akin to operations in a refinery or bulk chemical production plant.

Fuel decarbonizing applies to other sectors of the energy economy as well. Conversion from natural gas to electric power in commercial or domestic applications would move the carbon problem upstream and thus represent a strategy of decarbonizing of the consumption sector. Another example would be the transition to hydrogen in the transportation sector.[8] As long as coal and natural gas provide hydrogen at a fraction of the cost of the electricity that would enter into electrolysis, hydrogen is likely to be produced from fossil energy resources. Centralizing hydrogen production decarbonizes the transportation sector.[9]

Upstream capture also involves various gasification schemes that could be used to create a carbon-free chemical fuel from carbonaceous input. Typically, this fuel would be hydrogen, although other energetic compounds, such as ammonia,[10] metals (e.g., magnesium[11]), and metals hydrides (LiH[12]), have been considered in the past. Any carbon-free fuel could be consumed without concern over greenhouse gas emissions. Like any upstream technology change, the major cost of upstream CO_2 capture lies in the need to replace a large existing infrastructure.

As an example, consider methane steam reforming, water–gas shift, and partial oxidation producing hydrogen and CO_2, where the CO_2 is removed from the pressurized gas stream. Since hydrogen production is an established technology, this option is already available. Improvements would involve better gas separation techniques. Typical cleanup processes involve physical and chemical adsorption of CO_2. Glycol-based compounds (i.e., dimethylether of polyethylene glycol) and amine solutions are examples of the commercial solvents used for physical absorption that require a sufficiently high partial pressure of CO_2 ($>500\,kPa$). Other solvents include Selexol and Rectisol[13] and KS-2.[14] Other adsorption systems capture CO_2 on a bed of adsorbent materials such as molecular sieves or activated carbon.[15] CO_2 can also be separated from other gases by condensation at cryogenic temperatures.[16] Polymers, metals such as palladium, and molecular sieves are also being evaluated for membrane-based separation processes.[13] Although operating conditions require high pressures, most of these separation methods require low operating temperatures. Thus, the flue gas stream has to be cooled before the separation process, which leads to a rather large energy penalty. The details of these processes can be found in the following section.

On the other hand, hydrogen membranes and the reaction-based processes using solid sorbents can separate CO_2 while operating at the elevated temperatures of the gasifier. Such methods utilize the carbonation/calcination cycle of a solid metal oxide (MO).[17–19]

$$MO + CO_2 \leftrightarrow MCO_3 + \text{heat} \quad (1)$$

At low temperatures or high partial pressure of CO_2, the reaction proceeds to the right. At high temperatures or low partial pressure of CO_2, the reaction proceeds to the left. Gaseous CO_2 is bound into the solid matrix during the carbonation process, yielding metal carbonate. The metal oxide is then regenerated via either temperature or pressure swings. At temperatures beyond the calcination temperature that is specific for

the given partial pressure of CO_2, a pure CO_2 stream is produced as the metal oxide is regenerated. For the $CaO/CaCO_3$ system, the transition at 1 atm of CO_2 is at 890°C (calcination temperature), and, as the partial pressure of CO_2 increases, the carbonation/calcination temperatures of the system also rise. The advantages of the reaction-based separation process are: 1) CO_2 capture under A wide range of flue gas conditions (i.e., 150–700°C and <1 atm); 2) high equilibrium capacity; 3) low equilibrium concentration; and 4) generation of a pure CO_2 stream. $CaCO_3$, $MgCO_3$, $ZnCO_3$, $PbCO_3$, $CuCO_3$, and $MnCO_3$ are the potential candidates based on the range of carbonation and calcination temperatures, and reactivity.[17]

Downstream Flue Gas Scrubbing

The opposite approach to carbon capture is downstream flue gas scrubbing. The power plant remains unchanged until just prior to the release of flue gases. At this point, CO_2 sorbents or membranes are used to remove the CO_2 from the exhaust stream. Unlike the operating conditions in upstream designs, the temperature of the exhaust gas and the CO_2 partial pressure tend to be low for downstream capture. In pulverized coal combustion, CO_2 concentrations in flue gas are around 10–15%; in gas turbine exhausts, they are between 3% and 5%. Thus, in some cases, the flue gas has to be pressurized slightly to enhance the separation process. In addition to the chemical solvents listed earlier, alkanolamines [i.e., monoethanolamine (MEA) and diethanolamine (DEA)] can be used to separate CO_2. Particularly, the MEA process is currently considered to be the most attractive choice for separating CO_2 from flue gases, since this system can absorb CO_2 at low partial pressures.

Adsorption on solids is another well-known method of capturing gases from a gas stream. A column of adsorbent materials such as molecular sieves, activated carbon, and zeolite capture CO_2 on materials with high surface area. At high pressures, CO_2 is removed from the gas stream, and at low pressure, the adsorbed CO_2 is recovered. However, this method is usually low in capacity and often not very selective in the adsorption process. Cryogenic methods, while possible, are usually too expensive and are limited to purifying CO_2 for specialty applications.

Flue gas scrubbing is a very simple change in the design of a power plant, but since the CO_2 stream is large, the overall energy and cost penalty is large. Typical penalties are around 30–40% of the power output of the power plant. Thus, the cost per ton of CO_2 avoided includes the revenue loss due to the downrating of the power plant. Design improvements seem to have some potential to lower this cost.

Integrated Zero-Emission Power Plants

Not all power plant designs fit into an upstream or downstream category. Integrated systems let carbon move through the entire process, but they prevent normal dilution of the output flue gas, so that the effluent is concentrated CO_2. While most of the plants in this category are still in an early development phase, they promise to combine high efficiency, virtually zero atmospheric pollution, and complete capture of all CO_2. All avoid the intake of air.

If CO_2 is collected from the N_2-rich flue gas stream, the effluent from the power plant only contains condensable materials, making it possible to cap the flue stack and create a power plant with zero emissions to the air. Such plants integrate CO_2 capture with other pollutant control mechanisms and eliminate the expense of even more stringent flue gas scrubbing.

Oxyfuel combustion with flue gas recirculation represents a method of CO_2 capture that could be implemented today.[20] In this technique, input air is replaced by a mixture of recycled nitrogen-free flue gas (mainly CO_2) and pure oxygen. The recirculated CO_2 maintains an optimal oxygen concentration in intake gas, which, for a retrofit, would be near that of ambient air. The major cost and energy penalty in such a plant results from the operation of the oxygen plant, which consumes approximately one-third of the electricity output of the power station. At the current price of oxygen (US$ 4 per 100 m^3),[21] the oxygen would add US$ 0.018/kWh to the net electricity produced. However, once the oxygen demand and the economic scale of the oxygen production are increased, this cost is likely to be reduced. Noncryogenic approaches, such as high-temperature mixed solid oxide membranes, may be used to separate oxygen from air. The high-temperature units allow for much tighter integration into the power plant. For example, they could be integrated into the combustion unit of a gas turbine, which would then keep the compressed combustion products out of the turbine stream.[22]

Solid oxide fuel cells would integrate electricity production with air separation. The fuel need not be hydrogen; it could be any mixture of CO and H_2, or might even include methane, which undergoes steam reforming within the fuel cell chamber.[23] In the case of coal or biomass, the fuel gas is produced in an upstream gasification step. The fuel cell separates the oxygen from the air while generating electricity and heat. By transferring the heat to the upstream gasification process, it is possible to achieve extremely high rates of efficiency. The ZECA plant design aims at 70% conversion efficiency while delivering CO_2 in a concentrated stream.[24]

Another approach to bringing oxygen together with fuel is through a chemical looping process.

Chemical looping involves a sorbent, typically a metal or, more likely, a low-oxidation-state metal oxide that can be oxidized in air.[25] The oxide is reduced by fuel gases in a subsequent step. A variation of this approach oxidizes the metal not in air but in a chemical reaction with water, producing a pure stream of hydrogen. The advantage of this approach to hydrogen production is that it eliminates separation of hydrogen from the fuel gas, the use of a separate water–gas shift reactor, and the cleanup of fuel gas prior to hydrogen production.[26] The oxidized fuel gas is disposed of completely without any emissions to the atmosphere. From chemical looping, a high-pressure sequestration-ready CO_2 stream can also be produced.

Conventional gasification requires separation of hydrogen and CO_2 from the fuel gas mixture. This can be accomplished through chemical or physical sorbents or through membrane separation. As mentioned earlier, at low temperatures, physical and chemical adsorption is commonly used to separate hydrogen from the gas stream. Many of the zero-emission plants, however, could improve efficiency dramatically if CO_2 capture could be achieved at high temperatures. Solid chemical sorbents, such as CaO, have been considered potential candidates.

Membrane-based separation processes to capture either H_2 or CO_2 from the gasifier are new and less studied methods of CO_2 separation and capture. Membranes separate the desired gas component without requiring phase changes or chemical or physical sorption. The cost of membrane separation is generally dictated by the overall pressure drop. Membranes made of various types of materials such as polymers, metals, and rubber composites have been investigated.[10,27] Palladium and molecular sieves are currently under study.[10]

CAPTURE FROM DIFFUSE SOURCES

Capture of CO_2 at concentrated sources is easier than capture from the environment, but it requires significant changes in the existing infrastructure. Furthermore, approximately half of all emissions arise from small, distributed sources. Many of these emitters are vehicles, for which capture on board is not practical. For small, mobile emitters, the subsequent capture of carbon dioxide from the air provides another alternative.

The atmosphere represents a large and well-mixed buffer of carbon dioxide. Emissions over the course of a year are about 1% of the total CO_2 in the atmosphere. As a result, it is not necessary to capture a specific CO_2 emission; it suffices to capture an amount of CO_2 that cancels an emission that has happened or is about to happen. In general, CO_2 capture from air occurs at the disposal site and thus avoids the CO_2 transportation infrastructure necessary for capture at centralized sources.

Biomass sequestration, which has been embraced by coal companies as the least expensive way to start carbon management, relies on capture from air. Cofiring with biomass followed by sequestration also leads to a net CO_2 reduction in the atmosphere.[28] On a per-ton basis, this option is quite cost effective, but the land area that is required is too large to be practical. Consequently, it is worthwhile to consider other options. Currently, studies are underway that consider capture of CO_2 directly from the air by chemical means. These processes require good chemical sorbents that do not pose environmental concerns in their own right and that can be regenerated cost-effectively.

The scale of an air capture system is surprisingly small. At a wind speed of 6 m/s, the U.S. per capita emissions of 22 t/year flow through an opening of $0.2\,m^2$, the size of a television screen. Consequently, an air contacting apparatus, whether it just stands in the wind or utilizes wind flows through tower-like structures, can be very compact. The major challenge being addressed by current research is the design of a sorbent recycle system. Strong alkali solutions including NaOH and $Ca(OH)_2$ readily pull CO_2 out of the air, but the recovery is energy intensive. $Ca(OH)_2$ in contact with air turns into $CaCO_3$; NaOH turns into Na_2CO_3. The latter is reconverted to sodium hydroxide in a process used in the pulp and paper industry known as the Kraft process.[29] The effective equation is

$$Na_2CO_3 + Ca(OH)_2 \rightarrow 2NaOH + CaCO_3 \qquad (2)$$

In the end, both approaches require the calcination of limestone to lime. The energy penalty in this process is about 4.5–5 GJ per ton of CO_2, which amounts to a 30–40% energy penalty for a transportation sector that uses air extraction for managing its own CO_2 emissions. This is comparable to the energy penalty incurred in the conversion of fossil fuels into hydrogen as a transportation fuel.

TRANSPORT OF CO_2

A CO_2 transportation infrastructure would be a rather conventional approach. On land, pipelines for long-distance CO_2 transport already exist. For example, a pipeline system more than 800 km long connects CO_2 fields in Southern Colorado to oilfields in West Texas. The CO_2 is purchased at about US$ 15/t for tertiary oil recovery.

Ocean transport might involve pipelines or ships. Small CO_2 tankers already exist.[30] However, there is currently no use of larger vessels. Nevertheless, the

technology for large vessels seems less daunting than that for liquefied natural gas tankers, which is a well-established technology.

DISPOSAL OF CO_2

Disposal or long-term storage of CO_2 is the final step in the carbon management chain. It is made difficult by the large scale of storage. At current rates, the total CO_2 production for a century would be 650 Gt of carbon (GtC), or 2500 Gt of CO_2. For comparison, Lake Michigan contains 5000 Gt of water.

While the sequestration technology is still too new to settle on one specific approach, any storage option, to be useful beyond small niche markets, must have large capacity, be safe, be environmentally benign, and guarantee the long-term stability of storage. Storage lifetime constraints will become more stringent over time. The total leakage of all storage must be less than environmentally tolerable emissions. Leakage emissions, $L(t)$, are a function of time, t. They are related to total stored carbon, $S(t)$, and the representative lifetime of all storage, τ, through

$$L(t) = S(t)/\tau \tag{3}$$

Leakage rates start small, because S is initially small. As S increases, lifetime constraints grow more stringent. Until there is a comprehensive understanding of the global carbon cycle, the maximum allowable leakage rate will remain uncertain. It is, however, unlikely to surpass 1 GtC/yr. This suggests that τ will have to be in excess of 1000 years even before $S(t)$ reaches 1000 GtC. Unless fossil fuels are phased out, such amounts will be stored long before the end of the 21st century. This is a serious constraint: Biomass turnover is measured in years to decades, and ocean turnover times are measured in centuries.

In the following section, the various options in order of their likely capacity are discussed.

Biomass Sequestration

One of the largest natural carbon flows through the environment is driven by photosynthesis. Plants take up CO_2 and water and turn them into reduced carbon compounds such as starch and cellulose. Photosynthesis fixes about 100 GtC per year. Most of this is returned via respiration and decomposition, but it seems that over the last decade, mid-latitude forests have been net sinks for CO_2.[31] Trees and other plants sequester CO_2 during periods of growth. Thus, forestation and agricultural fixation of carbon, in either biomass or soil carbon, can play a role in carbon sequestration. A mid-latitude forest stores about 60 tC/ha aboveground and another 100 tC/ha belowground. Uptake rates can be as much as 3–10 tC/yr, but the capacity is limited. Worldwide biomass amounts to 600 GtC and soil carbon to 1400 GtC.[32] This defines the yardstick against which biological sequestration has to be measured. To match the CO_2 emission from a single GW coal plant, the forested area should be increased at a rate of 1 ha (2.5 acres) per hour. Keeping up with a GW plant requires a growing forest of 370,000 ha (950,000 acres). Biomass sequestration could make up for past deforestation, which is responsible for a small fraction of the increased atmospheric CO_2. Biomass sequestration is most useful when it is the by-product of other societal goals. Environmental concerns arise where monocultures for the purpose of biomass fixation replace less carbon-efficient natural systems.

Another biomass approach is ocean fertilization. This method spurs biomass growth in areas that are low in productivity due to lack of critical nutrients. It, too, is limited in capacity, and has raised environmental concerns over changes in the natural food chain. The cost of biomass conversion is often quite low. Paustian et al.[33] estimate that planting forests in developing countries could cost as low as US$ 3–10 per ton of CO_2 captured.

Ocean Sequestration

A large fraction of the emitted CO_2 is naturally absorbed by the ocean. Therefore, nonaction equates to partial ocean sequestration. In equilibrium, the partitioning of CO_2 between ocean and atmosphere is roughly 4 : 1.[34] As the partial pressure of CO_2 in the air rises, the ratio gradually moves toward a higher fraction of CO_2 remaining in the atmosphere. The CO_2 carrying capacity of the ocean is determined by its carbonate alkalinity, which is the charge-weighted sum of ion concentrations, excluding protons, hydroxyl ions, and bicarbonate and bicarbonate ions. Charge neutrality demands that the alkalinity A is equal to the sum of the ionic charge in these remaining ions:

$$\mathrm{A} = [\mathrm{OH}^-] + [\mathrm{HCO_3}^-] + 2[\mathrm{CO_3}^{2-}] - [\mathrm{H}^+] \tag{4}$$

For ocean water with a pH near 8, one can neglect protons and hydroxyl ions; thus,

$$\mathrm{A} \approx [\mathrm{HCO_3}^-] + 2[\mathrm{CO_3}^{2-}] \tag{5}$$

At constant alkalinity, the ocean can absorb more CO_2 by replacing one CO_3^{2-} with two HCO_3^-. Since 90% of all the inorganic CO_2 in the ocean is in the form of HCO_3^-, the uptake capacity of the ocean is far less

than the 39,000 GtC present in the ocean. Eliminating all carbonate ions would reduce the pH to about 4 and store no more than 3500 GtC. In equilibrium with 550 ppm of CO_2 in the air, the pH of the ocean would drop by 0.3, and if the CO_2 were stirred into the entire ocean, it could pick up about 1000–1500 GtC. Without active interference, the approach to this equilibrium would take millennia.[35]

In spite of these limitations, estimates for ocean storage capacity in excess of 100,000 billion GtC have been cited.[36] Such numbers would only be feasible if alkalinity (i.e., NaOH) is added to the ocean to neutralize the corresponding amounts of the carbonic acid. Over thousands of years, the dissolution of calcareous oozes at the bottom of the ocean could provide such alkalinity.[4,37]

Ocean disposal options fall into several categories, as illustrated in Fig. 1. One is to dilute the dissolved CO_2 at a depth below the mixed layer. Carbon dioxide can be stored using this method for decades to centuries, but capacities are limited. Another approach is to form lakes of CO_2 at the bottom of the ocean. Below 2700 m, compressed CO_2 is denser than seawater and sinks to the bottom. In addition, CO_2 reacts with seawater to form a clathrate, a cage structure with approximately six water molecules per CO_2.[38] Clathrates are solids that can form at temperatures slightly higher than the melting point of water and thus form spontaneously in the presence of liquid CO_2 near the bottom of the ocean. However, they are not stable, and as a result, they dissolve into ocean water once the CO_2 concentration in the water drops back to the normal levels. Since 1977, when Marchetti[39] first introduced the concept of direct ocean sequestration of CO_2, significant research effort has taken place, and now the cost for the direct disposal of CO_2 in the oceans is estimated to range from as low as US$ 1–6 per ton of CO_2,[40] to a more realistic estimate of US$ 5–15 per ton of CO_2.[41]

The environmental impact may be the most significant factor determining the acceptability of ocean storage, since the strategy is predicated on the notion that the impacts on the ocean will be less than the avoided impact of these emissions on the atmosphere. Environmental concerns in ocean sequestration focus on long-term chronic issues of changing the ocean chemistry as well as on the local effects of low pH (as low as 4) and its effect on marine organisms (e.g., stunting coral growth). While it is true that the oceans will get acidified as well, if the problem is ignored, the need for dealing with elevated levels of CO_2 in the atmosphere may not be limited to climate change concerns but also to changes in the ocean water chemistry. It does not help to replace one environmental problem with another. In addition, there is the possibility of sudden release of the sequestered CO_2 due to thermal plumes and volcanic action in the ocean. It has been reported that when a lake in Africa erupted, an enormous amount of CO_2 was discharged from the bottom of the lake, killing thousands of animals and humans by asphyxiation.[42]

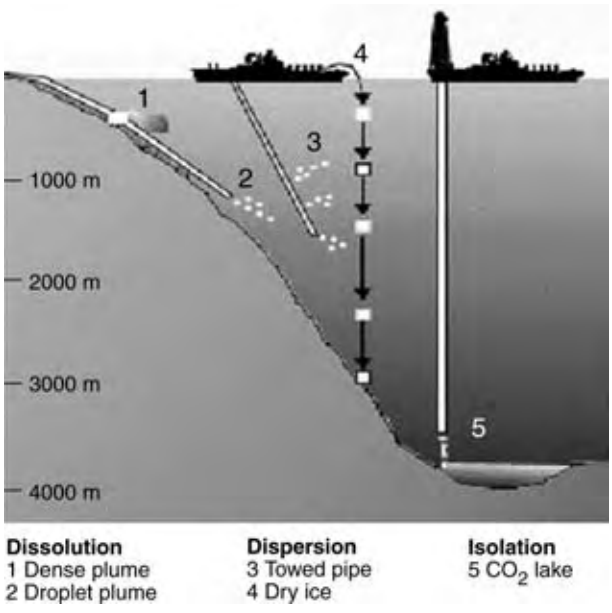

Fig. 1 Ocean disposal of CO_2: five injection scenarios. (From Ref.[34].) *(View this art in color at www.dekker.com.)*

Geological Sequestration

Underground storage in geological formations is a major option for disposing of CO_2 and is already practiced. Potential sites for geological storage are active oil fields, coal beds, depleted oil and gas reservoirs, deep saline aquifers, and mined salt domes and rock caverns.[43] In West Texas, approximately 20 million tons of CO_2 are consumed in tertiary oil recovery.[44] These injections do not qualify as sequestration as the CO_2 has been extracted from underground wells about 500 miles away. However, these projects and similar projects in Canada demonstrate that the disposal of CO_2 is practically feasible. Nevertheless, the capacity of tertiary oil and gas recovery is quite limited. Estimates range from 20 to 60 GtC.[45] Displacing methane tied up in deep, unmineable coal adds another small carbon sink to the portfolio of options. This method is attractive in the sense that most of the injected CO_2 will be immobilized by either physical or chemical absorption on the coal surface. On the other hand, in other reservoirs such as aquifers, the injected CO_2 will likely exist as a supercritical phase without being fully dissolved for thousands of years,

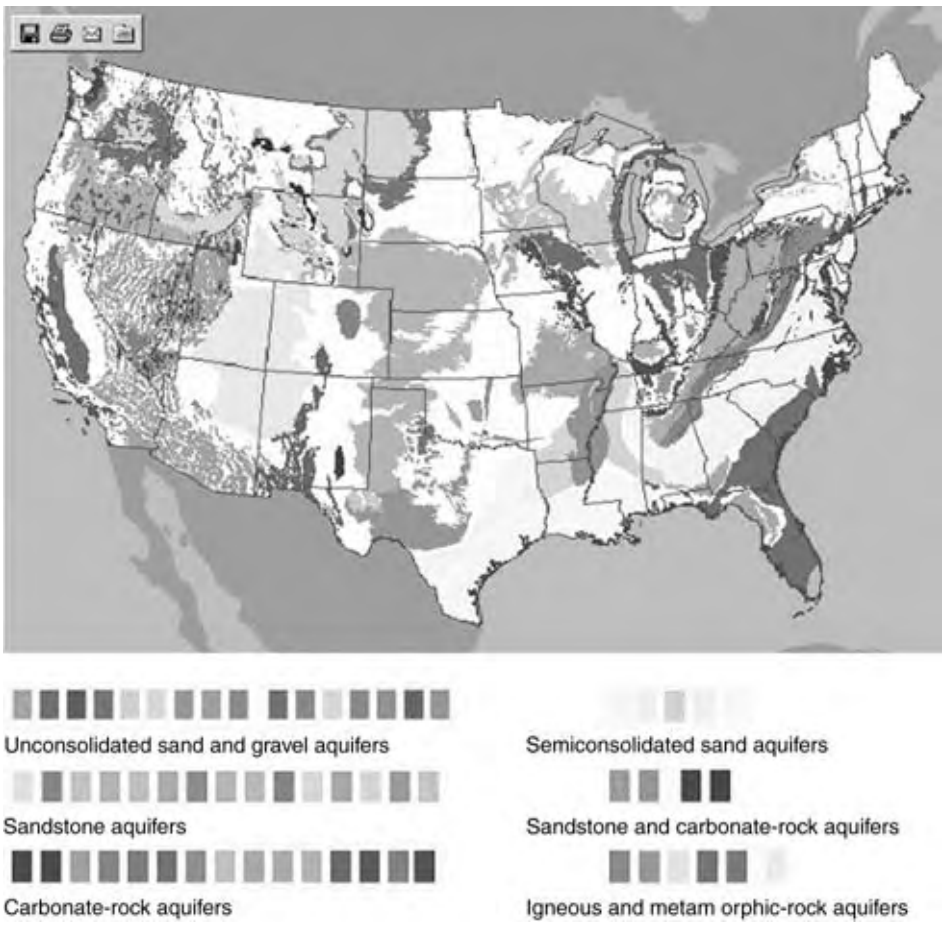

Fig. 2 Saline aquifers in the United States based on the U.S. Geological Survey. (From Ref.[45].) *(View this art in color at www.dekker.com.)*

and that creates a potential problem of a higher leakage rate.[46]

Beyond those examples where CO_2 can be utilized in the recovery of large underground reservoirs of oil and gas, deep aquifers represent the best long-term underground geological storage option. Such aquifers are generally saline and are separated from shallower aquifers and surface water supplies. The estimated storage capacities of these aquifers in the United States are 5–500 billion tons of CO_2.[47] This technology has been demonstrated by Statoil at the Sleipner project in the North Sea. It shows that injection into deep aquifers is economically feasible.[48] This project is ultimately driven by a tax of US$ 50 per ton of CO_2. Fig. 2 shows the location of deep saline aquifers in the United States.

There are a number of additional projects underway or being brainstormed that will further outline the viability and long-term capacity of geological sequestration. The central question is long-term safety, long-term leakage rate, and, ultimately, the capacity of these projects. It is likely that there will a large number of sites where CO_2 can be stored safely, for all practical purposes permanently. While some proponents of the scheme have suggested storage capacities of the order of 300 GtC, the real number at this point is still very uncertain and may prove to be much larger. For the application of geological sequestration, both near-surface and at-depth monitoring systems should also be developed to minimize CO_2 leakage from underground.

Mineral Sequestration

As the amount of CO_2 stored increases, it becomes progressively more difficult to guarantee a physical barrier that prevents CO_2 from returning to the atmosphere. Chemical conversion to a thermodynamically lower state would thus be desirable and is indeed possible. CO_2 is the anhydrous form of carbonic acid and therefore can be used to displace weaker acids such as silicic acid. The formation of carbonates from silicates is well known as geological weathering. Thermodynamically, CO_2 can be bound as a carbonate. In many instances, these carbonates dissolve in water, but some, such as magnesium and calcium carbonates, are remarkably stable as solids. Thus, mineral sequestration would provide a means of storing CO_2.

Fig. 3 Worldwide distribution of magnesium-rich ultramafic rocks. (From Ref.[49].) *(View this art in color at www.dekker.com.)*

Mineral carbonation is a new and, consequently, less studied method of sequestration. Mineral resources are plentiful for storing all the carbon that could ever be released in the consumption of fossil fuels. This sequestration process offers a safe and permanent method of CO_2 disposal, since there is almost no possibility of accidental release of CO_2 from the disposal site, as CO_2 is chemically incorporated into the mineral and immobilized. Furthermore, the reactions that bind CO_2 to the mineral are exothermic in nature, leading to the formation of thermodynamically stable carbonate forms.[49]

Ultramafic igneous rocks (primarily peridotites and serpentinites) contain large amounts of MgO bound into a silicate structure. Dunite is a rock made up entirely of olivine (Mg_2SiO_4). A more abundant ultramafic rock is serpentine [$Mg_3Si_2O_5(OH)_4$], which is hydrolyzed olivine. Both olivine and serpentine also contain some iron in place of magnesium. Peridotite and serpentinite rocks containing olivine and serpentine exist in amounts far exceeding fossil carbon resources, and Fig. 3 shows the map of the worldwide locations of those deposits. There are large deposits in the United States and Puerto Rico.[50] There are also large deposits of these minerals in Canada and parts of Europe.

Mineral sequestration can proceed in industrial processes or underground. Industrial processes could be based on gas–solid reactions, aqueous processes, or combinations of the two. While the cost of mining, mineral preparation, and tailing disposal is well known in industry and relatively inexpensive, the chemical reaction process is still too expensive for practical implementation.[51] The bottleneck is the slow kinetics of the process and the high cost of accelerating the process by various means. Heat treatment of serpentine, external attrition grinding, and acid dissolution have all been shown to work, but the cost of the process will still have to be reduced from current estimates of US$ 69 per ton of CO_2[52] to more acceptable numbers like US$ 30/t.[49] Since carbonic acid has proven to be too weak to dissolve serpentine or olivine with sufficient speed, some of the more promising approaches are based on the use of mixtures of weak acids that enhance the dissolution of serpentine and olivine while still allowing for their recovery at minimal energy cost.[53,54]

In the second process, CO_2 could be injected into selected underground mineral deposits for carbonation (in situ carbonation). This process envisions pumping CO_2 directly into an underground deposit of porous magnesium- or calcium-bearing rock. In contrast to permanent underground storage of CO_2 gas (as in aquifers and depleted oil/gas reservoirs), this process would result in chemically stable carbonates; it therefore poses substantially lower long-term risk. The reaction would be aided by naturally high pressures (overburden) and could proceed more rapidly than mineral weathering on the Earth's surface.

CONCLUSIONS

While, in the short term, the costs of CO_2 capture and transport are likely to dominate the cost of carbon sequestration, in the end, the cost of disposal will become more important. There are two major reasons. First, as technologies improve and power plants are designed around the concept of carbon capture, the incremental cost of capturing carbon dioxide will become smaller. Indeed, in some of the zero-emission designs, the capture processes separate CO_2 while capturing other pollutants, and thus the net costs of carbon capture may be close to zero.

Pipeline costs will get smaller as the pipeline network gets larger. At the same time, however, the demands on carbon dioxide storage will gradually increase. As the reservoirs get larger, concerns over environmental consequences will increase and the concerns over leakage will become greater. Meanwhile, the easily accessible sites will be used up, and the cost of monitoring will increase.

CO_2 sequestration technology is a viable contender among a set of options to stabilize the atmospheric CO_2 level over the next few decades.[55] The technical ability to start such a process exists today, but the institutional structures required to reduce CO_2 emissions are still missing. Carbon sequestration at the very least will buy time for alternatives to fossil fuels to become competitive. It is, however, equally possible that carbon sequestration may remove the major environmental obstacles to the use of fossil fuels, in which case they may prove competitive with alternatives for a long time to come.

Faculty of Forestry, Biomaterials Chemistry, The University of British Columbia, Vancouver, British Columbia, Canada

INTRODUCTION

Recently, environmental concerns have sparked interest in utilizing biodegradable and bio-derived materials in various industrial fields. Particularly, the utilization of plant-derived materials such as agricultural residues and forest products has received increasing attention. Lignin is one of the most abundant biomacromolecules existing in the plant kingdom. An enormous amount of lignin is produced as a by-product of the pulp and paper industry. As a result, a number of systems have been proposed for the utilization of lignin as a renewable polymeric material. However, lignin utilization is still limited, with less than 2% of the lignin produced being used in commercial applications; lignin is used as dispersants, adhesives, and surfactants. This has been attributed, at least partially to the fact that most of the systems being developed require chemical modification of the lignin or the use of noncommercial lignins such as organosolv lignins. Polymer blending is a convenient and inexpensive method to develop novel polymeric materials. In previous studies, we had shown that lignin forms a miscible polymer blend with poly (ethylene oxide) (PEO). Blending with PEO improved some of the unfavorable properties of lignin, such as moldability and flexibility. However, these blends are still unattractive as a commercial material because of their dark color and unsuitable mechanical properties for structural materials.

One potential application of lignin-based fibers is carbon fibers. Carbon fibers are lightweight materials with prominent mechanical properties. The conversion of lignin fibers into carbon fibers resulted in improved mechanical properties. In our research, it was found that the porosity of lignin–synthetic plastic-based carbon fibers could be controlled by careful selection of the blending synthetic plastic. Immiscible blend fibers resulted in hollow and porous fibers without any further treatment after carbonization. Due to the difference in thermal stability of the synthetic polymer and the lignin, careful control of thermal treatment conditions enables the removal of the synthetic polymer from the lignin fiber. In the manufacturing process of carbon fibers, three fundamental steps are involved: fiber spinning, thermostabilization, and carbonization. In the case of the lignin, the thermostabilization process is sometimes omitted because of the auto-oxidative reactions that occur when lignin is heated to the high temperatures during carbonization. However, the softening point of the lignin fiber is low, and this can make it difficult to maintain the fibrous form during carbonization. The addition of a synthetic polymer will also affect this process; the use of a low T_g material will decrease the softening point of the blend relative to lignin, whereas a high T_g material will increase it. Therefore, depending on the synthetic polymer being blended with the lignin, the necessity of the thermostabilization stage will vary.

In this entry, the effect of blending recyclable poly(propylene) (PP) and poly(ethylene terephthalate) (PET) with lignin on carbon fiber production is presented. We discuss the effects of lignin structure and specific intermolecular interactions on lignin thermal properties as well as the effect of blend composition on surface morphology, mechanical properties, and the manufacturing process of lignin/recyclable plastic-based carbon fibers.

UTILIZATION OF LIGNIN

Extensive cross-linking and strong intramolecular interactions of polymeric lignins constrain the utilization of polymeric lignin in solid material systems;[1,2] hardwood lignins are more easily processed than softwood lignins. Due to the inherent chemical and molecular weight heterogeneity, lignin and lignin derivatives have limited utility in applications demanding a constant well-defined feedstock. In fact, less than 2% of the total available lignin is reportedly used in higher value products.[3] In 1996, total sales in lignin-based specialty products, such as animal bypass protein, agrochemicals, dispersants, adhesives, and surfactants, were reported at $600 million.

One of the most important applications of lignin and its derivatives is in the area of plastic products. Lignin displays unique thermal behavior, showing not only thermoplastic but also thermosetting properties. Thermal properties, such as glass transition, thermal fluidity, and others, are also dependent on

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120039775

the isolation method and the lignin source (discussed earlier). Since the 1930s, lignin has been used in plastic materials.[4] As a result, a considerable amount of information exists regarding the modification of lignins toward the engineering of plastics. Unfortunately, in most cases, the incorporation of various monomers or polymers into the lignin structure results in properties unsuitable for structural materials.[1] Glasser and coworkers[5,6] have shown that through the manipulation of the network structure and substituents in lignin, the physical properties of lignin-based materials can be manipulated. They found that the noted brittleness of lignin, caused by the globular structure of lignin fragments, could be abolished by incorporating a variety of polyether components in the network structure. That is a decrease in glass transition temperatures and brittleness could be achieved through the introduction of ''soft'' molecular segments capable of a plastic response to mechanical deformation.

Lignin-based polyblends or polymer alloys have also been developed to enhance the thermoplastic behavior of lignin.[7] However, the amount of lignin incorporation into the polymeric materials is generally limited, because of the inherent brittleness of the lignin phase or phase separation due to immiscibility. Recently, Li, Mlynar, and Sarkanen[2] have produced homogeneous blends containing 85% (w/w) underivatized industrial kraft lignin with poly(vinyl acetate) and two plasticizers. Likewise, we have shown that incorporation of small amounts of PEO into blends with kraft[8] and organosolv[9] lignin can dramatically improve the thermal and physical properties of lignin-based materials. The various lignin-based thermoplastics exhibited promising mechanical properties, with the tensile behavior of these polymeric materials directly dependent upon the degree of association between the intrinsic kraft lignin components.

LIGNIN-BASED CARBON FIBERS

One area of lignin utilization that is receiving increasing attention is in the development of advanced composite fibers. Carbon fibers are one of the most important engineering materials in advanced composites. They are lightweight, fatigue resistant materials that possess high strength and high stiffness. These unique properties result from their flawless structure and the development of highly anisotropic graphic crystallites orientated along the fiber axis during the production process.[10] Carbon fibers are manufactured by thermally treating fibers at 1000–2000°C in an inert atmosphere while maintaining the fibrous structure. This is aided by a stabilization stage in which the precursor fibers are heated under tension at 200–300°C in the presence of air. This causes cross-linking on the fiber surfaces, among other reactions, and prevents shrinking, melting, and fusing.

The first commercially produced carbon filament was made from a cellulosic precursor for its application as an incandescent lamp filament in 1879.[11,12] Its use as a reinforcing material in composite products began in the 1950s as the aircraft and aerospace industries led the search for new materials with properties superior to the then available metals. Cost was seldom a deciding factor. As the years passed, the advantages of advanced composite materials in other applications became apparent. Today carbon fiber composite products are routinely used in sports equipment, marine products, construction and automotive industries to name a few. However, unlike in its infancy, the cost of carbon fiber production has limited its widespread use. The fundamental difficulty is reducing the cost of manufacturing the precursor, the so-called ''white fiber.'' There are primarily three types of precursor materials of commercial significance: pitch (petroleum or coal), viscose rayon, and polyacrylonitrile (PAN).[13] Of these three, PAN is most important for structural applications.[a] It is an excellent precursor material that has been widely researched and is in wide commercial production. Almost 80% of commercially available carbon fibers are derived from PAN. However, current PAN technology is expensive, thereby limiting its utilization in lower cost general performance (GP) applications, and research continues toward decreasing the PAN precursor costs, e.g., Amlon (BP Chemicals).[14]

The overwhelming success of PAN-based carbon fibers over rayon and pitch can be attributed to several key aspects.[13] Structurally, PAN has a faster rate of pyrolysis without much disturbance to its basic structure and to the preferred orientation of the molecular chains along the fiber axis present in the original fiber. By contrast, carbon fibers from rayon suffer from extremely low carbon yield (20–25%) due to chain fragmentation, which eliminates the orientation of the precursor fiber. While improved properties can be achieved by stretch graphitization, this process is expensive and does not compensate for the low yields.

Pitch-based carbon fibers, on the other hand, provide properties not readily obtainable with PAN-based fibers. PAN-based fibers have excellent tensile strength at a modulus of 200 GPa, but the strength decreases as the modulus is increased.[14] Pitch-based fibers have lower tensile strengths, but are capable of modulus levels up to the theoretical modulus of graphite, 1000 GPa, and have much better thermal and electrical conductivity properties than PAN-based fibers.

[a]Developed in the 1940s by DuPont and Union Carbide, PAN began to be used as a carbon fiber precursor material in the 1960s through work done in Japan (Toray) aand Great Britain (Courtaulds).

Thus, pitch and PAN-based fibers are really complementary to one another, each filling a different set of commercial needs.

In addition to rayon, pitch, and PAN, many polymeric materials have been used to make carbon fibers.[15–24] However, only the big three, rayon, pitch, and PAN, have endured the high-performance markets. Their price has dropped over the years, but remains high, accounting for over one-half of the production costs, too high for the GP markets. The literature supports that recycled petrochemical polymers and fibers and renewable cellulosics and lignins, which are inexpensive and widely available, may be potential feedstocks for GP carbon fibers.[15–24]

Carbon fibers have been manufactured from lignin. One of the first reports of lignin-based carbon fibers was from Otani et al.[25] Utilizing thiolignin, alkali lignin, and lignosulfonates, carbon fibers were produced by both thermal and solvent spinning followed by thermal processing to 600–1000°C. Lignin fibers were produced by thermal spinning of softwood and softwood/hardwood kraft lignin blends. A purification process was needed to remove impurities and facilitate fiber spinning. The fiber quality was poor, requiring slow winding rates (5–10 m/min) and producing low tensile strength (300 MPa) carbon fibers. Improvements in spinnability and tensile strength were obtained by using dry spinning. Satisfactory lignin fibers were formed from kraft lignin; alkali lignin; and lignosulfonate spun from water, alkaline water, and glycerol. Blending with poly(vinyl alcohol) (PVA) or PAN enhanced the spinnability and the tensile strength of the fibers. Winding rates of 600 m/min were achieved when softwood kraft lignin (SKL) was blended with PVA (3/4, w/w). Fine fibers with excellent mechanical properties were produced. In the production of carbon fibers, an oxidation process, referred to as stabilization or ''thermostabilization,'' is generally conducted to induce cross-linking to maintain fiber integrity during the subsequent carbonization process. It was expected that lignin-based carbon fibers, due to the high oxygen content in lignin, could be produced with shorter stabilization periods at lower temperature than other feedstocks. The various hydroxyl and ether groups, via oxygen-based radicals, were expected to facilitate cross-linking within the lignin. In fact carbon fibers were prepared with very little thermostabilization, and tensile strengths as high as 800 MPa were obtained.[25]

Around the same time, Mansmann and coworkers reported the production of carbon fibers from a variety of dry-spun materials, including lignin (lignosulfonates) by the simple addition of small amounts of PEO or acrylic acid–acrylamide copolymers.[26] Although similar to the procedure of Ohtani, Mansmann employed acidic rather than neutral and/or alkaline spinning conditions. It was reported that the spinning under acidic conditions enhanced the mechanical properties of the lignin and carbon fibers. Furthermore, the amount of synthetic polymer required to enhance spinnability was much less in comparison to the method of Otani. The concentration of the polymer required for favorable spinning was dependent on its molecular mass. Only 0.3–0.6% (wt%) PEO, DP = 100 K, was needed for good spinning. In addition, dry spinning from acidic conditions reduced the thermostabilization temperature to between 100°C and 150°C. Tensile strengths of ~100 MPa and ~600–800 MPa, and Young's modulus of 2–8 GPa and 33.3 GPa were reported for the lignin and carbon fibers, respectively.

Based on these encouraging results, pilot-scale production of lignosulfonate-based carbon fibers, Kayacarbon, was developed and made commercially available by Nippon Kayaku Co.[27] Carbon fiber was prepared by dry spinning a lignosulfonate plasticized with PVA. Pilot trials revealed that lignin-based carbon fibers could be produced at lower temperatures with shorter stabilization periods than other feedstocks, such as pitch, because cross-linking reactions that produce the graphitic structure are facilitated by oxygen-based radicals derived from the various hydroxyl and ether groups within lignin. Close examination of the carbon fibers produced showed poorly developed fibrillar structures and lack of homogeneity between the crystalline planes. A large number of inclusions were found, arising from catalytic graphitization by sodium impurities, which contributed to a weakening of the fibers.[28,29] Microvoids of complicated size and shape were also observed.[30,31] The sizes of microvoids, as well as of the solid phase around them, increased with increasing heat treatment temperature; stretching of the fiber promoted further increases. These flaws, combined with the lack of orientation, resulted in low modulus and low tensile strength carbon fibers. As a result, these carbon fibers were abandoned because they did not meet the specifications of the high-performance aerospace industry, which dominated the carbon fiber market.

Sudo and coworkers demonstrated that steam-exploded lignin could be converted into a pitchlike molten material using hydrogenolysis followed by solvent extraction and polycondensation under high temperatures.[32,33] The lignin pitch had H/C ratios between 1.03 and 1.06, a softening point of 110°C, and melted at over 145°C to form a viscous liquid with suitable properties for thermal spinning and thermostabilization. A continuous fine filament could be produced at a speed of over 100 m/min. The fibers were heated in air from 1–2°C/min to 210°C, converting the lignin fibers to an infusible material, enabling them to be carbonized at a heating rate of 5°C/min up to 1000°C in a stream of nitrogen. The typical properties

of the lignin-based carbon fiber were: fiber diameter = 7.6 ± 2.7 μm; elongation = 1.63 ± 0.29%; tensile strength = 660 ± 230 MPa; modulus of elasticity = 40.7 ± 6.3 GPa. Unfortunately, the overall yield of the carbon fiber was only 20.7%, well below that of other lignin-based carbon fibers. To enhance the overall yield, hydrogenolysis was replaced by phenolation using creosote.[34,35] This resulted in yields of 40.0–49.2%.

In addition to steam-exploded lignin, Alcell and acetic acid lignins were studied. The spinnability of the phenolated Alcell was better than that of the other phenolated lignins. The phenolated Alcell lignin had a softening point of 150–170°C and could be continuously spun for 500 sec at a winding rate of 1000 m/min. min. To improve the spinnability of the phenolated acetic acid lignin, it was blended with pitch in the ratio of 1/1 (w/w). The overall yield of the carbon fibers made by this method was substantially higher than that of the hydrogenolysis lignin. Overall yields of 40.0–49.2% and 49.6–57.3% were reported for the phenolated and pitch-added phenolated lignin-based carbon fibers, respectively. Superior properties to that of the Kayacarbon were observed, with a tensile strength of 614 MPa, Young's modulus of 31.8 GPa, and 1.94% elongation being reported for the phenolated acetic acid lignin carbon fiber.

More recently, Sano et al. produced lignin fibers suitable for carbon fibers by thermal spinning organosolv lignin obtained from aqueous acetic acid pulping of birch.[36–38] Unlike the previously reported acetic acid lignin fibers, this system did not require any chemical modification (e.g., phenolysis). The spinnability of the organosolv lignin was attributed to the polydispersity and partial acetylation of the lignin due to the pulping process. The raw acetic acid lignin showed poor spinnability due to the formation of pyrolyzed gaseous materials in the extruder nozzle. Thermal treatment at 160°C under vacuum for 30 min removed this pyrolyzable material permitting excellent fiber spinning at more than 400 m/min. Tensile strength of 30.8 ± 3.5 MPa, Young's modulus of 3.59 ± 0.43 GPa, and 0.81 ± 0.08% elongation were reported for this lignin fiber. This fiber was easily carbonized after a thermostabilization process (0.5°C min^{-1} to 250°C). Tensile strength of 355 ± 53 MPa, Young's modulus of 39.1 ± 13.3 GPa, and 0.98 ± 0.25% elongation was reported for this lignin fiber. The tensile strength increased with decreasing fiber diameter and was comparable to previously reported lignin-based carbon fibers if fine carbon fiber was made from this lignin. Overall carbon fiber yield of 32.7% was obtained, comparable to that of isotropic petroleum pitch, ~30–35%, but lower than that reported for the phenolated acetic acid lignin of Sudo and coworkers.[34] Shortly thereafter, Sano et al. reported on the production of carbon fiber from softwood acetic acid lignin. The infusible softwood lignin was made fusible by removing the infusible high molecular mass fraction (~30% of the lignin) by successive extraction with various concentrations of acetic acid. Good fiber spinning was produced after thermal treatment of this lignin fraction. Moreover, this fiber was converted to carbon fiber without a thermostabilization process. Tensile strength of 26.4 ± 3.1 MPa, 147 ± 51 MPa, Young's modulus of 3.59 ± 0.43 GPa, 19.5 ± 5.5 GPa, and 0.71 ± 0.14%, 0.75 ± 0.27% of elongation were reported for this lignin fiber and carbon fiber, respectively.

At about the same time, Itoh reported that lignin prepared by the organosolv pulping using phenols and water could be thermally spun into lignin fibers for the production of carbon fiber.[39] Fiber spinning was achieved at a spinning temperature of between 150°C and 250°C without any lignin modification required. Tensile strength of 3–60 MPa was reported for the thermostabilized fiber; however, no information about the properties of the carbon fiber has been reported.

Although both petrochemical polymers and lignin were successfully used as carbon fiber precursors with good carbon fiber properties, these materials were gradually abandoned as the high-performance aerospace market, which relied increasingly on PAN and pitch, came to dominate carbon fiber production. Today however, carbon fibers are routinely being used in marine products, construction, the transportation industry, and the like. Cost, not performance, is now the driving force in their utilization. Thus, any technology that can produce a low cost fiber precursor, suitable for carbon fiber, will have a great impact on these markets. As discussed, recycled petrochemical polymers and industrially produced lignins can be used to produce carbon fibers. However, in each system discussed here, problems concerning production costs exist. Either plasticization or lignin modification was required, or noncommercially produced lignins (e.g., steam-exploded, acetic acid) were used. Therefore, to overcome this we set out to utilize an industrially produced technical lignin for the production of carbon fibers with properties suitable for the general purpose carbon fiber market.

Recently, we reported the first carbon fibers produced from an industrially produced kraft lignin, without any chemical modification. The process involved thermal spinning followed by carbonization. A fusible lignin with excellent spinnability to form a fine filament was produced with a thermal pretreatment under vacuum. Blending the lignin with PEO further facilitated fiber spinning, but at PEO levels greater than 5–10%, the blends could not be stabilized without the individual fibers fusing together. Carbon fibers produced had an overall yield of 45%. The tensile strength and modulus increased with decreasing fiber

diameter and are comparable to those of much smaller diameter carbon fibers produced from phenolated-exploded lignins. In view of the mechanical properties, tensile strength 400–550 MPa and modulus 30–60 GPa, kraft lignin should be further investigated as a precursor for general grade carbon fibers.

Lignin is a renewable, nontoxic, commercially available, and low cost natural resource. Lignin has enormous potential as a raw material for the polymer and composites industries. In spite of many years of development effort, the full potential of lignin has not been fully utilized. One area of potential utilization is in polyblend fibers for composite applications. In our previous lignin/synthetic polymer blend carbon fiber studies, pure PEO has been used to improve spinning ability. More recently, we have developed the lignin-based carbon fibers using recyclable plastics, such as PET and PP. In this entry, we introduce the preparation method, processability, and properties of these hardwood kraft lignin (HKL)/recyclable plastics-based carbon fibers.

THERMAL AND CHEMICAL PROPERTIES OF LIGNIN

Lignin is a natural polymer found in wood. Lignin is readily available and relatively inexpensive. Lignin structure is dependent on wood species and processing conditions used to isolate it. Lignin does not have a well-ordered structure like most of the other natural and synthetic polymers. It is a polyaromatic polyol made up of phenyl propane monomer units linked by carbon–carbon and ether linkages. The monomer units can be classified into three different types: guaiacyl, syringyl, and 4-hydroxyl-phenyl propane structures (Fig. 1). These monomer units undergo random polymerization during the lignification process. The macromolecular structure of lignin, type and ratio of typical interlinkages of the monomer units differ between genera, tissues, and even cell wall layers within the same plant.

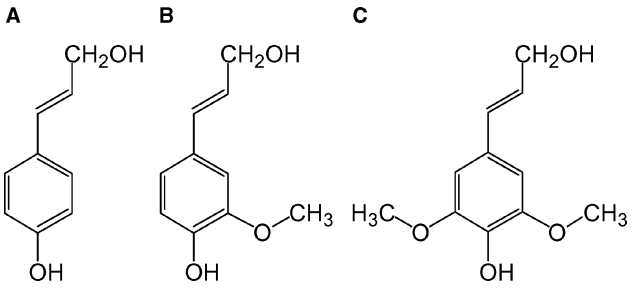

Fig. 1 Precursors of lignin biosynthesis. (A) *p*-Coumaryl alcohol (4-hydroxyl-phenyl propane); (B) coniferyl alcohol (guaiacyl); and (C) sinapyl alcohol (syringyl).

Currently, there is no method to isolate native lignin from plants in its native form. Chemical and physical modifications are unavoidable during the lignin isolation process. Commercial lignins, such as those isolated from alkaline, acidic, or organic solvent-based processes, have undergone extensive fragmentation and degradation. As a result, a wide variety of lignins, in terms of chemical properties and structures, can be obtained. Specifically, depending on the type and length of chemical processing, the lignins will vary in molecular weight, functional groups present, degree of condensation, types of inter-monomeric linkages, and types and ratios of monomeric units. However, the chemical structure of lignin is typically drawn as a statistical representation of the fundamental interunit linkages (Fig. 2).

There are several reports in the literature describing the effect of chemical structure on the observed thermal properties of lignin.[1,3,40–42] In the thermal processing of lignin for structural applications, the relationship between chemical structure and thermal properties is of extreme importance. Differential scanning calorimetric (DSC) analysis of HKL and SKL is shown in Fig. 3. The glass transition temperature (T_g) of the HKL appears at 93°C, much lower than that of the SKL, 119°C.

The observed difference in thermal transition temperatures between the softwood and hardwood lignins can be explained based on differences in the chemical structure between the two lignins. Hardwood lignins are made up of both guaiacyl (G) and syringyl (S) structures, whereas softwood lignins are primarily composed of guaiacyl units (Fig. 2). As a result, softwood lignins contain more condensed interunit linkages, such as 5-5′ and β-5. These ''cross-links'' or ''branch-points'' produce a more complex network-like structure, and hinder the rotational and translational motions within the lignin macromolecule increasing the T_g. Although a minor component of native lignins, accounting for approximately 20% and 10% of the interunit linkages in softwood and hardwood lignins, respectively, these condensed units are less reactive toward chemical processing. Thus, the relative amount of these condensed linkages increases, becoming more significant in residual and technical lignins.[43] In addition, processing conditions can also affect the functional groups and molecular weight of the respective lignins.[44]

To better understand the differences in thermal properties between the various lignins, further structural investigations were performed using nuclear magnetic resonance (NMR) spectroscopy. Fig. 4 shows the oxygenated aliphatic region of the HMQC NMR spectra for an HKL and an SKL. Included in the spectra are the assignments for the pinoresinol (β-β), phenylcoumaran (β-5), and β-*O*-4 structure along with α- and γ-hydroxyl group assignments. As can be clearly seen, β-*O*-4 structures survive chemical processing and remain in the industrial lignins. Further, qualitatively

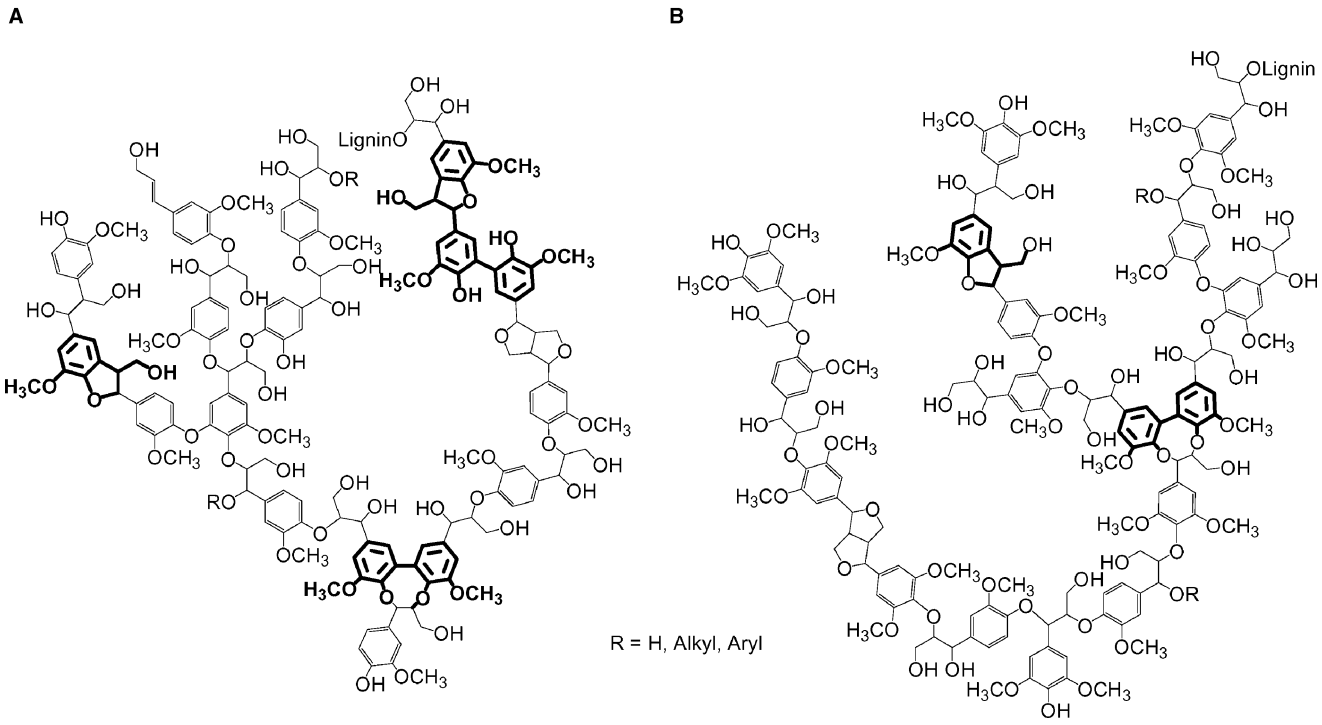

Fig. 2 Structural representation of softwood (A) and hardwood (B) lignin.

the two lignins contain many of the same interunit linkages and appear structurally quite similar. Therefore to better understand the differences in thermal behavior between the HKL and the SKL, other detailed chemical analyses were performed and the results are summarized in Table 1.

POLYMER BLENDING AND FIBER SPINNING

Generally, in thermoforming and/or molding of polymer blends, the processibility relates to the mixing property, e.g., miscibility. To determine miscibility of polymer blends thermal analysis, DSC in particular is widely used. In DSC, a single compositional-dependent glass transition temperature (T_g) is an indication of full miscibility at a dimensional scale between 5 and 15 nm.[45] Recently, we have investigated various lignin/synthetic polymer blends, including poly(ethylene) (PE), PET, PEO, and PVA.[8,9,46,47] Most polymer blends are immiscible due to the low entropy of mixing. In fact most of the lignin polymer blend systems we have studied are immiscible. However, we have found that lignin forms miscible blends with PEO and PET. DSC curves of HKL/PEO and HKL/PET are shown in Fig. 5. Only one T_g is observed in these blends appearing between the T_g values of the individual blend components. Further, a decrease in the melting temperature of the synthetic polymer component is also observed. The DSC results confirm the formation of miscible blends in the amorphous phase. By contrast, two T_gs are observed for HKL/PP blend fibers, as was the melting peak of the PP fraction in all blend fibers (Fig. 5B).

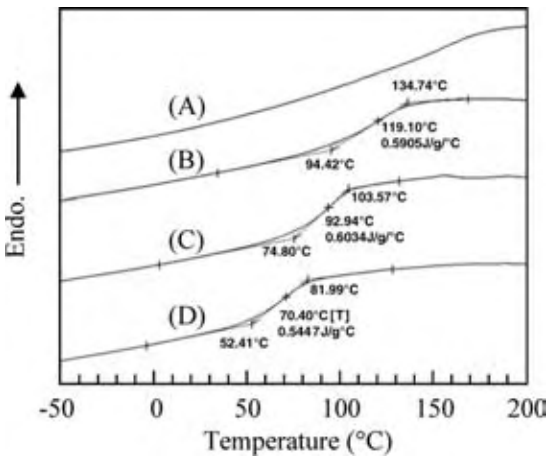

Fig. 3 DSC curves of isolated lignin. (A) Sodium lignosulfonate; (B) SKL; (C) HKL; and (D) organosolv lignin.

In all these systems, the lignin was prepared according to our thermal extrusion method for carbon fiber applications. It is known that lignin has unique thermal properties, wherein during typically thermal processing it undergoes polycondensation reactions. Although classified as a thermoplastic material, exposure to excess thermal energy can transform lignin into a thermosetting material. In our method, fine HKL fibers

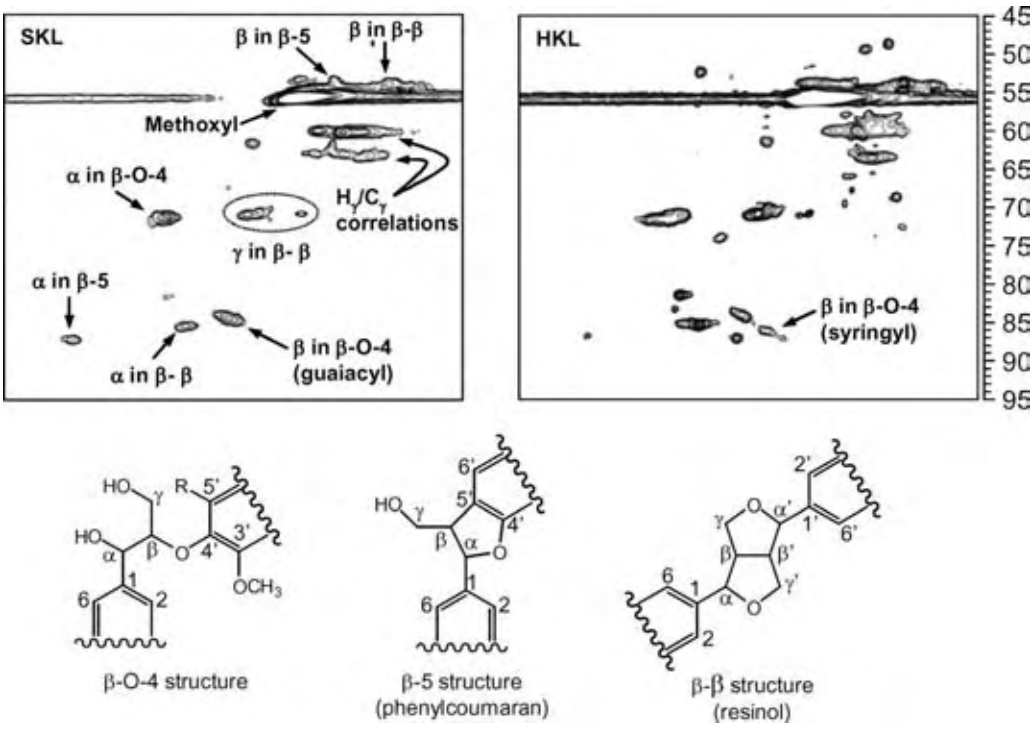

Fig. 4 Oxygenated aliphatic region of the HMQC NMR spectra of SKL and HKL.

can be spun by thermal extrusion without significant chemical modification. However, careful temperature control is required for successful fiber spinning. The thermal fiber spinning of lignin is improved through polymer blending. Our initial studies focused on using PEO kraft lignin blends. As discussed earlier, kraft lignin forms miscible blends with PEO. The blending with PEO dramatically improved the fiber spinning of the lignin-based fibers. However, incorporation of high levels of PEO had a negative impact on the subsequent carbon fibers. Due to the low glass transition temperature of PEO, during the thermostabilization process (discussed later), the lignin/PEO fibers fused together as a result of the heat treatment. Therefore, PEO levels of less than 5–10 wt% were necessary to maintain fiber integrity.

The thermal blending and the fiber spinning properties of HKL/synthetic polymer blends are not only affected by the T_g of the blending polymer, but also by the specific interactions formed between the blend components. As described earlier, PET is believed to form miscible blends with HKL. HKL/PET fibers can be prepared by thermal extrusion.[46] However, the thermal fiber spinning of HKL/PET blends is problematic. The thermal viscosity dramatically decreases at the spinning temperature, reducing the processibility of the HKL/PET blends. Such thermal viscosity behavior is not observed for either homopolymer. This suggests that specific interactions form between blend components during the spinning process. This is currently being further investigated.

By contrast, other polymers such as polyolefins and PVA form immiscible blends with HKL. In fact, phase separation is observed in fibers produced from the thermal spinning of HKL and PP. The fiber spinning properties of several PP samples having various melt viscosities and tacticities were examined. Most of the HKL/PP blends show poor or bad fiber spinnability. However, excellent fiber spinning was achieved with PP samples having a thermal viscosity comparable to the HKL.

Table 1 Chemical properties of SKL and HKL

	Functional groups (mmol g^{-1})					
	Hydroxyl groups				Molecular mass	
Lignin	Aliphatic	Phenolic	Methoxyl	S G^{-1}	M_w	Dispersity
SKL	5.6	3.8	4.2		2,800	2.0
HKL	4.1	4.3	5.9	1.2	2,400	1.8

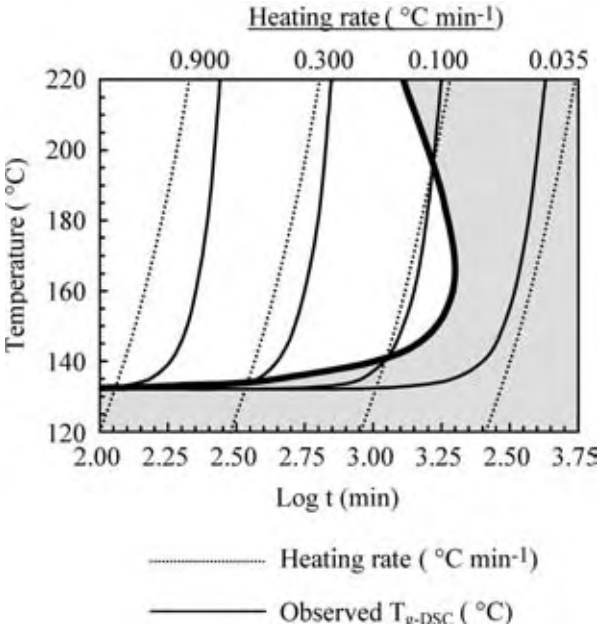

Fig. 7 CHT diagram for lignin oxidation.

FIBER MORPHOLOGY

Lignin/synthetic polymer blend fibers have varying surface morphology depending on the miscibility of blend components. Fig. 6 shows scanning electron microgram (SEM) images of HKL and HKL/PP blend fibers. The HKL fibers have a relatively smooth surface with the appearance of some large voids in the cross section. During thermal processing, some thermal decomposition may occur. These pores may be the result of entrained decomposed gases. However, specific fine pores are not observed on the fiber surface. The miscible lignin/synthetic polymer blend fibers also have smooth surfaces, although a fine regular pattern is observation under high magnification (160,000X).

By contrast, the immiscible lignin/PP blend fibers form unique core/shell structure due to the difference in molten viscosity between HKL and PP.[48,49] The PP component is located in the core of the fiber. Depending on the amount of PP incorporated, various morphologies are observed. In high HKL content blend fibers, the PP appears as nanoscale fibers bundled within the lignin shell. As the PP content is increased, the PP nanoscale fibers merge forming ribbonlike structures within the core (HKL/PP = 50/50 blend fiber).

THERMOSTABILIZATION PROPERTIES OF LIGNIN AND LIGNIN/SYNTHETIC POLYMER BLENDS

To convert the fibers produced from thermal spinning into carbon fibers, a thermostabilization stage is necessary to prevent fiber fusing. In the case of petroleum pitch, infused oxygen bridging and cross-linking mainly in the alkyl components is introduced by thermal oxidation during this process. However, in the case of lignin, the alkyl components are already partially oxidized (Fig. 2). Therefore, thermostabilization will also involve polycondensation and dehydration in addition to some oxidation of the lignin macromolecule. As a result, increases in molecular weight and in T_g will occur. As lignin contains various functional groups with the potential to undergo thermally induced chemical reactions during heating, it has been speculated that a thermostabilization step may not be necessary in the manufacturing process of lignin-based carbon fibers. However, our results indicate that these reactions do not produce a sufficient increase in the T_g to prevent softening during carbonization.

Ideally, the heating rate during thermostabilization must be slow enough to allow the T_g to increase faster than the thermostabilization temperature. To predict the behavior of lignin and its polymer blends during thermostabilization, we studied the effect of heating rate on changes in the thermal properties of lignin. A continuous heating transformation (CHT) diagram,

Table 2 Thermostabilization properties of HKL and HKL/synthetic polymer (75/25 w/w) fibers under air atmosphere

Fiber	Heating rate ($^\circ C\,hr^{-1}$)					
	12	30	60	120	180	300

which is similar to the ones used by Wisanrakkit and Gillham,[50] was constructed from the DSC analysis using various heat treated lignin under different heating rate. The lignin CHT diagram is shown in Fig. 7.

The CHT diagram is a phase diagram consisting of plots of reaction temperature and T_g vs. time for various constant heating rates. The dotted lines show the temperature of each heating rate in time. The solid black lines are the T_g contours. The bold curve represents the points for which reaction temperature equals the T_g. The region to the left of the bold curve represents conditions that lead to softening of the sample. In order to avoid softening, the sample must be heated at a rate that falls outside of this region (gray area).

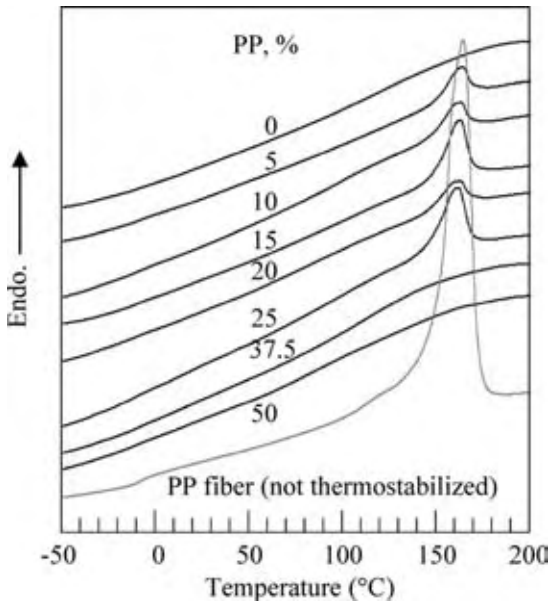

Fig. 9 DSC curves of thermostabilized HKL and all PP/HKL blend fibers.

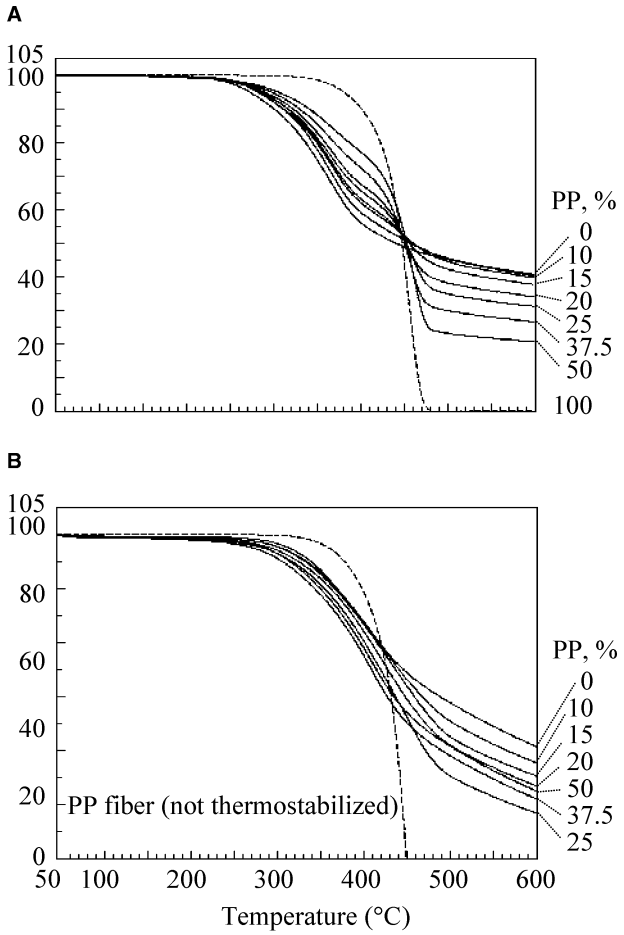

Fig. 10 TGA curves of thermostabilized HKL and all PP/HKL blend fibers. (A) HKL/PP blend fibers and (B) HKL/PP thermostabilized fibers.

As seen in Fig. 7, the fastest allowable heating rate for ground lignin is about $0.06^{\circ}C\,min^{-1}$. In the case of lignin fibers, diffusion becomes an issue in terms of overall conversion and T_g. Lignin fibers can be thermostabilized at a heating rate of $0.2^{\circ}C\,min^{-1}$ (Table 2), substantially higher than that required to maintain an increase in T_g. Not surprisingly T_g is not the only factor affecting fiber integrity. Other thermal properties, such as viscosity, will be very important. However, this result shows that thermostabilization is an essential process in lignin carbon fiber production.

The thermostabilization properties of the various lignin/synthetic polymers are included in Table 2. It can be seen that polymer blending with PET and PP affects the thermostabilization process differently. Significantly higher heating rates can be used in the thermostabilization of lignin/PET blend fibers than for lignin or lignin/PP fibers. (Both PET and PP homofibers cannot be thermostabilized.) This is attributed to the physical properties of the respective polymers. The melting temperature of PET (ca. 270°C) is

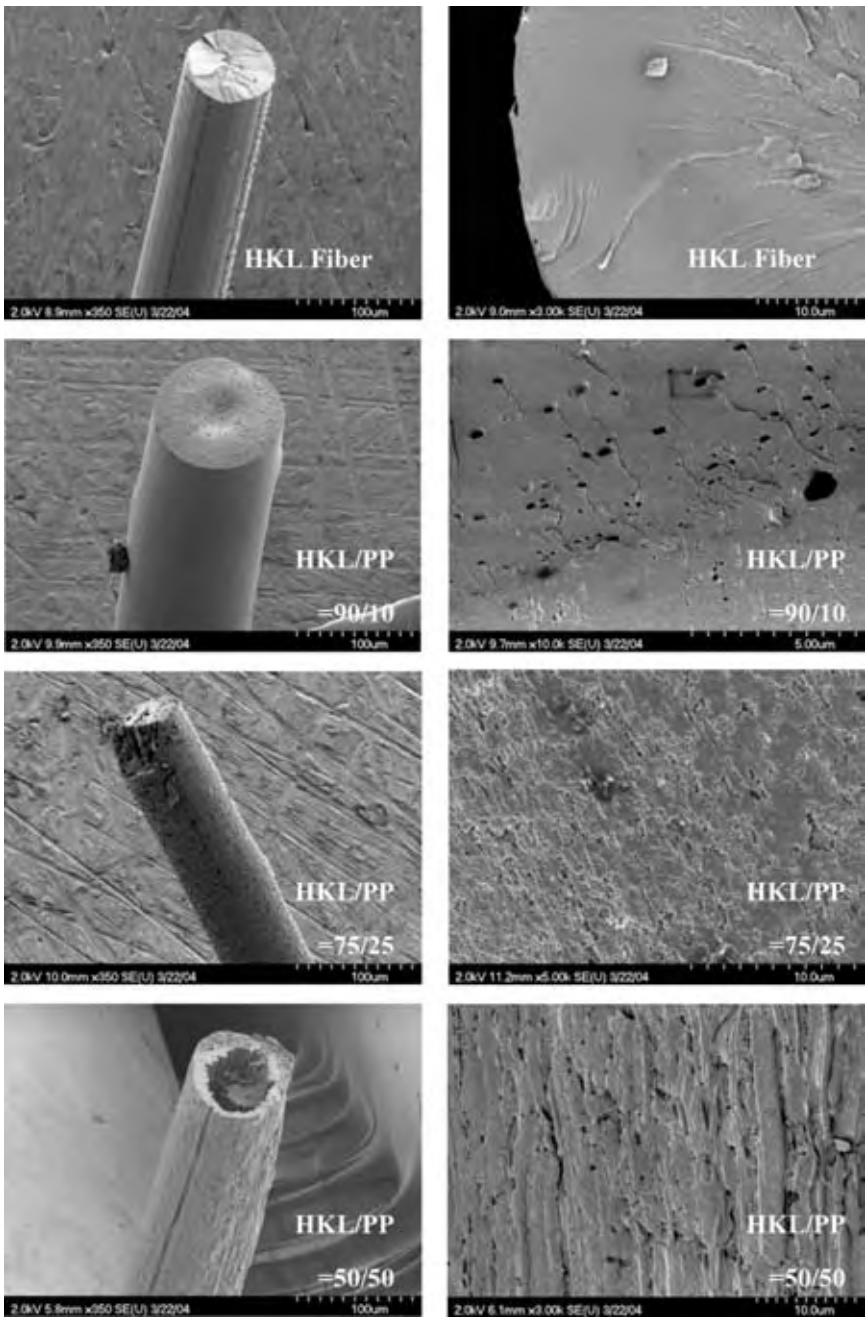

Fig. 11 SEM images of thermostabilized HKL and HKL/PP blend fibers.

higher than the softening point of lignin, even though the glass transition temperatures of both polymers are almost the same. Although the melting temperature of PET was decreased upon blending with lignin, it is still higher than the oxidation temperature. Moreover, the fiber spinning temperature of the HKL/PET blends is much higher than that of HKL. As discussed earlier, the higher spinning temperature is indicative of the higher thermal viscosity of the polyblend, the result of specific interactions between the components. By contrast, the HKL/PP blends show almost the same thermostabilization properties as the HKL fiber. The T_g and melting temperature of PP are lower than that of the HKL. Further, the fiber spinning temperature for PP is approximately the same as that of HKL. This, combined with the fact that the blends are immiscible and do not exhibit any specific interactions, makes it difficult to increase the heating rate of thermostabilization beyond that of the HKL fibers.

Polymer blending also affects the dimensional stability of the HKL-based fibers during the thermostabilization process. The HKL homofibers undergo more than 20% shrinkage during thermostabilization. This fiber deformation affects the utility and the

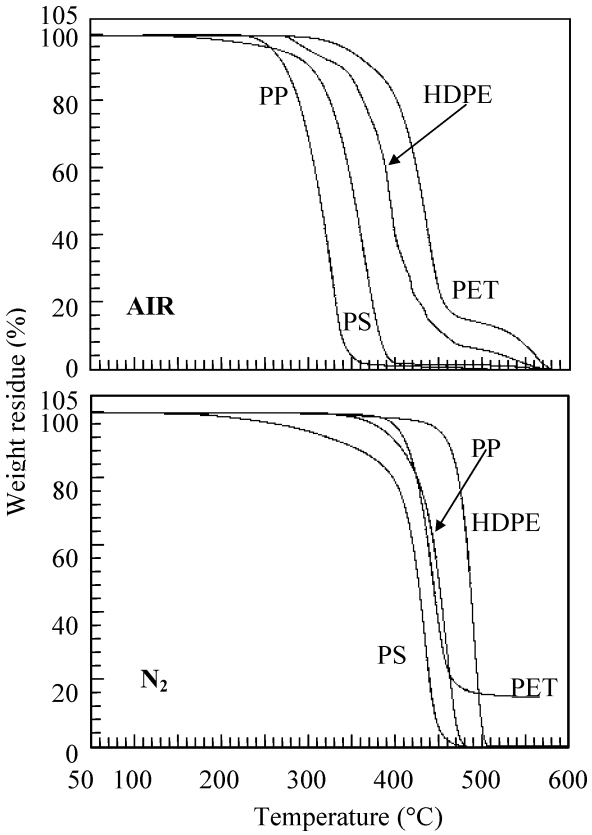

Fig. 12 TGA curves of various recyclable plastic measured under nitrogen and air conditions.

processibility of lignin for carbon fiber production; fiber shrinkage can destroy the fiber integrity. However, the dimensional stability of the lignin fibers can be improved through polymer blending with PET and PP. Fig. 8 shows the effect of blend components on fiber shrinkage. Increasing incorporation of both PP and, especially, PET effectively improves fiber stability, with fiber shrinkage decreasing with increasing polymer blending.

MORPHOLOGICAL CHANGES OF HKL/PP BLEND FIBERS IN THE THERMOSTABILIZATION PROCESS

Of the various lignin-based fibers, the HKL/PP fibers displayed the most dramatic change in morphology. DSC curves of the thermostabilized HKL and various PP/HKL blend fibers are shown in Fig. 9. The T_g of HKL was not observed, indicating consistent thermostabilization of the various fibers under these conditions. The melting peak of the PP fractions was also observed with the exception of HKL/PP = 50/50 and 62.5/37.5 blends, even though the original PP content of these fibers is higher than the other blend fibers. This suggests that there are no crystalline PP structures in these HKL/PP blend fibers. However, the T_g of the amorphous fraction of the PP component was also not observed. Thermogravimetric analysis (TGA) of the thermostabilized HKL/PP blends is shown in Fig. 10B. The TGA profile is different from the original HKL/PP blend fiber (Fig. 10A). The residual weight at 600°C for the thermostabilized HKL/PP = 50/50 and 62.5/37.5 blends is higher than that of the HKL/PP = 75/25 fiber. It appears that in the 25 wt% PP fibers sufficient lignin is lost in conjunction with the PP during thermal treatment. This is not the case in the fibers with high PP content, 50 wt%, and to a lesser extent, 37.5 wt%. It is likely that in the 25 wt% PP fibers, a sufficient amount of lignin is entrapped within the PP phase, which with increasing PP incorporation decreases due to an increase in the PP domain size. Further support of this can be seen from microscopy analysis of the fibers.

Table 3 Yields of HKL/synthetic polymer blend carbon fibers in each step of carbon fiber production

Precursor	Production step			
	HT	Thermostabilization	Carbonization	Overall
HKL 100%	99.0	94.4	51.6	34.3
HKL/PP				
95/5	99.1[a]	95.4	53.2	47.7[b]
87.5/12.5	99.1[a]	94.3	50.5	44.8[b]
75/25	99.3[a]	92.7	43.0	37.6[b]
50/50	99.5[a]	80.6	35.0	26.6[b]
HKL/PET				
95/5	99.1[a]	94.4	51.6	45.8[b]
87.5/12.5	99.1[a]	93.0	48.7	42.7[b]
75/25	99.3[a]	92.5	44.1	38.4[b]
Tar-pitch	40.0	110	80	33.4

[a]Calculated from yield for 100% HKL fiber.
[b]Yield of spinning process for blend sample is assumed to be 95%.

Scanning electron micrograms of the thermostabilized fibers are shown in Fig. 11. In contrast to the precursor fibers, there are small pores observed on the surface of the HKL thermostabilized fibers, but not in the cross section. By contrast, the thermostabilized blend fibers have pores of various sizes throughout the fiber. The thermostabilized HKL/PP = 75/25 fiber has fine pores on both the surface and the cross section. Interestingly, the thermostabilization of HKL/PP = 50/50 fibers has a porous surface, hollow core morphology. Comparison to the lignin fibers reveals that the pores are created during low temperature thermal processing. TGA analysis of various recyclable plastics measured under nitrogen and air atmospheres is shown in Fig. 12. The weight loss of PP in air is much faster than that under a nitrogen atmosphere. Thus, the pores observed in the HKL/PP thermostabilized fiber are the result of the oxidative degradation of the PP component during heat treatment in air.

CARBONIZATION

In addition to physical properties, an important aspect in carbon fiber production is yield. Higher weight losses or lower yield result in higher production costs. The carbon content of lignin is lower than that in petroleum and coal tar pitch. However, the total production yield of our HKL-based carbon fiber is higher (Table 3). In the case of pitch-based materials, several treatments, such as thermal pretreatments for polycondensation reactions and hydrogenation, are performed to convert the pitch-based material into suitable materials for fiber spinning. As a result of these processing steps, a critical loss in mass occurs. Due to its structure, lignin requires only a simple thermal treatment prior to the spinning process. The accompanying weight loss is very low ~1%. Unlike pitch, a small loss in yield is observed during the thermostabilization (ca. 3–7%) of lignin fibers. As lignin has a highly oxidized/functionalized structure, as described earlier, a net loss in weight/yield is observed during thermostabilization. In pitch, due to the unoxidized structure, a weight/yield increase occurs because of the introduction of oxidized functional groups into the pitch molecules. The majority of weight loss in lignin-based fibers occurs during the carbonization step. This weight loss is substantially higher than that observed for pitch (20%) due to the lower carbon content of lignin (~60%). However, the yields obtained from our kraft lignin-based carbon fibers are approximately 10% higher than those previously reported for the carbonization of organosolv lignins and comparable to those from phenolated steam-exploded lignins. The blending of PP and PET, due to the pyrolyzable properties of

Table 4 Typical mechanical properties of HKL and HKL/recyclable plastic carbon fiber

Precursor fiber	Tensile strength (MPa)	Young's modulus (GPa)
HKL	605	61
HKL/PP		
95/5	332	57
87.5/12.5	437	54
75/25	155	29
50/50	167	28
HKL/PET		
95/5	669	84
87.5/12.5	682	84

Activated carbon fiber (pitch)	100–250	—

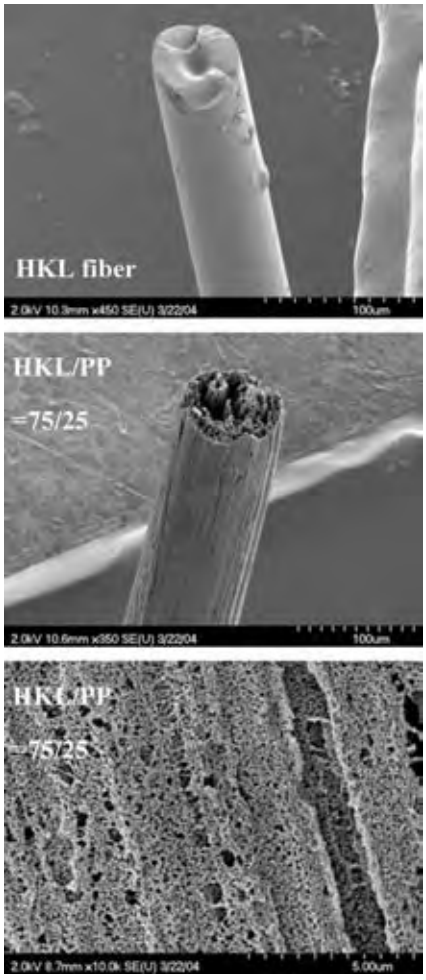

Fig. 13 SEM images of HKL and HKL/PP blend carbon fibers.

these polymers, decreased carbon fiber yield relative to lignin alone.

The mechanical properties of the carbon fibers are listed in Table 4. Tensile strength of the HKL/PET-based carbon fibers increased with PET content up to a maximum at 25% PET. Increasing the PET content beyond 25% leads to a decrease in mechanical properties, which is likely the result of off gases generated due to the pyrolysis of the PET component. The tensile strength and the Young's modulus of the HKL/PET = 75/25 carbon fibers are comparable and three times greater, respectively, than that of GP grade pitch-based carbon fibers. By contrast, the mechanical properties of the HKL/PP blend carbon fibers decreased with increasing PP content. As expected, various sized pores are observed on the carbon fiber surfaces, with pore size increasing with PP content.

Scanning electron micrograms of the HKL/PP carbon fibers are shown in Fig. 13. The pores observed on the HKL thermostabilized fiber decrease in size and/or disappear after carbonization. This indicates that a reorganization of the lignin molecules occurs during the carbonization process. The HKL/PP carbon fibers also show some differences as compared to the thermostabilized fibers. There are a lot of fine pores observed on the fiber surface and cross sections as compared to the corresponding thermostabilization fiber. From the DSC (Fig. 9) and TGA (Fig. 10) analysis of the thermostabilized HKL/PP fibers, it was observed that some PP component remains in the fiber after the oxidation process. Therefore, the small pores in the HKL/PP blend carbon fibers are likely due to the pyrolysis of the residual PP from the carbonized lignin framework. All of the various thermal treatments, pretreatment, thermostabilization, and carbonization, produce pores in the HKL/PP blend fibers. However, the mechanism(s) of pore growth are different between these processes. Pores are created by the oxidative degradation of PP during the thermostabilization process, while the gasification of pyrolyzable PP is the main factor for pore growths under carbonization.

INTRODUCTION

Carbon nanotubes (CNTs) are tubular sp^2-like carbon molecules with nanoscale dimensions that exhibit fascinating physicochemical properties that make them potentially useful in the fabrication of novel nanotechnology devices. Carbon nanotubes consist of rolled graphene (a hexagonal sp^2 carbon layer) cylinders of nanometer size in diameter; they could be either single- or multiwalled (nested cylinders).[1–3] The diameters of such tubules could be in the Fullerene size range (around 1 nm), and the minimum diameter that has been observed is 0.4 nm.[4,5] Multiwalled carbon nanotubes (MWNTs) are strongly related to three-dimensional graphite or turbostratic hexagonal carbon (see Fig. 1). The nanotube curvature introduces some sp^3-like bonding into the sp^2 planar bonding of the graphene sheet. Unusual properties of CNTs arise from the curved sp^2 graphene layers by imposing additional quantum confinement and topological constraints in the circumferential direction of the cylinders. In the following sections, their structure, growth, and applications of CNTs are presented. We will also discuss the synthesis, properties, and applications of another family of tubular carbon, known as vapor-grown carbon fibers (VGCFs).

BONDING NATURE OF CARBON ATOMS

Carbon is the sixth element in the periodic table, and has the lowest atomic number of any of the elements in column IV. Each carbon atom has six electrons, which occupy $1s^2$, $2s^2$, and $2p^2$ atomic orbitals. The $1s^2$ orbital contains two strongly bound core electrons. Four more weakly bound electrons occupy the $2s^22p^2$ valence orbitals. In the crystalline phase, the valence electrons give rise to 2s, $2p_x$, $2p_y$, and $2p_z$ orbitals, which are important in forming covalent bonds within carbon materials. Since the energy difference between the upper 2p energy levels and the lower 2s level in carbon is small compared to the binding energy of the chemical bonds, the electronic wave functions for these four electrons can readily mix with each other, thereby changing the occupation of the 2s and three 2p atomic orbitals, so as to enhance the binding energy of a C atom with its neighboring atoms. The general mixing of 2s and 2p atomic orbitals is called hybridization, whereas the mixing of a single 2s electron with one, two, or three 2p electrons is called sp^n hybridization with $n = 1, 2, 3$, respectively.

Thus, three possible hybridizations could occur in carbon: sp, sp^2, and sp^3, while other group IV elements, such as Si and Ge, exhibit primarily sp^3 hybridization. Carbon differs from Si and Ge because it has no inner atomic orbitals, except for the spherical 1s orbitals, and the absence of nearby inner orbitals facilitates hybridizations involving only valence s and p orbitals for carbon. The various bonding states are connected with certain structural arrangements, so that sp bonding gives rise to a chain structure such as carbynes, sp^2 bonding to planar structures such as graphene, and sp^3 bonding to a tetrahedral structure such as diamond.

A CNT is a graphene sheet appropriately rolled into a cylinder of nanometer size diameter (see Fig. 1).[1–3] The curvature of the nanotubes admixes a small amount of sp^3 bonding so that the force constant (bonding) in the circumferential direction is slightly weaker than along the nanotube axis. Since the single-walled CNT (SWNT) is only one atom thick and has a small number of atoms around its circumference, only a few wave vectors are needed to describe the periodicity of the nanotubes. These constraints lead to quantum confinement of the wavefunctions in the radial and circumferential directions, with plane wave motion occurring only along the nanotube axis, corresponding to a large number of closely spaced allowed wave vectors. Thus, although CNTs are related to a two-dimensional (2D) graphene

sheet, the tube curvature and the quantum confinement in the circumferential direction lead to 1D properties that are different from those of a graphene sheet.

STRUCTURE OF CARBON NANOTUBES

The structure of CNTs has been explored early on by high-resolution transmission electron microscopy (HRTEM) and scanning tunneling microscopy (STM) techniques, yielding direct confirmation that the nanotubes are seamless cylinders derived from the honeycomb lattice representing a single atomic layer of crystalline graphite, called a graphene sheet (Fig. 2A).[1,6–8] The structure of a single-wall CNT is conveniently explained in terms of its 1D unit cell, defined by the vectors $\boldsymbol{C_h}$ and $\boldsymbol{T}$ in Fig. 2A.

The circumference of any CNT is expressed in terms of the chiral vector $\boldsymbol{C}_h = n\boldsymbol{a}_1 + m\boldsymbol{a}_2$, which connects two crystallographically equivalent sites on a 2D graphene sheet (Fig. 2A).[9] The construction in Fig. 2A depends uniquely on the pair of integers (n, m) that specify the chiral vector. Fig. 2A shows the chiral angle θ between the chiral vector $\boldsymbol{C_h}$ and the "zigzag" direction ($\theta = 0$) and the unit vectors $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$ of the hexagonal honeycomb lattice of the graphene sheet. The zigzag and armchair nanotubes, respectively, correspond to chiral angle $\theta = 0$ and 30°, and chiral nanotubes correspond to $0 < \theta < 30°$. The intersection of the vector $\overrightarrow{OB}$ (which is normal to $\boldsymbol{C_h}$) with the first lattice point determines the fundamental 1D translation vector $\boldsymbol{T}$. The unit cell of the 1D lattice is the rectangle defined by the vectors $\boldsymbol{C_h}$ and $\boldsymbol{T}$ (Fig. 2A).

The cylinder connecting the two hemispherical caps of the CNT (Fig. 3) is formed by superimposing the

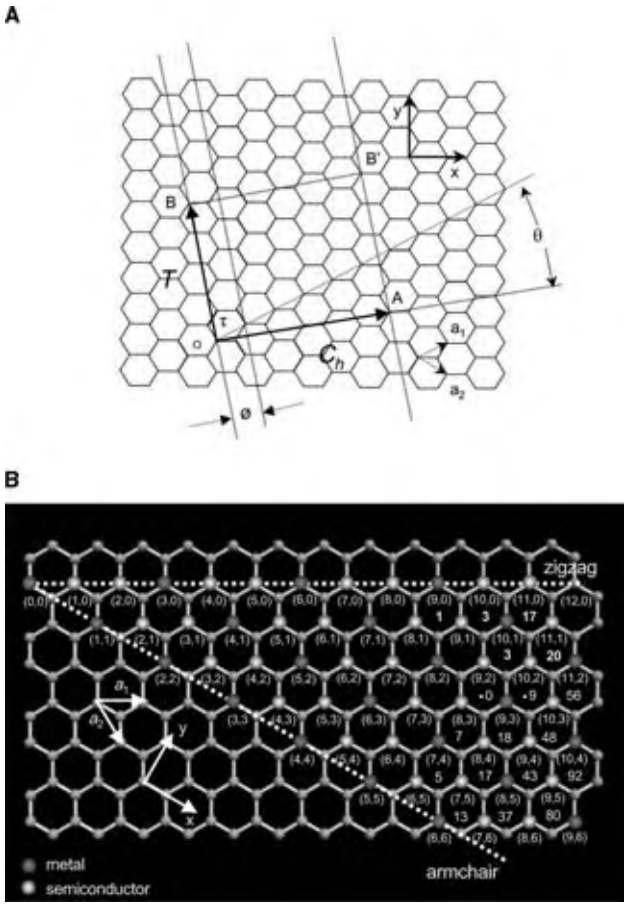

Fig. 2 (A) The chiral vector $\overrightarrow{OA}$ or $\boldsymbol{C_h} = n\mathbf{a}_1 + m\mathbf{a}_2$ is defined on the honeycomb lattice of carbon atoms by unit vectors $\mathbf{a}_1$ and $\mathbf{a}_2$ and the chiral angle θ with respect to the zigzag axis. Along the zigzag axis $\theta = 0°$. Also shown are the lattice vector $\overrightarrow{OB} = \boldsymbol{T}$ of the 1D nanotube unit cell and the rotation angle ψ and the translation τ, which constitute the basic symmetry operation $R = (\psi/\tau)$ for the CNT. The diagram is constructed for $(n, m) = (4, 2)$. (From Ref.[9].) (B) Possible vectors specified by the pairs of integers (n, m) for general CNTs, including zigzag, armchair, and chiral nanotubes. Below each pair of integers (n, m) is listed the number of distinct caps that can be joined continuously to the CNT denoted by (n, m). (From Ref.[9].) The encircled dots denote metallic nanotubes while the small dots are for semiconducting nanotubes. (From Ref.[3].). *(View this art in color at www.dekker.com.)*

two ends of the vector $\overrightarrow{\boldsymbol{C_h}}$ and the cylinder joint is made along the two lines $\overrightarrow{OB}$ and $\overrightarrow{AB'}$ in Fig. 2A. The lines $\overrightarrow{OB}$ and $\overrightarrow{AB'}$ are both perpendicular to the vector $\boldsymbol{C_h}$ at each end of $\boldsymbol{C_h}$.[9] In the (n, m) notation for $\boldsymbol{C_h} = n\mathbf{a}_1 + m\mathbf{a}_2$, the vectors $(n, 0)$ or $(0, m)$ denote zigzag nanotubes and the vectors (n, n) denote armchair nanotubes. All other vectors (n, m) correspond to chiral nanotubes.[10] The nanotube diameter d_t is given by

$$d_t = \sqrt{3}a_{C-C}(m^2 + mn + n^2)^{1/2}/\pi = \boldsymbol{C_h}/\pi \quad (1)$$

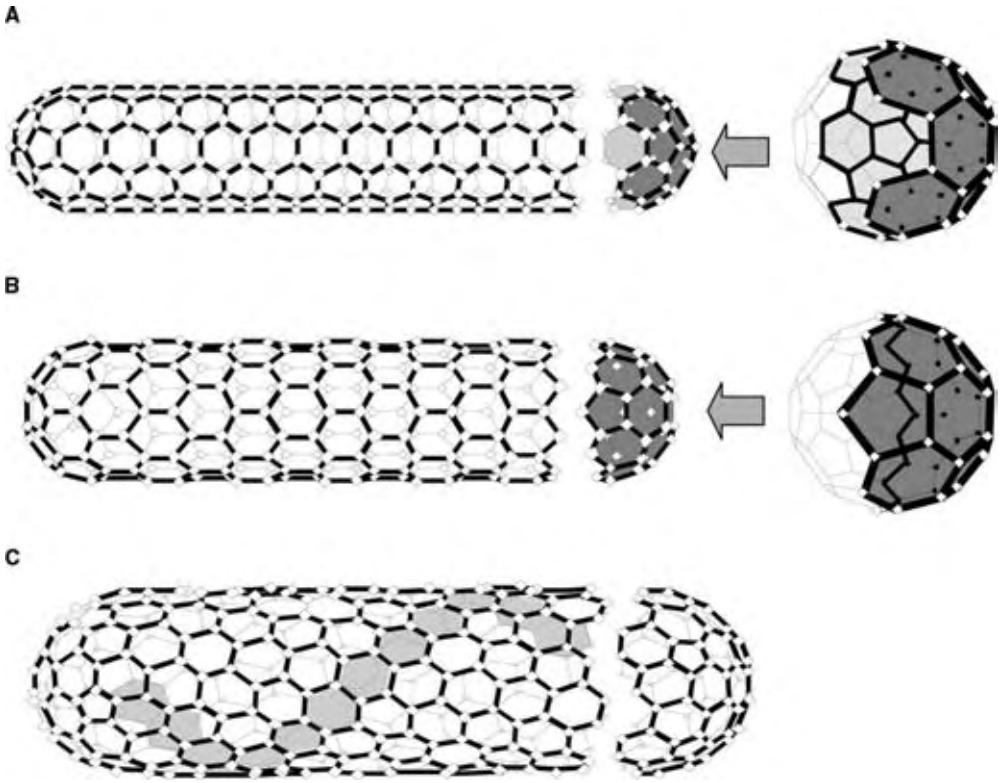

Fig. 3 Schematic model for single-wall CNTs with the nanotube axis normal to the chiral vector, which, in turn, is along (A) the $\theta = 30^\circ$ direction [an "armchair" (n, n) nanotube], (B) the $\theta = 0^\circ$ direction [a "zigzag" $(n, 0)$ nanotube], and (C) a general θ direction, such as $\overrightarrow{OB}$ (see Fig. 2), with $0 < \theta < 30^\circ$ [a "chiral" (n, m) nanotube]. The actual nanotubes shown here correspond to (n, m) values of: (A) (5, 5), (B) (9, 0), and (C) (10, 5). The nanotube axis for the (5, 5) nanotube has fivefold rotation symmetry, while that for the (9, 0) nanotube has threefold rotation symmetry. *(View this art in color at www.dekker.com.)*

where $\boldsymbol{C_h}$ is the length of $\boldsymbol{C_h}$, a_{C-C} is the C–C bond length (1.42 Å). The chiral angle θ is given by

$$\theta = \tan^{-1}\left[\sqrt{3n/(2m + n)}\right] \tag{2}$$

From Eq. (2) it follows that $\theta = 30^\circ$ for the (n, n) armchair nanotube and that the $(n, 0)$ zigzag nanotube would have $\theta = 60^\circ$. From Fig. 2A it follows that if we limit θ to between 0° and 30°, then by symmetry $\theta = 0^\circ$ for a zigzag nanotube. Both armchair and zigzag nanotubes have a mirror plane and thus are considered as chiral. Differences in the nanotube diameter d_t and chiral angle θ give rise to differences in the properties of the various CNTs. The symmetry vector $R = (\psi/\tau)$ of the symmetry group for the nanotubes is indicated in Fig. 2A, where both the translation unit τ (or pitch) and the rotational angle ψ are shown. The number of hexagons, N, per unit cell of a chiral nanotube, specified by integers (n, m), is given by

$$N = 2\left(m^2 + n^2 + nm\right)/d_R \tag{3}$$

where $d_R = d$ if $n - m$ is not a multiple of $3d$ or $d_R = 3d$ if $n - m$ is a multiple of $3d$ and d is defined as the largest common divisor of (n, m). Each hexagon in the honeycomb lattice (Fig. 2A) contains two carbon atoms. The unit cell area of the CNT is N times larger than that for a graphene layer and consequently the unit cell area for the nanotube in reciprocal space is correspondingly $1/N$ times smaller. Fig. 2B indicates the nanotubes that are semiconducting and those that are metallic, and shows the number of distinct fullerene caps that can be used to close the ends of an (n, m) nanotube, such that the fullerene cap satisfies the isolated pentagon rule.

On the other hand, in MWNTs, generally no graphitic 3D AB or ABC stacking is established, even though an individual shell of the multilayers consists of perfect graphene sheets. Also, each individual tubule forming the MWNT has different and independent chirality, which might contribute to a larger intershell spacing (e.g., 0.342 nm) than that found in graphite (e.g., 0.335 nm). Multiwalled carbon nanotubes relate closely to the layer stacking of graphite because the interlayer spacing is found to vary from 3.4 to 3.6 Å between adjacent cylinders, possibly due to glide defects and

tube curvature.[11] Magnetoresistance measurements provide a highly sensitive measure of the degree of 3D crystalline order using the following equation:

$$\Delta\rho/\rho_0 = [\rho(B) - \rho(0)]/\rho(0) \quad (4)$$

where $\rho(B)$ and $\rho(0)$ are the electrical resistivity with and without a magnetic field B, respectively. As shown in Fig. 4, highly oriented pyrolytic graphite with the highest degree of structural 3D perfection shows large positive transverse magnetoresistance, with smaller values of positive $\Delta\rho/\rho_0$ [mesophase-pitch carbon fibers (MPCFs) at 3000 °C] corresponding to more disordered graphite.[12] As more disorder is introduced, the 3D ordering disappears and the materials assume a 2D or turbostratic ordering, where there is no interlayer site correlation between adjacent graphene planes. The magnetoresistance for the turbostratic carbon is characteristically negative, with the magnitude of the negative magnetoresistance decreasing as the disorder increases. For the case of VGCFs heat treated at 2000 °C and MWNTs, the negative magnetoresistance strongly suggests that the stacking of the shells is quite similar to that of turbostratic graphite regarding their electronic properties along the tube axis (see the dotted curve in Fig. 4).[12,13] The curvature of the coaxial layers, however, excludes the possibility of the AB or ABC stacking of the graphene layers, and in this sense, the stacking of layers in an MWNT is equivalent to turbostratic stacking. Also, for small-diameter CNTs, there are a limited number of possible nanotube diameters, and these depend also on the nanotube chirality, so that it is not, in general, possible to find a nested set of nanotubes that all have the same chirality and also show a close packing of cylindrical shells. Thus, the electronic properties of MWNTs have some differences and some similarities when compared with turbostratic carbons. These characteristic structures of single- and multiwalled CNTs indicate that they are unique 1D materials with fascinating electronic and mechanical properties.

CARBON NANOTUBES DERIVED FROM VGCFs

Carbon fibers were developed in the early 1960s, and have provided many breakthroughs to carbon science due to their unique fibrous morphology. Therefore, it is necessary to compare the structure and properties of CNTs with conventional carbon fibers exhibiting diameters around 10 μm. Furthermore, there are also very important materials that can be related to both CNTs and carbon fibers. These are called the VGCFs synthesized directly by the catalytic decomposition of hydrocarbons.[6,14–16] Vapor-grown carbon fibers have diameters ranging from 1 nm to 10 μm, the thinner ones corresponding to CNTs and the thicker ones similar to carbon fibers. It has been reported that the

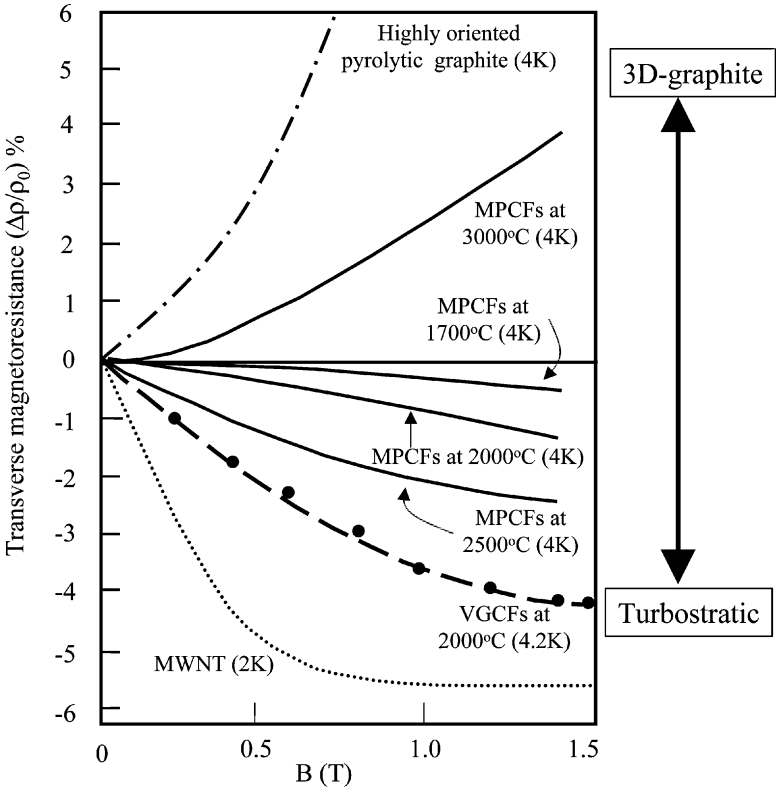

Fig. 4 Comparative study of transverse magnetoresistance at low temperature (as indicated in parentheses) for highly oriented pyrolytic graphite (the dot–dash curve), typical MPCFs heat treated at different temperatures (the solid curves), VGCFs (the dashed curve), and MWNTs (the dotted curve). Vapor-grown carbon fibers exhibit a similar magnetoresistance behavior to that of MWNTs.

central core of a VGCF consists of a CNT.[17] Through precise control of the synthesis conditions, it is possible to produce CNTs and carbon fibers on a large scale. Both materials have been industrialized for different practical applications. Therefore, the structures of CNTs and carbon fibers as well as VGCFs, in which the latter connects both typical materials, are strongly emphasized in this account. Vapor-grown carbon fibers have a very special structure like annular-rings (see Fig. 5A) and are synthesized by a somewhat different formation process than that used to produce polyacryonitrile-based carbon fibers and MPCFs. In particular, VGCFs are not prepared from a fibrous precursor, but rather from hydrocarbon gas, using a catalytic growth process outlined in Fig. 5B.[6,14–17] Ultrafine transition metal particles, such as iron particles with diameter less than 10 nm, are dispersed on a ceramic substrate, and a hydrocarbon, such as benzene diluted with hydrogen gas, is introduced at temperatures of about 1100 °C. Hydrocarbon decomposition takes place on the catalytic particle, leading to a continuous carbon uptake by the catalytic particle and a continuous output by the particle of well-organized tubular filaments of hexagonal sp^2-carbon. The rapid growth rate of several tens of micrometers per minute, which is 10^6 times faster than that observed for the growth of common metal whiskers, allows the production of commercially viable quantities of VGCFs. Evidence in support of this growth model is the presence of catalytic particles at the tips of the resulting VGCFs (Fig. 5C).[18] The primary thin hollow tube is first formed by the catalytic process (with a diameter of less than several nanometers), and the tube is then thickened by a successive CVD (chemical vapor deposition) process, corresponding to the deposition of pyrolytic carbon layers on the primary tubular core (Fig. 5D).

Such a high growth rate of the primary core tube provides the possibility of employing a 3D growth process involving a floating catalyst in a reaction chamber without the presence of a solid substrate (see Fig. 6A). In this process, the nanometer-sized catalytic particles of metal can float (or be suspended) for a specified time in the hot zone of the reaction chamber in order to produce thin (80 nm homogenous diameter) nanotubes of several hundred micrometers in length.[18,19] The resulting nanotubes shown in Fig. 6B consist of straight fibers with high purity, implying that the individual tubes experienced uniform reaction conditions as they passed through the reactor.[19] By proper choice of growth conditions, large quantities of high-purity nanotubes can be obtained continuously. Furthermore,

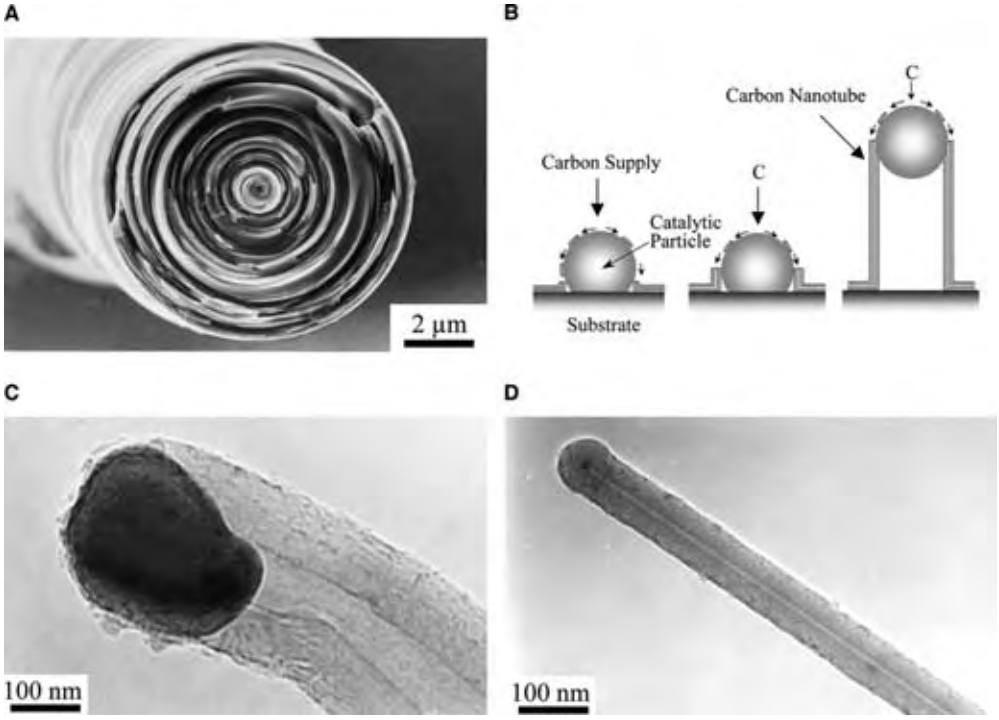

Fig. 5 (A) Scanning electron microscopic image of VGCFs. (From Ref.[19].) (B) Suggested growth mechanism of VGCFs using ultrafine catalytic metal particles. (From Ref.[6].) (C) Very early stage of fiber growth in which the catalytic-particle is still active for promoting elongation growth. The primary fiber thus formed acts as a core for VGCFs. (From Ref.[19].) (D) The fiber is obtained through a thickening process, such as the pyrolytic deposition of carbon layers on the primary thin fibers. (From Ref.[20].) The encapsulated catalytic particle can be seen at the tip of the hollow core. *(View this art in color at www.dekker.com.)*

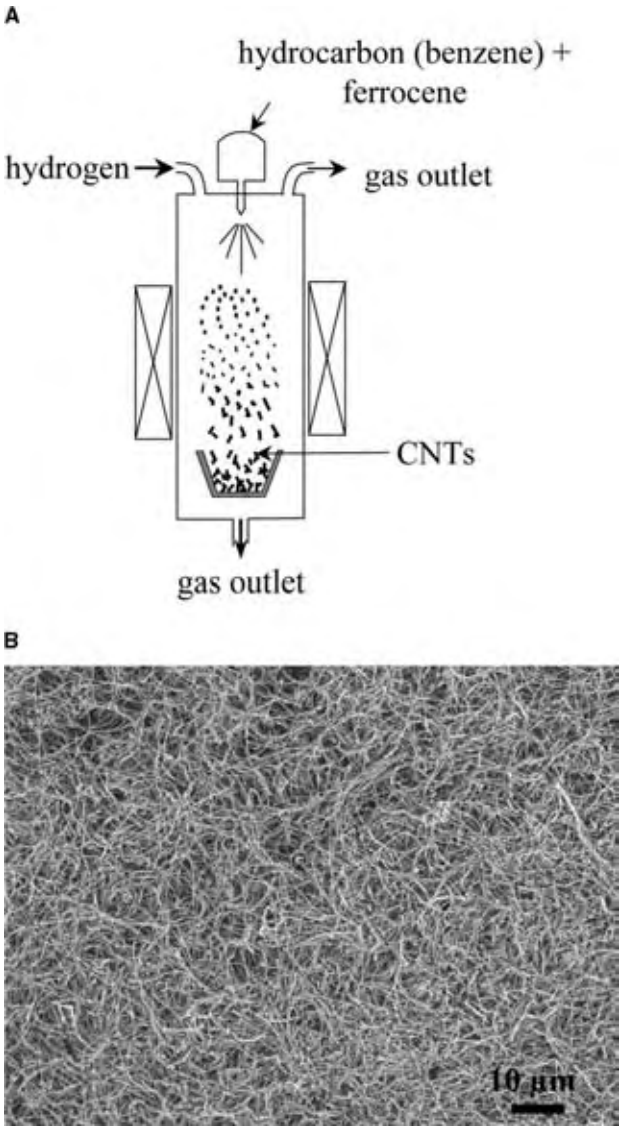

Fig. 6 (A) A vertical-type fiber synthesis system for the floating reactant method in which benzene vapor containing an organic–metallic compound such as ferrocene is introduced into a vertical-type reactor by hydrogen gas. The fibers grow while the catalytic particles are floating in the growth region of the reactor. (B) Vapor-grown carbon fibers, obtained under controlled growth conditions, exhibit relatively homogenous diameter along the fiber length and also high purity. (From Ref.[18].)

the tube diameter can be varied through control of the residence time of the tube in the reaction zone and of the pressure of the hydrocarbon feedstock. This basic process could be used for the large-scale production of CNTs by a CVD process based on the catalytic growth.[16]

In Fig. 7A, we observe the broken edge of a thick VGCF. At the center of the annular ring structure, we can clearly observe an extruded CNT (with a diameter of ~5 nm), which serves as a template for growing the

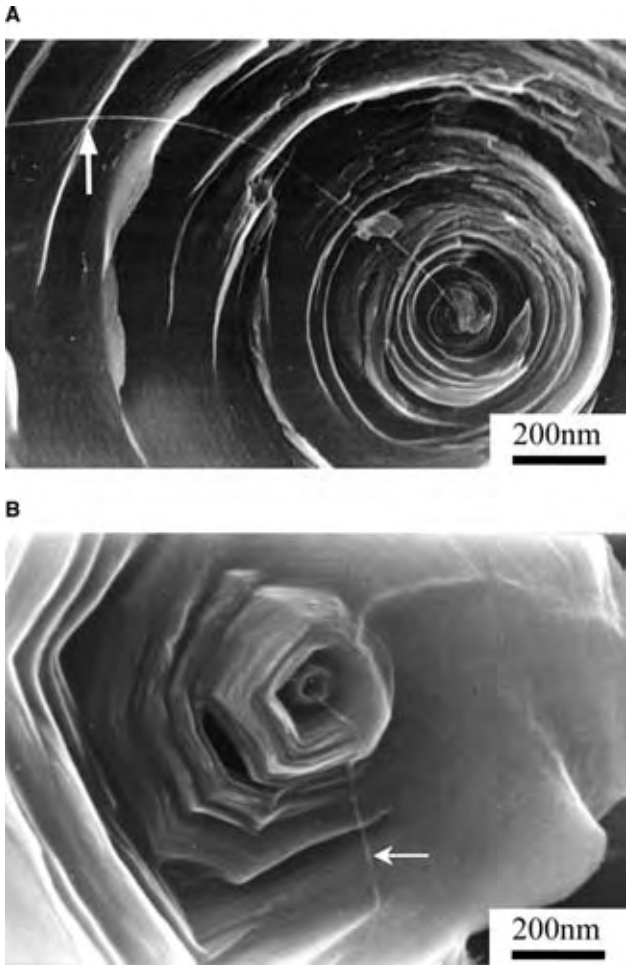

Fig. 7 (A) Carbon nanotube exposed at the breakage edge of a VGCF as (A) grown and (B) heat-treated at 3000 °C. The sample is fractured by pulverization and the core diameter is ~50 Å. (B) These photos suggest a structural discontinuity between the nanotube core of the fiber and the CVD deposited carbon layers. The images show the strong mechanical properties of the nanotube core, which maintains its form after breakage of the periphery. (From Ref.[20].)

thicker carbon fiber.[17] This tubular core implies a discontinuity in the structure between the core and the thickened periphery of the carbon fiber. Such a discontinuity in structure is retained even after heat treatment at temperatures as high as 3000 °C. This graphitization process introduces a fully developed graphite structure in the peripheral region of a VGCF exhibiting a polygonal shape (see Fig. 7B). Fig. 8A shows the early stage of fiber growth of a thin tubule corresponding to an SWNT, which has both a bare region and a region partially coated with pyrolytically deposited carbon.[20] Sometimes it is possible to observe an isolated double-walled carbon nanotube (DWNT) without a pyrolytic carbon coat at the early stage of formation (Fig. 8B) [6] This type of nanotube can be produced by the same process as VGCFs by carefully

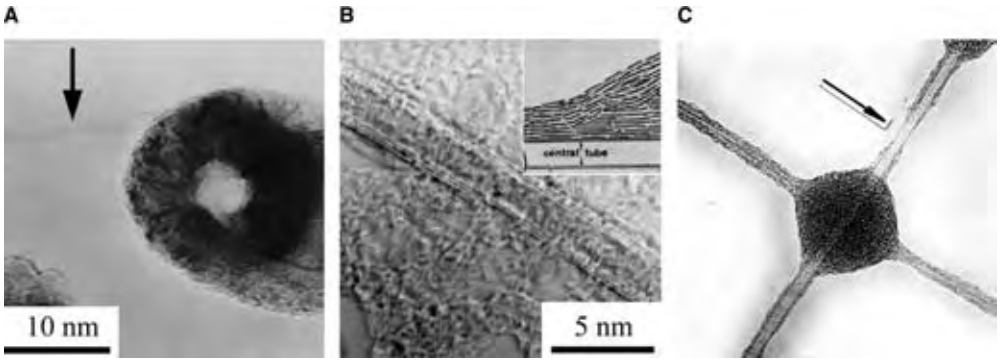

Fig. 8 (A) Coexistence of a VGCF and an SWNT (with a diameter of about 20 nm) obtained by the catalytic decomposition of benzene. (From Ref.[20].) The deposition of a partial carbon layer on a carbon nanotube during the thickening process is observed. (B) Double-walled carbon nanotube (obtained by benzene decomposition) and subsequently heat treated at 2800 °C, yielding the same structure as nanotubes prepared by the arc method. (From Ref.[6].) Insert is a schematic diagram of DWNTs. (From Ref.[6].) (C) High-resolution transmission electron microscope image of two crossing SWNTs coated with amorphous carbons indicates that the structure consists of an individual graphene cylinder in projection. (From Ref.[6].)

controlling the vapor pressure of the hydrocarbon and using a much smaller size of catalytic particle.[6] Fig. 8(C) exhibits an HRTEM image of crossing single-wall carbon nanotube coated with amorphous carbons.To my knowledge, this report in 1976 imaged the first ever observed SWNTs and MWNTs, which were tubular graphite of nanometer scale.[6]

SYNTHESIS OF CARBON NANOTUBES

Up to now, various synthetic methods for producing carbon nanotubes have been reported. Among them, we consider the three main synthetic techniques: 1) arc discharge of graphite electrodes; 2) laser vaporization of graphite–metal targets; and 3) thermolysis of hydrocarbons over metal catalysts. The synthesis of MWNTs via arc discharge involves the passage of a direct current through two high-purity graphite electrodes in a He atmosphere. Under this process, some carbon atoms, which are evaporated from the anode, condense on the cathode (negative electrode) forming a deposit. In addition to MWNTs, SWNTs can be produced using the arc-discharge method if a transition metal catalyst is added in the process. The production of SWNTs using this technique was reported almost simultaneously by two research groups.[21,22] Nowadays, SWNTs can be produced using the carbon arc method in conjunction with different metals such as Gd, Co–Pt, Co–Ru, Co, Ni–Y, Rh–Pt, and Co–Ni–Fe–Ce. For Ni–Y–graphite mixtures, Journet et al. found that high yields (<90%) of SWNTs (average diameter of 1.4 nm) can be produced.[23] This Ni–Y mixture is now used worldwide for production of SWNTs in high yield. The arc method usually involves high-purity graphite electrodes, metal powders, and high-purity He and Ar gases: thus, the costs associated with the production of SWNTs and MWNTs are high. Although the crystallinity of the material is also high, there is no control over the length and diameter of nanotubes. Also, by-products such as polyhedral graphite particles, encapsulated metal particles, and amorphous carbon are also formed.

In 1996, the discovery by the Rice group of a synthetic method involving laser vaporization of a graphite target that leads to high-quality single-wall nanotubes had a great impact on nanotube science.[24] The technique involves the laser evaporation of a target composed of Co–Ni/graphite at 1200 °C. The x-ray diffraction and TEM showed that the bundles (ropes) mainly contained (10, 10) nanotubes (13.8 Å diameter) packed in a crystalline form, and also consist of 100–500 SWNTs packed in a 2D triangular constant lattice of 17 Å. This technique has the advantage of producing high (above 70%) yields of SWNTs, but not economical advantage due to the presence of high-purity graphite rods, high-power lasers, and a relatively low production yield.

Synthesis of CNTs by a catalytic CVD method involves the catalytic deposition of hydrocarbons (e.g., benzene, acetylene, ethylene, etc.) over the surface of metal particles (e.g., Co, Ni, Fe, and Pd on substrate).[6,16] By simultaneously feeding hydrocarbons and catalytic particles in the gas phase into the reaction chamber (microsprayer or evaporation), MWNTs were synthesized on a large scale. On top of that, this type of tube was commercialized as the conductive filler in anode material of lithium-ion secondary battery.[25] Recently, the trend is to synthesize CNTs using a catalytic CVD method because this technique is very promising for the large-scale production of both SWNTs and MWNTs, especially using a floating reactant technique.[16] For SWNTs, the development of high-pressure carbon monoxide (HiPCO) process

(9 kg/day) gave impetus on the scientific study and applications of SWNTs.[26] In terms of the manufacturing process, this process has been shown to be more controllable and cost efficient as compared to either the arc discharge or the laser vaporization methods. Through exact control of synthetic conditions, it is possible to synthesize DWNTs selectively by using this technique. For the fabrication of a CNT transistor, this synthesis technique appears to be highly efficient due to the reproducibility and low cost when compared to other routes.

Recently, DWNTs, which consist of two concentric cylindrical shells, have attracted the attention of numerous scientists because it is believed that these tubes are more thermally and chemically stable and mechanically strong when compared to single-walled carbon nanotubes (SWNTs) (see Figs. 9A and 9C). In addition, as with SWNTs, these double-layered tubes should behave as quantum wires due to its narrow diameters (e.g., <2 nm). Through the right combination of judiciously selected catalyst metals using the seeding method (called a catalytic CVD method), which has been considered as a powerful tool for mass production of nanotubes, and the optimizied purfication method, highly purified DWNTs with a narrow diameter distribution, exhibiting a hexagonally packed array, were obtained as shown in Fig. 9B.[6,16] It is well known that the radial breathing mode frequency is inversely related to tube diameter. For as-grown DWNTs (Fig. 9D), Raman peaks appear above 250 cm^{-1} (corresponding to the inner shells of DWNTs), and below 250 cm^{-1} (usually associated with the outer shells of DWNTs). We envisage this material to be useful in the fabrication of novel sensors, nanocomposites, field emission sources, nanobearings, nanotube bi-cables, and electronic devices.

THE SMALLEST FREESTANDING SWNTs

The demand for small-diameter CNTs is important for taking advantage of the size effect that is predicted to lead to properties different from those of larger nanotubes. The SWNTs were produced by means of a nanozeolite floating reactant method. By combining improved versions of both the floating reactant method

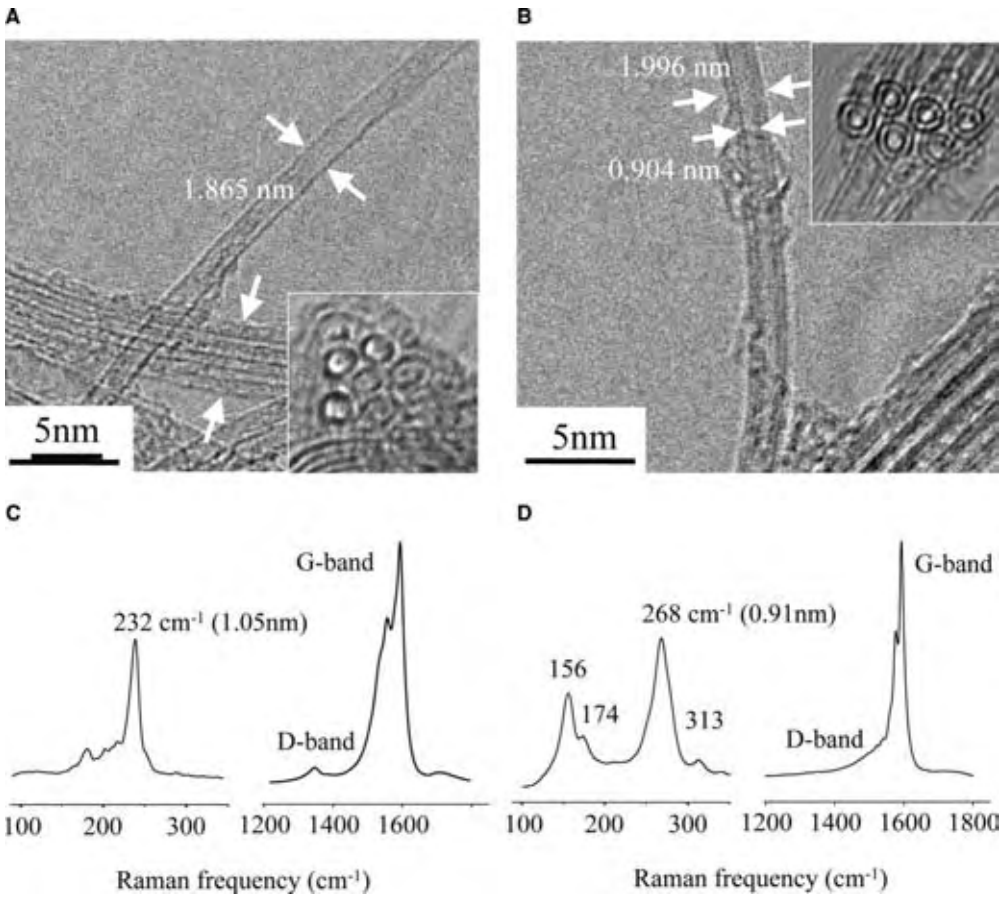

Fig. 9 (A) Typical HRTEM image of SWNT (insert is a cross-sectional TEM image). (B) Typical HRTEM image of DWNTs (insert is a cross-sectional TEM image). (C) Raman spectra of SWNT. (D) Raman spectra of DWNTs. Note that the bent nanotube is passed through the image [see inserts in (A) and (B)].

and the zeolite template method, a very attractive method for the mass production of thin SWNTs was suggested.

Transmission electron microscopic images of these SWNTs are very different from those shown in previous publications because in the latter SWNTs are not embedded on an amorphous film that disturbs the observation, nor is the tube located inside the central core part of an MWNT. Another important point is that the small-diameter SWNTs were produced in an unconfined system unlike those reported previously, using either a zeolite or an MWNT as templates. These distinctions are very important for the advancement of nanotube field and applications because the production of isolated and suspended SWNTs of small diameter is very important. In this context, a small-diameter SWNT (Fig. 10A) was found to be isolated from other bundles and could be clearly observed through the use of an energy filter attached to the transmission electron microscope.[5] The diameter of the tube was measured to be ca. 0.426 nm, which is the smallest-diameter nanotube yet to be produced by the CVD method, and observed as a freestanding (isolated) structure. The tube was unstable under electron beam irradiation during TEM observation in comparison with other thicker SWNTs, and deformed within a minute. From the observed diameter, and also based on the comparison with the observed and simulated TEM images of the SWNT model, we conclude that this particular nanotube can be assigned to the (5, 1) indices with a diameter of ca. 0.436 nm. We could not find the end of this particular tube due to its extreme length and because it was mostly overlapped with either bundles of SWNTs or carbon particles. It is noteworthy that the diameter of this small tube is highly consistent with the diameter of a C_{20} molecule, which could be related to the end of a (5, 1) nanotube (see inset of Fig. 10A, which is capped with six adjacent pentagonal rings). There are two major mechanisms for the catalytic growth of CNTs depending on the location of the catalyst during growth. As shown in Fig. 10(B), one is the tip-growth mechanism whereby the catalyst particle is at the tip of the tube, and the other is the root-growth mechanism, whereby the catalytic particle is placed at the root of the growing tube.

PHYSICOCHEMICAL PROPERTIES OF CARBON NANOTUBES

Exceptional mechanical properties of CNTs are expected due to their strong carbon–carbon bond, if few structural defects are present. The TEM image (Fig. 11A) and a theoretical simulated image (Fig. 11B) demonstrate that CNTs have nearly ideal mechanical properties because nanotubes do not break even after twisting, bending, or flattening. The first report on Young's modulus of isolated MWNTs carried out inside the TEM indicated values of 1–1.8 TPa, which are much higher than those of commercially available carbon fibers (ca. 800 GPa).[27] From the theoretical calculation, Young's modulus of SWNTs, of around 1 nm, is in the

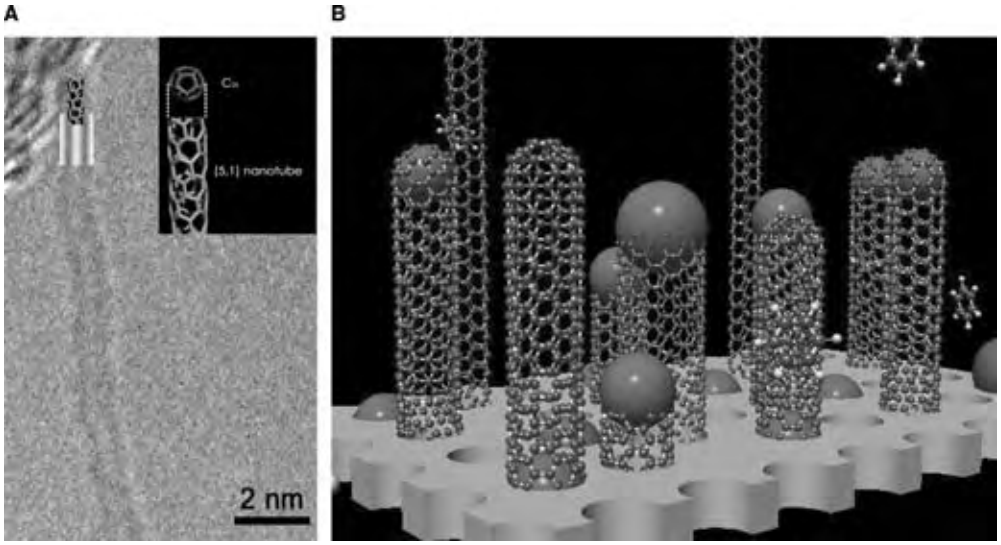

Fig. 10 (A) High-resolution transmission electron microscope image of a small-diameter SWNT. Inserted images are the model of (5, 1) tube and the TEM simulated image, which is in good agreement with the observation. (From Ref.[5].) [Inserted image is simulated model of the cap of a (5, 1) nanotube. The cap consists of six pentagonal rings, just like part of a C_{20} molecule, but slightly deformed.] (B) Schematic image of the tip-growth and root-growth models, in which the catalytic particles (red balls) are located at the tip and at the root, respectively. The blue balls are the carbon atoms and the brown base is the simplified model of a zeolite. (From Ref.[5].) *(View this art in color at www.dekker.com.)*

range of 0.6–0.7 TPa. It is remarkable that the density-normalized modulus and strength of SWNTs are ca. 19 times higher than those of a steel wire.

Transport conductivity measurement on a single MWNT revealed that MWNTs exhibited both metallic and semiconducting behavior (resistivities at 300 K of $\sim 1.2 \times 10^{-4} - 5.1 \times 010^{-6}\,\Omega\,\text{cm}$; activation energies <300 meV for semiconducting tubes).[28,29] This experimental result indicates that the geometric difference (e.g., defects, chirality, diameter, etc.) and degree of crystallinity (hexagonal lattice perfection) strongly affect the electronic structure of MWNTs. In 1997, the first transport measurement on individual SWNTs (1 nm in diameter) demonstrated that SWNTs could behave as quantum wires, in which electrical conduction occurs via well-separated, discrete electron states that are quantum-mechanically coherent over long distances.[30] By utilizing scanning tunneling spectroscopy (STS) on individual SWNTs, it was found that they could be either metallic or semiconductors depending on small variations in the chiral angle or diameter.[31] Carbon nanotubes have the highest thermal conductivity because the phonon contribution dominates at all temperatures. The measured thermal conductivity of individual MWNTs (3000 W/m/K) is higher than that of diamond and that of graphite (ca. 2000 W/m/K).

CNT APPLICATIONS

The potential applications of CNTs due to their small dimension and excellent physicochemical properties make them useful in wide ranges from multifunctional composites, electrochemical electrode, and/or additives, field emitters, to nanosized semiconductor devices. Up to now, commercialized fields of CNTs are the filler in anode materials of lithium-ion secondary battery.[25] The desirable characteristics of MWNTs as composite fillers, especially in the electrodes of Li-ion batteries are summarized as follows: 1) The small diameter of the tubes makes it possible to distribute the fibers homogenously in the thin electrode material, thus introducing a larger surface area that could react efficiently with the electrolyte. 2) The improved electrical conductivity of the electrode is related to the high electrical conductivity of the tubes, and the network formation of the tubes in the anode forms a tube-mat. 3) As compared with that of conventional whiskers, the relatively high intercalation ability of MWNTs did not lower the capacity of anode materials upon cycling. 4) High flexibility of the electrode is achieved due to the network formation of MWNTs in the fiber-mat structure. 5) The high endurance of the electrode is because MWNTs absorb the stress caused by intercalation of Li-ions. 6) There is improved penetration of the electrolyte due to the homogenous distribution of the tubes surrounding the anode material. 7) As compared with that of carbon black, the cyclic efficiency of the Li-ion battery was improved for a relatively long cycle time. In the near future, the application of MWNTs as a filler material in various electrochemical systems is expected to become widespread due to their outstanding properties, especially for applications where improved conductivity is needed.

By utilizing MWNTs as scanning probe microscope tips, high-resolution images are obtained. On top of that, chemically functionalized tubes gave a high sensing ability for chemical and biological groups interacting with a different surface. Flat-panel display using SWNTs and MWNTs as a field emission electron source will be commercialized in the near future because CNT has a small diameter, high structural integrity, high electrical conductivity, and chemical stability. Also, utilization of CNTs as platinum support material in the fuel cell system will be realized.

In addition, the combination of high-aspect ratio, small diameter, excellent strength, stiffness, low density, and high conductivity makes nanotubes ideal candidates as fillers in polymer composites. Improved mechanical properties of nanotube/semicrystalline polymer composites are thought to enhance the crystallization of semicrystalline polymer because CNTs could act as nucleation sites that result in enhanced stress transfer from the matrix to the fillers. Further progress has to be done in order to fully utilize these nanotube/polymer composites, such as the optimization of surface properties, the homogenous dispersion without physical damages, the development of the alignment method (also evaluation method) and processing.

The fabrication of supercapacitors and electrochemical actuators that could be used as artificial muscles is another alternative for nanotube applications. Supercapacitors already were built on hybrid vehicles because this could provide rapid acceleration and store braking energy electrically. When using sheet electrodes with SWNT and MWNTs, it is possible to obtain specific capacitance of 180 and 102 F/g and power densities of 20 and 8 kW/kg, respectively.[32] On the other hand, nanotube actuators can work at low voltages and temperatures as high as 350 °C. For example, maximum stress observed in SWNTs is ~26 MPa, a value that is 100 times larger than that observed in natural muscles.

The possibility of using carbon nanotubes as nanowires is envisaged due to their observed ballistic transport. Unfortunately, the large contact resistance between the nanotube and the external circuitry has to be solved for this application. For the fabrication of nanotube field effect transistors, SWNTs were connected to metal nanoelectrodes (see Fig. 12). The performance is excellent in terms of switching speed owing to low capacitance.[33] An inherent problem associated with CNT lies in the difficulty in manipulating them. From a commercial viewpoint, further technical progress is required, such as selective growth of nanotubes using self-assembly techniques.

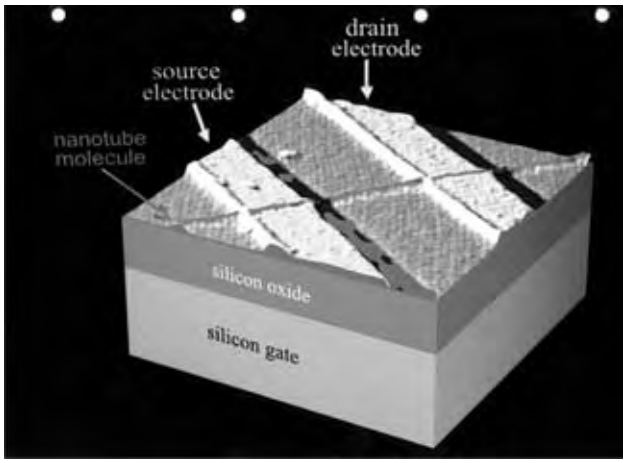

Fig. 12 An electronic device based on a single rolled-up sheet of carbon atoms. (From Ref.[33].) In the figure, a CNT (red; about 1 nm in diameter) bridges two closely spaced (400 nm apart) platinum electrodes (labeled source and drain) atop a silicon surface coated with an insulating silicon oxide layer. Applying an electric field to the silicon (via a gate electrode, not shown) turns on and off the flow of current across the nanotube, by controlling the movement of charge carriers onto the nanotube. *(View this art in color at www.dekker.com.)*

CONCLUSIONS

The 19th century can be remembered as an iron age while the 20th century is recognized to be the century founded on silicon technology. Now much attention is paid to tubular nanocarbon, ''carbon nanotube,'' as one of the promising candidates that could revolutionize technology in the 21st century. Carbon nanotubes are blooming as among other nanomaterials, and they could be visualized as connecting bridges between molecular and macrodevices. However, some challenges have to be solved in order to realize the potential uses of CNTs. The first one is the large-scale synthesis producing defect-free CNTs at low costs. Second, it is important to control the size and chirality of CNTs. The final and most important theme is how to manipulate these tiny molecules in order to fabricate novel nanodevices and materials. We envisage that in less than 10 yr various nanotube-based devices will be taking the place of emerging technologies.

Catalyst Preparation

X. D. Hu
Michael W. Balakos
R&D, Süd-Chemie Inc., Louisville, Kentucky, U.S.A.

INTRODUCTION

Heterogeneous catalysts are defined as solids or mixture of solids that are used to accelerate a chemical reaction without undergoing change themselves. The types of solids used in industry as heterogeneous catalysts include simple oxides, mixed oxides, metal salts, solid acids and bases, metals, and dispersed metals. Catalysts are used in a wide variety of chemical and environmental processes worldwide. The global value of fuels and chemicals produced by catalytic routes is about US$ 2.4–3 trillion per year.[1,2] About 20% of all products produced in the United States are derived from a catalytic process of some form.[1] As important as catalysis is to the world economy, the number of various chemicals used as a catalyst as well as the form and shape of the material vary as much as the number of processes that use catalysts. Fig. 1 is a picture of a number of various types of catalysts and illustrates the numerous possibilities of shapes and sizes. Naturally, the preparation processes of such a wide variety of products is also numerous.

The preparation of heterogeneous catalysts is a series of unit operations, particularly involving the processing of solids, to produce a catalyst with specific chemical and physical properties that are important in the performance of the material in the chemical process that it is being used.[3–6] The type and order of unit operations involved in the preparation vary greatly from catalyst to catalyst. There are numerous possibilities of manufacturing processes for particular catalyst formulations with each affecting the chemical and physical properties of the final product.

HETEROGENEOUS CATALYSIS

The choice of catalyst for a specific process depends on the performance of the material. For a catalyst to be economically effective, it must possess good activity, selectivity, and stability.[7] Activity is the rate at which the reaction proceeds with a specific volume of catalyst and flow rate of reactants. It is desirable to maximize the activity per volume of a catalyst, thereby minimizing the volume of the reactor. Selectivity of a catalyst is the ratio of the rate at which the desired reaction takes place over a catalyst to the rate of undesired side reactions. Since the side reactions convert feed to an unwanted product, a highly selective catalyst is economically desirable. The stability of a catalyst is a measure of the deactivation rate. For a catalyst to be viable, the deactivation rate should be low so that the catalyst change-out frequency is low, minimizing process down-time, catalyst costs, and turnaround costs.

The components of catalysts vary widely from process to process, but the common goal is to maximize the active material on the surface. In the case of a metal oxide, the oxide should have a large surface area, thereby exposing a large amount of active sites to the reactants. When the active species is a reduced metal or an expensive material, it is common practice to deposit the metal on a high surface area oxide support to maximize the active sites. The percentage of active metal that is exposed to the surface is the dispersion of the metal. If the metal atom is considered the active site, then a high dispersion is desirable to obtain a high activity per unit metal.

To eliminate intraparticle transport limitations, the particle size and average pore size must be carefully controlled during manufacture. Other physical properties that become important in industry have to do with the physical integrity of the catalyst particles. These properties include bulk density, crush strength, resistance to abrasion, and attrition. These properties are very important when working with reactors that contain a large amount of a particular catalyst. Fig. 2 lists a number of chemical and physical properties that affect catalyst performance.

The physical and chemical properties discussed above are influenced by every step of the preparation process as well as the choice of raw materials. In addition, several preparation routes may be available to obtain a catalyst with specific properties. On developing a catalyst for industrial applications, the influence of the preparation procedure on these properties must be taken into consideration as well as economical production of a material. Examples of industrial catalytic processes and the method of manufacture of the catalysts are shown in Table 1. This table illustrates the many different types of catalysts as well as preparation methods used in industry.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007693

UNIT OPERATIONS OF CATALYST PREPARATION

The preparation of a heterogeneous catalyst consists of a series of unit operations that mostly deal with solids processing. A partial list of unit operations that are used in catalyst manufacture is given in Table 2. The table is segregated into four basic categories needed for the manufacture of heterogeneous catalysts: 1) precursor formation, 2) purification, 3) posttreatment,

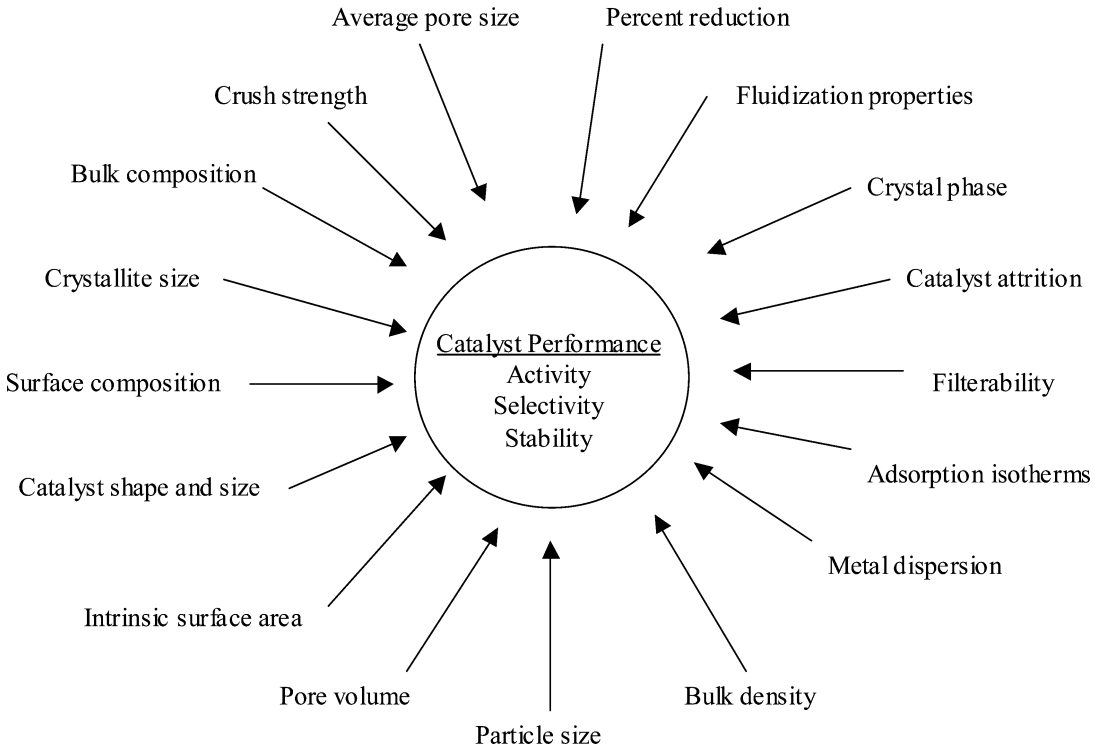

Fig. 2 Properties of heterogeneous catalysts that may be important in performance under industrial conditions.

Table 1 Examples of industrial catalytic reactions, the type of catalyst used and the typical preparation method

Industrial reaction	Catalyst	Catalyst preparation method
Ethylene oxychlorination	$CuCl_2/Al_2O_3$	Impregnation/thermal spreading
Ethylene hydration	WO_3/SiO_2	Precipitation/deposition
Polygas oligomerization	H_3PO_4/SiO_2	Compounding
C_5/C_6 isomerization	Pt/mordenite	Precipitation/ion-exchange/dipping
CO hydrogenation to liquid fuels	Cu-Fe-K/SiO_2, Co/support	Co-precipitation/impregnation
CO hydrogenation to methanol	$CuO/ZnO/Al_2O_3$	Co-precipitation
N_2 and H_2 to ammonia	Fe_2O_3	Fusing/smelting
Selective hydrogenation	Pd/Al_2O_3	Impregnation
Benzene hydrogenation	Ni/Al_2O_3, Pt/Al_2O_3	Precipitation/ionic-adsorption
Fats and oils hydrogenation	Ni/SiO_2-Al_2O_3	Precipitation
Ethylbenzene dehydrogenation	Fe_2O_3	Compounding
Ethylene oxydehydrogenation	Bi-Mo/SiO_2	Fluid bed impregnation
Ethylene epoxidation	Ag/Al_2O_3	Vacuum impregnation
Propylene oxidation	MMO	Precipitation
Butane oxidation	VPO	Precipitation

and 4) particle size enlargement. The preparation of catalysts may include all or only one of the four main steps. In addition, the steps may be combined and repeated in many different ways to achieve the desired properties as economically as possible. How the unit operations are carried out and the types of precursors greatly affect the properties of the catalyst can determine the activity, selectivity, and lifetime of the catalyst in an industrial process.

Precursor Formation

Precursor formation is the initial formation of the active solid material. This can be done by precipitation or coprecipitation of the required chemical species, decomposition, hydrothermal synthesis, adsorption or impregnation of active species onto a support, and other methods of synthesis.

Precipitation

The starting materials of the active components of catalysts are often in the form of soluble metal salts that are precipitated to form a solid precursor to a catalyst. Among the very limited soluble salts, metal nitrate is the preferred salt over fluoride, chloride, phosphate, or sulfate because of less corrosiveness and low residual anion on finished catalyst. Sometimes more expensive metal carboxylates such as formate, acetate, glycolate, or oxalate are used in the situation where disposal of nitrate is prohibited by environmental regulations or residual nitrogen is detrimental to the reaction.

The precipitation of solid catalyst precursor is caused by acid–base neutralization. The solution of metal salts is normally acidic while the base typically uses carbonate, bicarbonate, ammine, or hydroxide. The coprecipitated precursor is typically composed of mixed basic carbonates, hydroxycarbonates, and hydroxides. These compounds have the general formula[8]

$$Me^{2+}{}_x Me^{3+}{}_y (OH^-)_{2x+3y-az} (A^{a-})_z \cdot nH_2O \quad (1)$$

where Me^{2+} = metal cations with 2+ valence (Mg, Mn, Fe, Co, Ni, Cu, or Zn, etc.); Me^{3+} = metal cations with 3+ valence (Al, Fe, or Cr, etc.); A^{a-} = compensating anions (CO_3^{2-}, SO_4^{2-}, NO_3^-, or Cl^-, etc.); x, y, z, n = stoichiometric constants.

The conditions and procedures of precipitation play a significant role in catalyst morphology, texture, pore structure, physical strength, and consequently the performance (activity, selectivity, and stability) of the catalyst. By merely changing the sequence of solution addition, catalyst components can be precipitated simultaneously or sequentially. The methods of precipitation most often used are constant pH coprecipitation, sequential precipitation, acid-to-base precipitation, and base-to-acid precipitation.

Constant pH coprecipitation takes place by feeding acidic and basic solutions simultaneously into the precipitation tank. Usually, acidic solution is fed at a constant rate and the feed rate of basic solution is varied to maintain constant pH, typically at the acid–base neutralization point. The acid feed rate is predetermined based on consideration of residence time, batch time, or aging time. The coprecipitation reaction is typically controlled isothermally at 40–70°C with a constant stir

Table 2 Unit operations involved in catalyst manufacture

Precursor formation	Precipitation
	Co-precipitation
	Decomposition
	Hydrothermal synthesis
	Adsorption/impregnation
Solid-solution separation and purification	Impurity removal from solid Washing Ion exchange Decomposition
	Water or solvent removal Filtration Drying
	Volatiles removal
	Waste recovery
Posttreatment	Calcincation
	Reduction
	Stabilization
Catalyst formation	Preparation of coarse solid Mixing Milling
	Spray agglomeration
	Granulation Tabletting Pelletizing Extruding Spheridizing
	Washcoating

at 300–1500 rpm.[9] The precipitation can be batch or continuous operation. In the case of continuous operation, the slurry is continuously withdrawn from the precipitation tank to either an aging tank or an in-line filter press.

A uniform distribution of catalyst components in the precipitated agglomerates is expected by constant pH coprecipitation; however, there may still exist a concentration gradient from the surface to the core of the particle due to solid-state diffusion. As an example, copper is surface deficient, as evidenced by x-ray photoelectron spectroscopy (XPS) analysis on an industrial $CuO/ZnO/Al_2O_3$ catalyst for methanol synthesis reaction. Table 3 illustrates how the components of the catalyst can vary from the surface to the core of the particle.[10]

Sequential precipitation is used when a nonuniform distribution of catalyst components throughout a catalyst particle is desirable. In this method, the pH of the precipitation is controlled at specific levels at different

Table 3 A $CuO/ZnO/Al_2O_3$ catalyst shown to be Cu deficient on the surface by XPS analysis

Sample no.	Surface Cu/(Cu + Zn)	Bulk Cu/(Cu + Zn)	Surface/bulk	Relative rate const.
A	0.30	0.41	0.63	1.00
B	0.33	0.43	0.69	1.23
C	0.33	0.42	0.67	1.33
D	0.38	0.48	0.78	1.48
E	0.36	0.45	0.77	1.42

(From Ref.[10].)

times so that the individual component of the catalyst is precipitated sequentially. For example, in preparing a zinc–aluminum binary oxide catalyst, the precipitation of aluminum hydroxide takes place at a pH of 5.5 and the precipitation of zinc hydroxycarbonate takes place at a pH of 7.0–7.5.[11] Likewise, in preparing a copper–zinc–alumina ternary oxide catalyst, precipitation of aluminum can be as early as a pH of 2.9 and precipitation of copper hydroxycarbonate occurs at 4.4.[11] To create a multicomponent catalyst with desired heterogeneity by design, the components can be fed at different times even though they may precipitate at a similar pH.

Acid-to-base precipitation is used for batch operation, in which the mixed metal salt solution is fed into the basic solution (precipitation agent) in the reactor. During the acid-to-base operation, the pH continuously decreases to a predetermined lower value. The end pH can be further adjusted by adding an additional amount of acid or base. Base-to-acid precipitation is also an alternative, with the pH continuously increasing during the precipitation.

The physical and chemical properties of precipitated particles can be tailored by the precipitation conditions such as solution concentration, precipitation temperature, pH, method of addition, and mixing intensity.[4] The adjustment of these conditions can be achieved by using equipment with a setup similar to that depicted in Fig. 3.[9] The parameters most often controlled are the solution concentration, precipitation temperature, and the pH of solution.

The precipitation process, the reverse of solid dissolution, is dictated by solution thermodynamics. The solution reaches saturation state when the dissolution rate equals the precipitation rate. Nucleation starts when the solution concentration exceeds the saturation concentration. The solution concentration affects the crystallite size of the precipitated catalyst. For example, diluted solution is beneficial to crystal growth due to slow nucleation and the presence of a few nuclei. In contrast, submicrometer- or even nano-sized amorphous gel or sol can be formed starting with a more concentrated solution.

In general, nucleation and crystal growth rates reach a respective maximum with increasing temperature. In many systems, the temperature of the maximum nuclei formation rate is lower than that of the maximum crystal growth rate. Therefore, an intermediate precipitation temperature may be chosen for obtaining fine particles.

To determine precipitation temperature on a commercial scale, consideration is also given to such factors as production time, material handling, ease of subsequent processes, and production efficiency. Many catalyst manufacturing processes choose a precipitation temperature between 70°C and 80°C.

The pH of precipitation can be calculated from thermodynamic data such as the solubility product

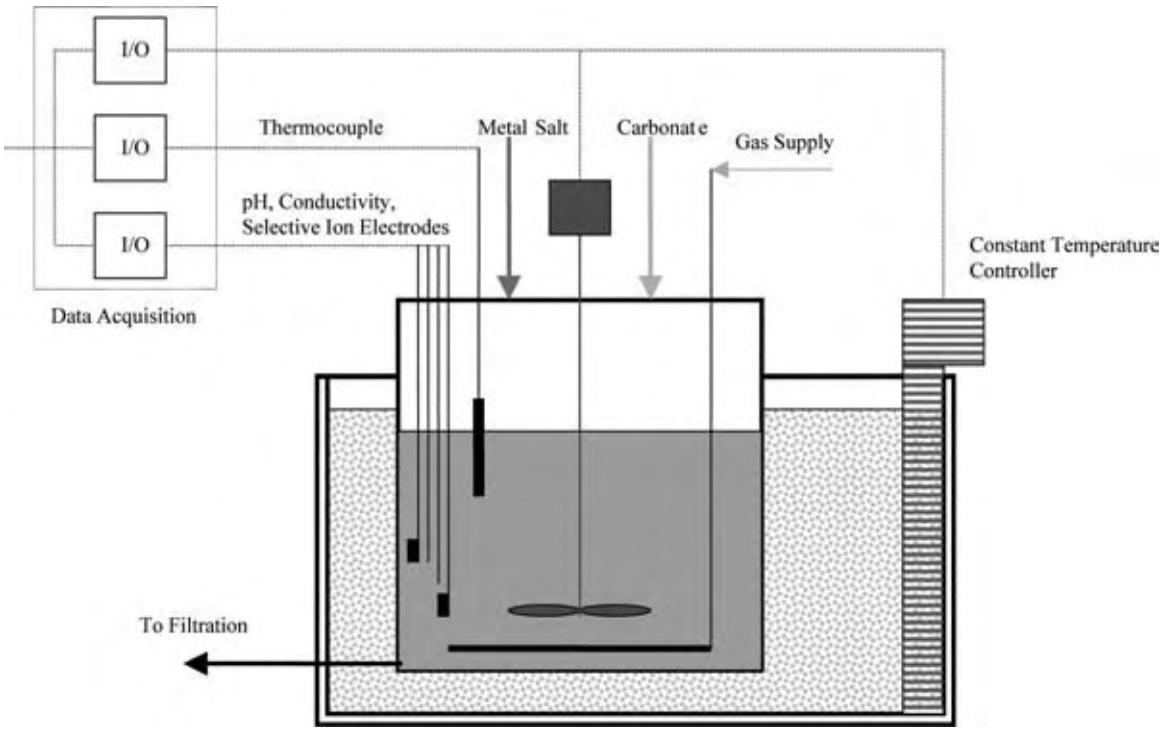

Fig. 3 Schematic of the precipitation process. *(View this art in color at www.dekker.com.)*

Table 4 Calculated solution pH for forming simple hydroxides of various compounds

Hydroxide	pH	Hydroxide	pH
$Mg(OH)_2$	10.5	$Fe(OH)_2$	5.5
Ag(OH)	9.5	$Cu(OH)_2$	5.3
$Mn(OH)_2$	8.5–8.8	$Cr(OH)_3$	5.3
$La(OH)_3$	8.4	$Zn(OH)_2$	5.2
$Ce(OH)_3$	7.4	$Al(OH)_3$	4.1
$Co(OH)_2$	6.8	$Zr(OH)_4$	2.0
$Ni(OH)_2$	6.7	$Fe(OH)_3$	2.0

constant for simple compounds or determined from a titration (neutralization) curve for solid mixture. The pH of forming a simple hydroxide solid is listed in Table 4. A pH of precipitation higher than the theoretical neutralization point is usually chosen to ensure completion.

Decomposition Deposition

In contrast to precipitation, deposition of a solid can occur by decomposition of a premixed solution upon changing temperature and pH. For example, by heating a mixture of aluminum salt and urea solution to 90–100°C, aluminum hydroxide will be precipitated due to an increase of the solution OH^- group from urea hydrolysis:

$$(NH_2)_2CO + 3H_2O \longrightarrow 2NH_4^+ + 2OH^- + CO_2 \quad (2)$$

The aim is to form a less soluble or nonsoluble solid deposited onto a support by decomposition, disproportionation, or hydrolysis of complexes or other organic compounds.

An example is the thermal decomposition of a metal onto a support involving an ammine complex having the formula $[Me(NH_3)_6]^{2+}$ CO_3^{2-} where Me is the metal. In this complex, six ammonia molecules coordinate symmetrically from the central metal ion and form an octahedral structure. It is therefore possible to form small metal crystallite-sized catalyst by using ammine complex as a precursor. The unique features of a catalyst made from ammine decomposition include uniform distribution of metal throughout the catalyst particles, smooth and homogenous surface morphology, and high thermal stability.[11,12]

A common procedure in decomposition deposition involves mixing ammine solution with a highly dispersed carrier material, and then slowly raising the reaction temperature to the decomposition temperature.[12] During the process, ammonia is released from the complex and the metal hydroxycarbonate species are deposited onto the carrier material. As shown in a typical process flow sheet for this method in Fig. 4,

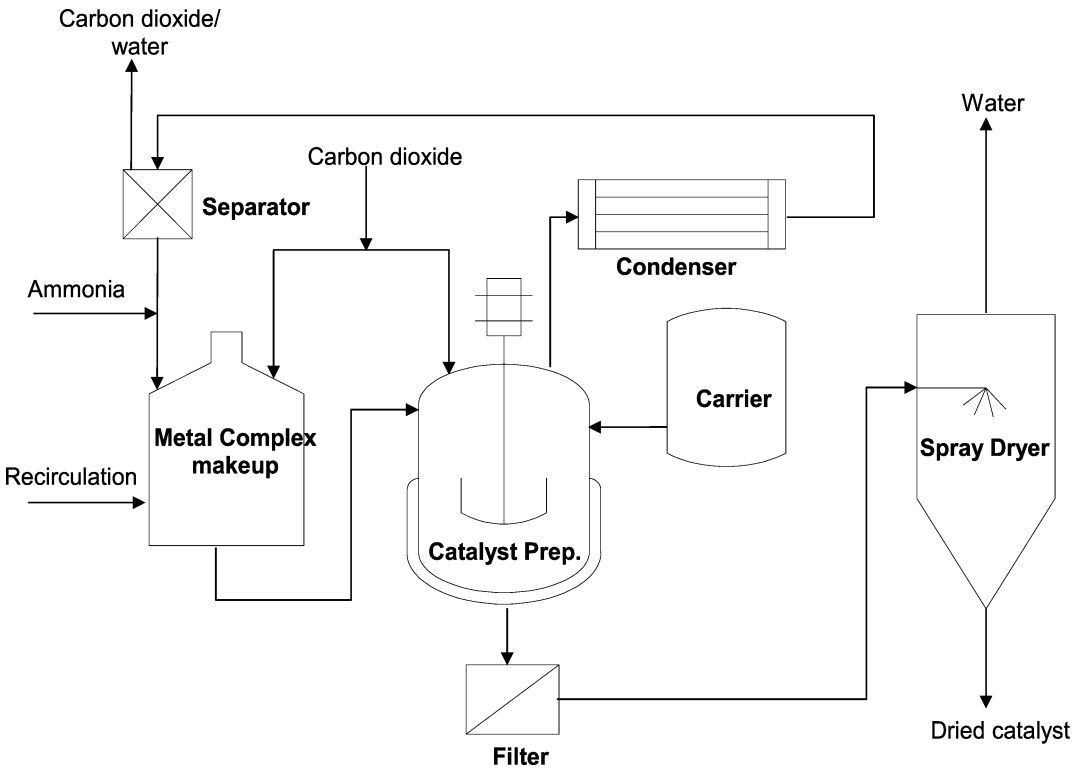

Fig. 4 Schematic of ammine decomposition process.

ammonia and carbon dioxide are recovered. Water is separated from the catalyst precursor and can be recovered as well. Therefore, the water consumption in the decomposition deposition process is much lower than in acid–base coprecipitation process.

Compounding

Physical mixing of different components of a catalyst is one of the simplest methods of catalyst preparation. The catalyst components can be added in a mixer in one step or in several steps. Good mixing is a key to ensuring a homogenous dispersion of all the components. The advantage of the compounding method is that it usually does not require filtration and washing, so no wastewater is generated. The disadvantage of the method is that interdispersion of the components is poor in some cases and dust pollution is problematic.

An example of using the compounding method is an iron catalyst for dehydrogenation of ethyl benzene to styrene.[13] For making a catalyst containing 11.2% potassium oxide and 88.8% iron oxide, a mixture of the required amounts of potassium carbonate and unhydrated iron oxide is dry-blended with a small amount of organic lubricant. Water is then added into the oxide mixture to form an extrudable paste that is then formed in cylindrical pellets, dried, and calcined at 600°C. It should be noted that not only can the compounding method be used to make a mixture of oxides, it can also be used to make nano-phased mixed oxide through solid-state reaction using solvent-aided intensive mixing and appropriate posttreatment. In many cases, compounding is therefore not only physical mixing but also chemical activation and physicochemical modification of the solid under the influence of mechanical energy. An illustration of such activation is the preparation of a supported copper catalyst.[14] First, $CuCl_2$ is compounded homogenously with γ-Al_2O_3. The solid mixture is then subjected to a heat treatment at 300°C. During mixing and heat treatment, $CuCl_2$ is spontaneously dispersed onto alumina to form a monolayer. The highly dispersed chloride compound cannot be detected by x-ray diffraction.[14]

Wet compounding is another way to hasten the formation of a solid solution. In this method, a homogenous solution or a colloidal solution containing active components of the catalyst is mixed with other components of the catalyst in solid form. The reaction between solution and solid is activated by vigorous mixing and subsequent calcination. Solid phosphoric acid catalyst for hydrocarbon polymerization is prepared by this method.[15]

Compounding can be carried out by several different types of mixers/blenders. Based on the degree of mixing and time required, mixers are selected in accordance with their capabilities to generate diffusive, convective, and/or shear mixing. A tumbler gives diffusive mixing where movement of individual particles in random motion leads to a high degree of homogeneity in a long period of time.[16] A mix muller, shown in Fig. 5, is a type in which pan and muller turret move in opposite directions, and gives mostly convective mixing. For rapid compounding, a rotating pan mixer equipped with baffle and agitator blades is very often used. As shown in Fig. 6, the pan mixer generates actions of both shearing and convective mixing.

Impregnation/Coating

This method is used to incorporate active components (as solution) onto solid support. The support can be in the form of tablet, beads, extrudates, granules, or even powder. The processes of the preparation include incipient wetness, excess solution adsorption, and surface coating. The driving force of the solute moving from solution to solid in a porous support is either van der Waals (physical adsorption), chemical binding (chemical adsorption), or capillary. The pore radius in most porous supports ranges from several to several hundred angstroms. The capillary force calculated from such small pores can be equivalent to a value of tens to thousands of bars. By considering the viscosity of impregnation solution, the time required to penetrate into the internal pore structure can be estimated by the following equation:

$$t = \frac{2\eta}{\delta \cos\theta} \frac{r^2}{\overline{R}} \tag{3}$$

where η is the viscosity coefficient of impregnation solution, r is the penetration distance (depth) at time

Fig. 5 Mix muller-type mixer. (Courtesy of Süd-Chemie Inc.) *(View this art in color at www.dekker.com.)*

Fig. 6 Rotating pan mixer. (Courtesy of Eirich Machines, Inc.) *(View this art in color at www.dekker.com.)*

t, δ is the surface tension of solution, $\overline{R}$ is the mean pore radius, θ is the contact angle between solution and support surface.

The equation can also be expressed as in Ref.[17]:

$$\xi = \Omega t^{0.5} \tag{4}$$

where ξ is the dimensionless penetration depth, Ω is the penetration coefficient, t is the impregnation time.

In incipient wetness, the volume of solution used is equal to the pore volume of support to ensure total adsorption of solution into the mesopores. This process may be repeated several times in order to reach the desirable concentration level of the active components. If there is an excess amount of solution, it will be coated on the surface of the carrier to form an active component eggshell.

In excess solution adsorption, the support material is submerged in excess amount of impregnation solution (the volume of impregnation solution is much higher than the pore volume of the support). The excess solution is filtered after adsorption equilibrium is reached. In many cases, competitive adsorption between solvent and solutes and/or between different solutes leads to a nonuniform distribution of active components throughout the support particles. This phenomenon can be utilized to enhance performance (normally selectivity) of certain types of catalysts. The distribution of the active components can also be tailored by the manipulation of the pore structure of the support, pH and viscosity of the solution.[17]

One of the most important parameters of the solid surface is the isoelectric point (IEP), or point of zero charge (PZC). As a rule, an oxide particle dipped in a solution at a pH lower than IEP tends to polarize positively to adsorb compensating anions. The same particle dipped in a solution at a pH higher than the IEP has a negative surface charge that is compensated by adsorbed cations. Thus, by choosing the isoelectric point of the oxide, the pH value of the impregnating solution, or the type of impregnating compound, the adsorption strength and, consequently, the behavior of thermal stability of the catalyst can be altered as shown in Table 5.[18]

Novel Preparation Methods

The activity and selectivity of a solid catalyst toward a desirable product are often limited by the randomness of the molecular arrangements of the active components in the catalysts prepared by traditional methods. It is therefore most challenging to devise new solid catalyst preparation methods to control metal dispersion, metal–support interaction, and pore structure on the molecular or nanometer level. It is equally challenging to form a heterogeneous catalyst without the need for further steps (catalytic or noncatalytic) to treat the effluents in the entire preparation process. Emerging new techniques in catalyst preparation are summarized in the following areas.

Nano-scale synthesis

The methods that are commonly used to produce semiconductors and electronic materials are now being used in catalyst preparation. As recently reported, lithography has been used to deposit metal in predetermined patterns.[19] Deposition of small clusters using nano-scale scanning tunneling microscopic tip has also been demonstrated.

Table 5 Effect of point of zero charge (PZC) on adsorption strength

Adsorption strength	Strong	Weak

High-throughput synthesis

Combinatorial synthesis of intermediates in the pharmaceutical industry is being widely used for efficient preparation of solid catalysts. The high-throughput combinatorial method is particularly useful in making a large array of samples for combinatorial testing. By this method, it is possible to search for ''out-of-box'' formulations as well as systematically investigate new reaction and preparation conditions. For example, a new robotic workstation has been reported to allow wet or dry impregnation of solution containing Mo/V/Nb/W on 48 alumina samples in parallel.[20]

Preparation using alternate energy source

In contrast to traditional energy sources, microwave, laser, and sonic energy can be delivered to specific solid sites or small areas by fine-tuning frequencies and energy levels. It is especially suitable for preparation of nano-structured catalyst. For example, inherent ''eggshell'' catalysts can be produced with sonochemical preparation by which nano-dispersed metal particles are formed with instantaneous decomposition of metal solution by high-intensity irradiation of ultrasound in local area. In the preparation of Mo_2C on ZSM-5 with ultrasound at 20 kHz, narrowly distributed particles of about 2 nm in diameter are uniformly dispersed on the outer surface of the ZSM-5 support.[21]

Green chemistry synthesis

New methods are focused on the preparation of solid catalysts without release of gaseous or liquid waste streams.[22] In zeolite synthesis, the chemical compounds generated during combustion of templates (structure-directing agent) are often hazardous and harmful to the environment. A new method teaches disassembling the template within zeolite pore space into small fragments without combustion.[23]

Solid–Solution Separation and Purification

Before forming into a shape, the precursor in slurry needs to be purified and then concentrated from the mother liquor. Because most industrial catalysts cannot tolerate many trace impurities (Na, K, Cl, S, P, etc.), the purification process is often exhaustive with single or even multistep unit operations such as decantation, ion exchange, and filtration.

Ionic impurities are adsorbed on the surface of the catalyst precursor, especially on gelatinous material with high surface area. Water washing with up to several hundred times more than the amount of solid may not be sufficient to remove the impurities to the desired low level. In those cases, ion exchange with ''benign'' ionic compounds, which are not detrimental to the reaction, removed by heat treatment are frequently used. For example, dilute NH_4OH solution is used to replace Na in purifying alumina gel. However, washing and ion exchange are often a continuation of the aging process. One often observes color change during extensive washing, indicating transformation of crystallite phases of the precursor. Therefore, the aging effects of washing on properties of the catalyst precursor must be considered when choosing a proper washing method, equipment, conditions, and ion exchange reagent.

Posttreatment

The purpose of heat treating a solid precursor is to remove volatiles (typically water) and to convert the solid to a desirable amorphous or crystallite phase. It is during heat treatment that the precursor converts to a physically robust and chemically active catalyst. It affects such properties of the catalyst as surface acidity, number of active sites, surface area, pore structure, and crush strength. Several operations that involve heat treatment include drying, calcination, reduction, and stabilization and they are frequently employed in multiple steps before and after forming catalyst pellets.

Drying is defined as the process of eliminating the solvent from the solid precursor. Drying is accomplished by diffusion of the solvent from the solid interior to the surface and by evaporation of the solvent with heat and/or vacuum. The pore structure may start to form during this process.

Solvent can be associated with the solid in different chemical and physical states. It can be part of the crystalline structure, chemically adsorbed in solid interior or physically penetrated/adsorbed inside the interstices of the solid. The interstices of the solid are subjected to a large capillary tension upon drying. The force exerted to solid can be estimated by Laplace's law:[21]

$$\Delta P = \frac{2\delta}{r} \tag{5}$$

where δ is the surface tension of the solvent (70 dyn/cm for water) and r is the radius of the capillary.

The large capillary force tends to collapse the interstices among the solid particles and bring the particles together.[21] For example, a pressure of about 800 bar is created within 8 nm particle interstices.

Drying under supercritical conditions proceeds in the absence of liquid/gas interfaces and, therefore, is free of the effects of surface tension. Supercritical drying avoids collapse of the solid matrix and forms an aerogel with extremely high surface area and high

Table 6 Effect of drying conditions on physical properties of the alumina catalyst after drying

Drying conditions	Density (g/cm^3)	BET surface area (m^2/g)	Radical shrinkage (%)
Ambient evaporation	1.214	171	74
Supercritical CO_2	0.058	718	8
Supercritical acetone	0.146	716	34

(From Ref.[24].)

pore volume with low density.[24,25] However, the disadvantage of aerogel as catalyst material is that it cannot withstand high temperature calcinations. A comparison of conventional and supercritical drying is given in Table 6.[24]

Several unit operations can be adapted for drying purposes according to the location of the solvent in the solid and requirement of pore volume and surface area of the final catalyst. Besides oven drying, the common drying methods include spray drying, vacuum drying, and fluid bed drying. A drier of 7–30 ft in diameter equipped with an atomizer is commonly used for spray drying. A double cone mixer with vacuum capability is used for vacuum drying. A fluid bed coater can also be used for fluid bed drying. Fluid bed drying can be used in conjunction with impregnation in one step or in separate steps. The effects of drying methods on catalyst surface area and pore volume are demonstrated in drying of silica material, as shown in Table 7.[26]

Calcination is a process of heat treatment at temperatures higher than the drying temperature. The phenomena of thermal decomposition, crystallization and recrystallization, and sintering are observed during calcination.

Thermal decomposition is the process wherein the structure of the catalyst is formed by the heat treatment of the precursor after volatile components are decomposed or chemical water associated with the lattice structure of the solid is removed. Examples of such a phenomenon are the decomposition of metal nitrate, hydroxide, carbonate, chloride, sulfate, phosphate, hydroxy salts, or oxy salts to corresponding oxides. The following equation shows the decomposition of cobalt nitrate coupling with partial oxidation of Co^{2+} to Co^{3+} and formation of spinel Co_3O_4.

$$3Co(NO_3)_2 \rightarrow Co_3O_4 + 6NO_x + (7 - 3x)O_2 \ (x < 2.333) \quad (6)$$

As seen from the equation, two moles of NO_x are generated for every mole of $Co(NO_3)_2$ decomposed. Caustic scrubbing or catalytic reduction is most commonly used in commercial catalyst production for NO_x removal.

During calcination, the precursor undergoes a continuous crystallization and recrystallization process during which thermodynamically unstable or metastable phases are converted to more stable ones. X-ray diffraction patterns in Fig. 7 show phase transformation of hydrous titanium oxide from 100°C to 550°C.[27]

Sintering is a phenomenon that occurs at a calcination temperature higher than the Tamman temperature or roughly above two-thirds the melting temperature (in K) of the solid. Sintering results in agglomeration of solid particles. During calcination, the surface area of the solid may initially increase due to recrystallization and then decreases monotonically due to sintering. As shown in Fig. 8, addition of rare earth metals to the oxide (hydrous titanium oxide in this case) may delay sintering and, consequently, stabilize the surface area of the catalyst.[27]

It should be noted that pore volume and average pore size of the catalyst are changing with the decrease of surface area during calcination according to the relationship

$$\bar{r} \propto \frac{2V}{S} \quad (7)$$

The average pore radius will be increased if pore volume (V) remains constant upon heating. The average pore radius will decrease or remain constant if pore volume is also decreased. As shown in Table 8, surface area of zirconia is gradually decreased from 165 to $\sim$2 m^2/g when being calcined to higher temperatures, whereas mesopores less than 100 Å initially become more populous and are eventually eliminated when the material is severely sintered.

Table 7 Effect of drying methods on physical properties of a silica catalyst

Drying methods	BET surface area (m^2/g)	Pore volume (cm^3/g)
Spray	105	0.15
Vacuum	132	0.21
Fluid bed	145	0.26

(From Ref.[26].)

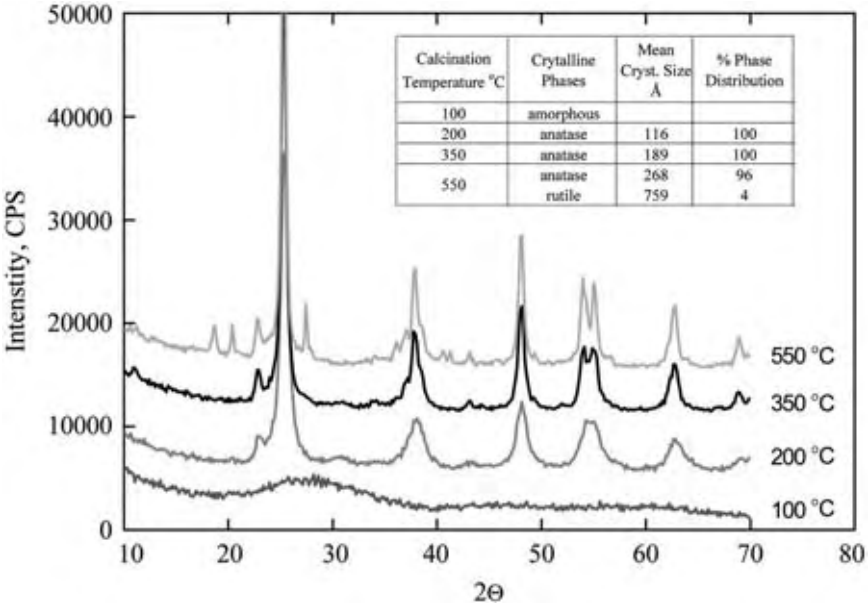

Fig. 7 XRD pattern of TiO_2 showing phase transformation upon calcination. (From Ref.[27].) *(View this art in color at www.dekker.com.)*

Calcination on an industrial scale usually uses a box kiln, belt calciner, or rotary calciner. A rotary calciner is the most widely used calcination equipment owing to its good solid–solid mixing, enhanced solid–gas energy exchange, large contact area with heating surface, short residence time, and economic operation. It is also used in the reduction of precious metal on support and catalyst regeneration.

The time of passage (TOP) or mean residence time of catalyst particles is stated to be the primary variable affecting rotary calciner operation.[28] It can be expressed as a function of feed rate or rotation speed:

$$\text{TOP} = \text{Holdup/Feed rate} = \text{W/Fw} \tag{8}$$

$$= \alpha \frac{L}{\tan\theta N^b D} \tag{9}$$

where α is a constant between 0.2 and 0.3, b is a constant between 0.9 and 1.0, θ is an angle of inclination on holdup, N is the rotation speed of the rotary, D is the diameter of the calciner, and L is the length of the calciner.

The TOP of a commercial scale rotary calciner is typically 30–60 min and depends primarily on feed rate and tube length. The TOP in a rotary calciner is much shorter than that in a belt calciner. A continuous multipass operation is sometimes employed for materials requiring a long calcination time.

The majority of base metal and precious metal catalysts used in industry are active in the reduced state.[7,29] Flowing hydrogen diluted in nitrogen over the oxide at elevated temperatures is the most common procedure for reducing the oxide to its most active state.[7] Reduction can be done in situ in the industrial reactor before the catalyst is put into service or at the catalyst manufacturing plant. In a catalyst manufacturing plant, the reduction is done in a fixed bed or fluid bed furnace. Since water is the by-product of reduction, the hydrogen concentration must be high enough to reduce the oxide in a reasonable time frame while low enough to prevent the product steam from sintering the metals. In addition, reduction of metal oxides is typically an exothermic process; therefore, a lower H_2 concentration prevents thermal runaway.

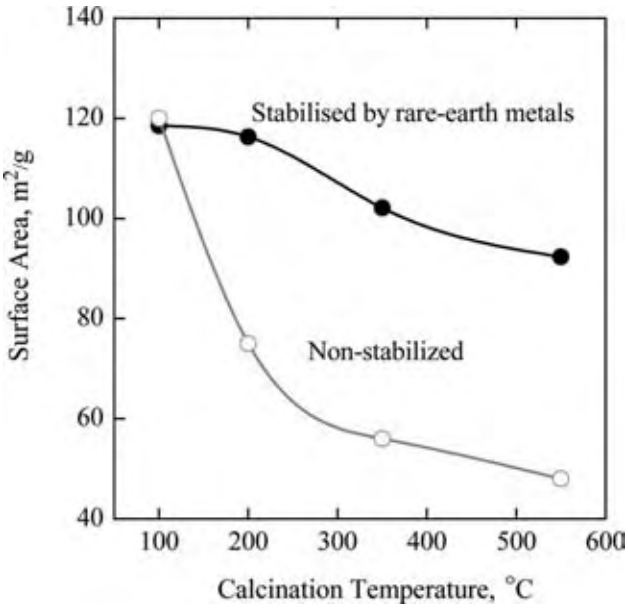

Fig. 8 Stabilization of hydrous titanium oxide surface by the addition of rare-earth oxide to the support. (From Ref.[27].) *(View this art in color at www.dekker.com.)*

Table 8 Effect of calcination conditions on a ZrO_2 support

Material	ZrO_2			
Pretreatment conditions	300°C	550°C	700°C	1200°C
Surface area (m^2/g)	165	81	47	2.4
Pore volume (cm^3/g)	0.22	0.33	0.29	0.14
Particle size distribution (Å)				
<100	14.98	34.38	34.07	1.05
100–1000	5.52	5.93	4.53	9.08
1000–5 μm	79.51	59.59	61.40	79.73
5–10 μm				10.13

Some metal compounds can be reduced by a chemical reagent such as formaldehyde, formic acid, or hydrazine. These methods are generally more expensive and are used only when conventional hydrogen methods are not feasible.

Once reduced, the metals may be pyrophoric or self-heating upon exposure to air. This is problematic if the reduction is done at the catalyst manufacturing plant and must be shipped to the end-user's plants. In this case, a stabilization procedure is employed at the catalyst manufacturing plant so the material is safe for transport as per U.S. Department of Transportation standards.

Typically, stabilization of the catalyst consists of forming an oxide layer on the outer surface of the metal, while keeping the inner surface reduced. This is the result of controlled oxidation of the catalyst at low temperature. The effect is that 5–20% of the metal is oxidized and shields the inner reduced material from air. The outer oxide layer readily reduces in situ with hydrogen or with the reactant gases at a temperature often lower than the bulk reduction temperature when the plant is started.

Another common stabilization procedure is to submerge the reduced catalyst into a solvent under N_2 atmosphere. Since air cannot get to the catalyst surface, the catalyst can be shipped, submerged in the solvent. The catalyst is carefully loaded into the reactor without exposure to air and the solvent washed away. Normally, a solvent that is similar to the reaction product is used for such stabilizations.

An example of immersion stabilization is nickel catalysts for the hydrogenation of edible oils.[30] The nickel catalyst is a powder that is used in batch slurry reactors. Since nickel is pyrophoric, the material must be stabilized for shipment to end user plants. After reduction in a fluid bed furnace, the catalyst is dropped under a N_2 atmosphere into melted, fully hydrogenated edible oil. The thick slurry is then pastillated into droplets and solidified at room temperature. The result is small droplet-shaped solids of reduced nickel catalyst embedded in hardened edible oil. When used at the edible oil facility, the fully hydrogenated oil readily dissolves in the reaction mixture, exposing the catalyst to the reactants.

Catalyst Particle Forming

In order to be uniformly filled in a commercial reactor without causing flow distribution problems, an industrial catalyst must be formed in a certain shape and size. The specifications for catalyst size, shape, and mechanical strength are decided in accordance with the energy balance, pressure drop, and flow dynamics of the reactor design.

Forming (or granulation) is a process of particle enlargement by agglomerating small particles together into large pellets, tablets, extrusions, spheres, and microspheres.[31] In fluid bed reactors, microspherical catalyst powders with medium particle size of 60–80 μm give the best fluidization properties. Shaped extrudates, tablets, or pellets are generally used in fixed bed reactors. The particles that provide the largest external geometric surface areas (EGSA) are usually desirable. Relative pressure drops of the catalyst with different shapes and sizes are shown in Table 9.

The methods of forming can be put into four categories: pressure forming, rotation forming, liquid-bound agglomeration, and oil-drop forming. The applicability of the particles from different forming methods is summarized in Table 10.

Pressure forming by tabletting, pelletizing, or extruding is used most frequently in industrial catalyst production. A tabletting machine is employed for compacting dry powder into cylindrical tablets. The momentum of the compacting force is delivered by two moving punches to a die. During the tabletting process, powder is continuously fed into the die from a feeder and tablets are continuously ejected from the die. Fluidity of the catalyst powder is the key to forming a strong tablet. If the powder lacks the required fluidity and lubricity, two measures are usually taken—powder densification by an additional kneading step and/or addition of lubricating material such as graphite, paraffin oil, clay, talc, stearic acid, or metal stearate.

Table 9 Relative pressure drop across a catalyst bed of various geometry and size

Shape	Height (inch)	Diameter (inch)	Hole diameter (inch)	EGSA (sf/cf)	Void	Relative ΔP. (%)
Cylinder	>0.24	0.12	n/a	231.6	0.49	1.00
One-hole ring	0.16	0.16	0.079	368.8	0.54	1.04
Three-hole ring	0.20	0.22	0.067	311.4	0.57	0.89
Trilobe	0.20	0.22	0.067	393.2	0.53	0.78

Pressure forming can also use a pellet press (or pellet mill or pelletizer) operating at a relatively lower pressure. Pellets are agglomerated by forcing them through orifices of the die by a rotating (gear) or rolling (roller) element. Similar to the tabletting machine operation, the material is densified, deformed, and pressed into large particles. For material sensitive to heat generated by compression, the feed hopper and rolls are usually cooled to control the temperature of the material. Lubrication is critical for adequate friction between the surfaces of the catalyst and die. Polymers are often used as a lubricant. The melting point of the polymer chosen should be slightly higher than the maximum temperature in the chamber of the press.

Compaction conditions affect the total pore volume and shape of pores for some materials. In general, pore volume is smaller for a catalyst granulated by a tabletting machine than that by a pellet press. Partial pore closure is possible for tablets having a very high crush strength.

A screw extruder is another type of pressure forming equipment used. The material is fed into the rear of the extruder, conveyed along the screw inside the barrel, and forced through an orifice die plate. The barrel can be heated or cooled to mediate the flow properties of the material. The screw is driven by a motor with variable speeds. The orifice of the die plate can be shaped into tri-lobe, quad-lobe, or other geometric shapes. The material flow within the barrel is primarily due to the drag force of the screw and can be estimated using the equation (for a single-screw machine):

$$Q = 0.5\pi^2 D^2 NL \sin\theta \cos\theta \quad (10)$$

where: Q = volume flow rate, D = barrel diameter, L = chamber length, N = screw speed, and θ = screw flight angle.

Binder is needed for forming extrudates. Besides water, colloidal alumina, silica, or cellulose are frequently used as binding material. The crush strength of the extrusion is normally weaker than the products granulated by compaction or compression. However, the advantages of extruding are high capacity and low cost.

Catalysts on structured supports are becoming more common in industry. The main application for such materials has been for environmental processes such as NO_x abatement and autocatalytic converters, but the concept has been gaining ground on other industrial applications.[32] The most common form of structured catalyst is the monolith, which is made of many channels where the active catalytic component is on the walls of the channels. Such structures can be made to have up to 1200 cpsi (channels per square inch) or more. The advantages of monolithic-type catalysts are lower pressure drop, greater geometric surface area, and no attrition due to vibrations. The disadvantages are that laminar flow through the small channels may cause mass transport limitations and no interconnectivity between channels causes poor radial heat conductivity.

The monolithic substrate can be made of either ceramic or steel. Ceramic monoliths are extruded in the form with cordierite being the main material used. Metallic monoliths are made by corrugation, followed by rolling or folding the metal into monoliths of the desired shape and size.

The washcoating procedure may be such that the catalyst powder is put onto the surface of the substrate

Table 10 Characteristics of catalyst forming methods

Forming method	Used for reactor type	Common shapes	Normal size range (mm)
Compacting	Tubular bed	Tablet, ring,	3–55
Compressing	Fixed bed	Pellet, ring	1.5–10
Extruding	Fixed bed	Extrudate, ring	1.2–6
Rotating	Fixed bed	Spheres	2–5
Oil-drop	Moving bed	Small spheres	1–3
Spraying	Fluid bed, bubble column	Micro-spheres	0.2–1.0

or the oxide support is put onto the substrate and then the active metal component is put on by impregnation, adsorption, or ion exchange.[33] Washcoating is the operation of dipping the substrate into a slurry of the material to be washcoated, followed by drying and calcination. The calcination fixes the powder to the surface of the substrate so that the walls of the channels are covered to the desired thickness. The operation is much more complicated in that process parameters such as density, viscosity, pH, particle size, and others affect the thickness and adhesion of the catalytic layer.

CONCLUSIONS

The preparation of heterogeneous catalysts is a complex operation that can incorporate many unit operations. The operation involves the formation of the catalyst precursor, separation, and purification, posttreatment, and forming. These operations can be carried out in many ways. All of these operations affect the physical and chemical properties of the final catalysts, which affect the performance in industrial use. Last, the economics of the process that uses the catalyst will be affected and is the ultimate driving force.

Catalytic Combustion for Thermal Energy Generation

Daniel G. Löffler
Quarens Technologies, Inc., Bend, Oregon, U.S.A.

INTRODUCTION

Catalytic combustion became probably the most ubiquitous catalytic reaction after the implementation of the automotive converter 30 years ago. Other uses include space heaters, flammable gas detectors, and miniaturized reactors for endothermic reactions. More recently, it has been applied to reduce NO_x production in gas turbines for power generation. This article describes the engineering principles of catalytic combustion and discusses in some detail their application to gas turbines. The breakthrough inventions that allowed catalytic combustion to move forward in the field of power generation are illustrated using a simple computer model. The discussion is limited to catalytic combustion applications involving thermal energy production; exhaust gas cleanup applications, such as unburned hydrocarbon or volatile organic compound removal are not discussed. Therefore, citations are limited mostly to contributions that resulted in significant advances to the development of catalytic combustion for heat generation.

CATALYTIC COMBUSTION IN POWER GENERATION

Conventional gas turbines use diffusion flame combustors which operate at temperatures high enough for reactions of nitrogen and oxygen in air to form substantial amounts of nitrogen oxides (NO_x), predominantly nitric oxide (NO) and smaller amounts of nitrogen dioxide (NO_2) and nitrous oxide (N_2O). Low levels of nitrogen oxides in the air cause eye and respiratory tract irritation and contribute to the formation of acid rain that damages vegetation. Other ill consequences of nitrogen oxide emissions include the formation of atmospheric particles that cause visibility impairment, and the formation of toxic chemicals such as nitrate radicals, nitroarenes, and nitrosamines, that could cause biological mutations. In addition, nitrous oxide is a greenhouse gas contributing to global warming. For these reasons, current regulations mandate NO_x levels of <10 ppm in combustion effluent streams.

Fig. 1A shows a schematic representation of a gas turbine fitted with a diffusion flame combustor. The turbine drive and the air compressor are connected by the power shaft, which can also be connected to any system using the power of the turbine, such as an electrical generator. A portion of the compressed air stream is mixed with the fuel and burned in the combustor. The effluent from the combustor is mixed with the remaining air and directed to the drive, where the gases are expanded to impart rotating power to the turbine shaft. The adiabatic flame temperature of the fuel/air mixture must be high, typically around 1800°C, for the diffusion flame to be stable. The combustion flue gas is then mixed with the remaining air to lower the temperature of the mixture to 1300°C. Gases at this temperature can be safely injected into the turbine expander without damage to the turbine blades.

Diffusion flame combustors are inexpensive to build and simple to operate. Their main drawback is that they produce substantial levels of nitrogen oxides. Fig. 2 shows plots of NO_x concentration vs. temperature in a well-mixed reactor under conditions typical of turbine combustors. The level of NO_x increases exponentially with temperature, reaching over 300 ppm at the operating temperature of the diffusion flame combustor. It is clear from the figure that essentially no NO_x would be formed if the combustion could be sustained at the temperature at which the gases enter the turbine drive. This suggests that adjusting the amount of fuel to keep the adiabatic flame temperature at around 1300°C upstream of the burner could reduce the formation of NO_x. Unfortunately, the lean combustion mixtures required to reduce NO_x to single-digit ppm levels lead to unstable flames. Frequent flameout and reignition events generate vibrations that impair the operation and even the mechanical stability of the turbine. In contrast, fuel and air mixtures sustain stable combustion on a catalyst at much lower temperatures and without the requirement for a flame.

Catalytic Combustor

The fundamental features of a catalytic combustor for a gas turbine were disclosed in a patent granted in 1975, but it took three decades and several additional inventions to turn that concept into a commercial product.[2] In late 2003, the first commercial gas turbine equipped with a catalytic combustor was put into operation, providing power to 120 buildings in a health care facility in California.[3] It should be noted that the only reason to use a catalytic combustor instead of a

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120025013

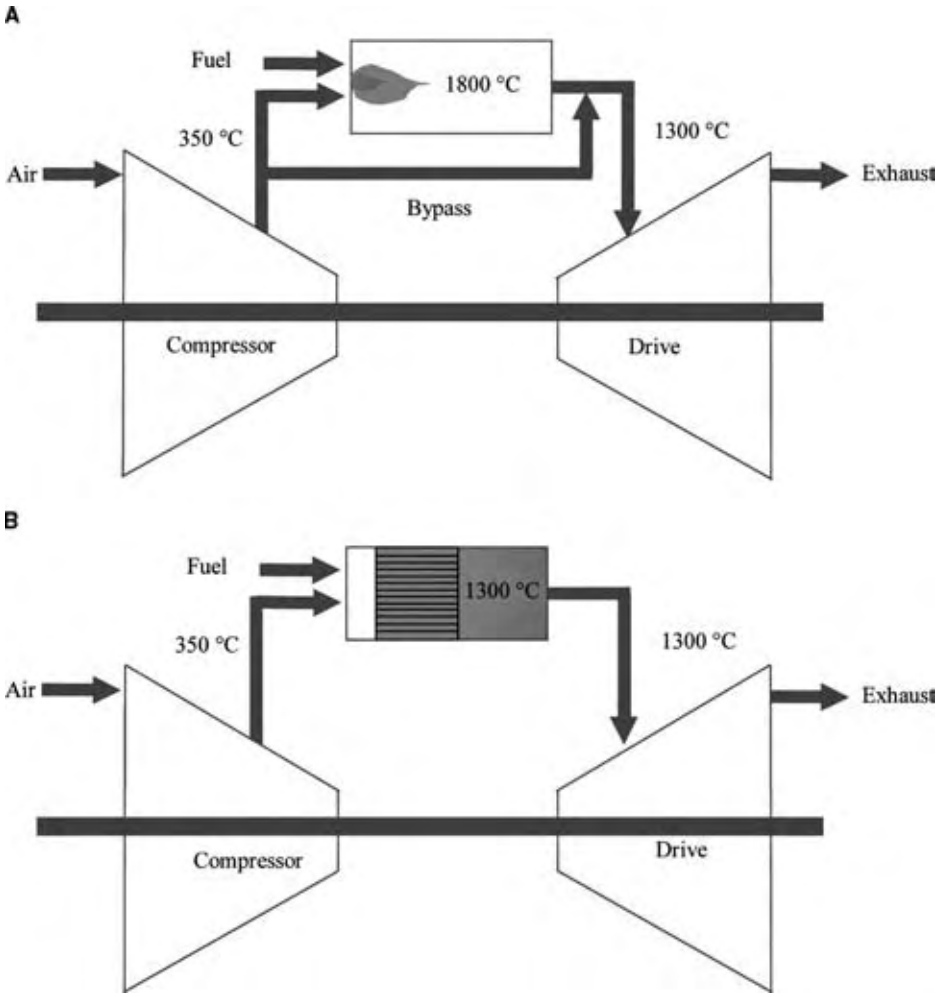

Fig. 1 (A) Schematic representation of a gas turbine fitted with a diffusion flame combustor and (B) fitted with a catalytic combustor. The bypass air stream is used to lower the temperature of the diffusion flame outlet to a level not damaging to the turbine blades. The catalytic combustor requires no bypass stream because the catalyst sustains stable combustion at 1300°C. *(View this art in color at www.dekker.com.)*

conventional diffusion flame combustor to generate the hot gas stream needed to drive a gas turbine is to reduce the level of nitrogen oxides produced in the combustion process. The use of catalytic combustion technology is then regulation-driven because there is no reduction in capital cost or gain in fuel efficiency. But without some type of nitrogen oxide abatement system, gas turbines would have been legislated to extinction in most of the industrialized world.

Fig. 1(B) shows a schematic representation of a gas turbine fitted with a catalytic combustor.[2] The entire air stream from the compressor is mixed with fuel and fed to the combustor. The adiabatic temperature of this mixture is 1300°C, therefore, the combustor exhaust gases are fed to the power turbine directly and without further dilution. Fuel is uniformly distributed over the cross-section of the combustor and mixed with air upstream of the catalyst. The catalyst is most frequently dispersed within a washcoat coated onto the surface of a monolith to minimize pressure losses and intraparticle transport restrictions.

Monolithic catalysts can be described as ''continuous unitary structures that contain many small, mostly parallel passages,'' with catalytic materials usually washcoated on the walls of those passages or channels.[4] Thus, the monolith can be visualized as a bundle of wall-coated parallel plug flow reactors. Little or no heat transfer occurs in the radial direction; hence, to ensure uniform temperatures over the cross-section of the monolith, the fuel/air ratio and the flow rates at the channel inlet must be the same for all channels. In those channels, the interplay of heat and mass transfer phenomena associated with fast and highly exothermic combustion reactions generate conditions conducive to ''hot spots'' and multiple steady states with the consequent appearance of ignition–extinction behavior.

The catalysts used in catalytic combustors must be active enough for the combustor to ignite (light off) at relatively low inlet temperatures, preferable below the compressor discharge temperature, to avoid using flame preheaters that would add complexity and possibly generate NO_x. Precious metals typically palladium and platinum show high activity for methane oxidation. Those metals are generally dispersed on porous supports to maximize the exposed surface area, and consequently, the catalytic activity per unit volume.

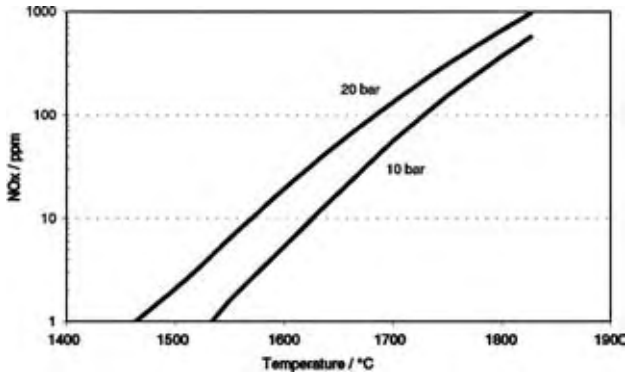

Fig. 2 Calculated NO_x levels vs. temperature for the pressures indicated. Curves were calculated using the GRI-Mech combustion kinetics database for an isothermal combustor with 20 msec residence time and an inlet composition showed in Table 1. (From Ref.[1].) *(View this art in color at www.dekker.com.)*

Early catalytic combustors built according to the teachings of reference[23] deactivated rapidly because high wall temperatures led to sintering of support materials and to evaporation of precious metals.[2] A staged combustor was suggested to solve this problem.[5] In this approach, an ignition stage, having a metal catalyst, was used to start the combustion. The subsequent stages, operating at high temperatures, carried the combustion to completion. The temperature in the ignition stage was to be controlled by simply reducing the length of the ignition catalyst so that not all the fuel was consumed. This approach failed because although exit gas temperatures were lower in the shorter ignition stage, wall temperatures were unchanged by these changes in residence time. A detailed understanding of heat and mass transfer in catalytic combustion became essential to recognize why shorter monoliths did not result in lower wall temperatures and to devise methods to control local temperatures at reactor walls.

The key interplay of reaction kinetics and transport phenomena in a catalytic combustor must be treated using rigorous reactor models. In the next section, we use a simple model to describe the behavior of a catalytic combustor and to interpret the technology breakthroughs that led to the successful implementation of catalytic combustion to reduce NO_x in power generation. The model will be kept simple, even though its additional complexities are readily incorporated, because our purpose is to show the main characteristics of a catalytic combustor rather than to provide accurate simulations of expected performance.

A mathematical model for a catalytic combustor

A number of mathematical models with various degrees of detail have been developed to simulate the behavior of monolith catalytic combustors. The simplest models reduced the simulation of the entire monolith to a description of a single channel by assuming adiabatic reactor operation, no thermal interaction between adjacent passages (thus, no net radial heat transfer), and equal flow rates in all monolith passages. The complete set of assumptions required for these models is described in reference.[4]

We shall develop next a single-channel model that captures the key features of a catalytic combustor. The catalytic materials are deposited on the walls of a monolithic structure comprising a bundle of identical parallel tubes. The combustor includes a fuel distributor providing a uniform fuel/air composition and temperature over the cross section of the combustor. Natural gas, typically >98% methane, is the fuel of choice for gas turbines. Therefore, we will neglect reactions of minor components and treat the system as a methane combustion reactor. The fuel/air mixture is lean, typically 1/25 molar, which corresponds to an adiabatic temperature rise of about 950°C and to a maximum outlet temperature of 1300°C for typical compressor discharge temperatures (~350°C). Oxygen is present in large stoichiometric excess and thus only methane mass balances are needed to solve this problem.

Assuming identical passages and uniform temperature and fuel distribution over the cross section of the monolith, we obtain the axial composition and temperature distributions by using mass and thermal energy balances over a plug-flow volume element in one channel. If we ignore homogenous gas phase reactions, all composition and temperature changes in the gas phase are due to mass and energy transfer through the washcoat interface. We assume further that there are no radiation losses, that the gas is well mixed radially across the channel, and that all resistances for mass and heat transfer between the gas phase and the washcoat can be lumped into the mass and heat transfer coefficients. The steady state mass and heat balances for the gas phase are described by two coupled ordinary differential equations similar to those for plug flow tubular reactors, except that the chemical reaction and heat generation terms are now located on the wall rather than in the bulk fluid.

$$\frac{d\xi}{dz} = \frac{S\,km(y_g - y_w)}{G} \tag{1}$$

$$\frac{d(T_g)}{dz} = \frac{ha_L(T_g - T_w)}{G\,cp_g} \tag{2}$$

where ξ is a dimensionless extent of reaction, z is the passage length, S is the cross-sectional area, km is a mass transfer coefficient, y_g and y_w are the molar fractions of methane in the bulk gas and at the washcoat

interface, respectively, T_g and T_w are the bulk gas and washcoat temperatures, respectively, G is the mass flow rate, h is a heat transfer coefficient, a_L is the area of the tube wall, and cp_g is the heat capacity of the gas. For methane combustion rates that are first order in methane and zero order in oxygen concentration, the rates of heat removal and heat generation are given by Eqs. (3) and (4), respectively.[6]

The rate of heat removal from the washcoat is proportional to the heat transfer coefficient and to the temperature difference between the gas and the washcoat, while the rate of heat generation is the product of the rate of mass transfer times the heat of reaction ($-\Delta H$), as indicated by Eqs. (3) and (4) below, where k_r is a first-order reaction rate constant. At the steady state the rates of heat generation and removal are equal.

$$Q_r = h(T_w - T_g) \tag{3}$$

$$Q_g = (-\Delta H) y_g \Big/ \left(\frac{1}{k_r} + \frac{1}{k_m}\right) \tag{4}$$

$$Q_g = Q_r \tag{5}$$

Eqs. (1), (2), and (5) must be solved simultaneously to obtain the methane conversion and temperature profiles for the monolith. Gas phase composition y_g and temperature T_g are calculated for each volume element from the mass and heat balances, Eqs. (1) and (2), and then substituted in the washcoat heat balance, Eq. (5). At the inlet of the monolith, where both the composition and the temperature of the gas phase are known, Eq. (5) can be solved independently.

Monolith with all channels coated with catalysts

Fig. 3 shows plots of Q_g and Q_r vs. T_w at the inlet of the monolith for three different gas inlet temperatures. The rate of heat generation has a sigmoidal shape, while the rate of heat removal is represented by straight lines. At low temperatures, Q_g presents an Arrhenius temperature dependence because k_r is the dominant term in Eq. (4). As the washcoat temperature increases, the process becomes mass transfer controlled, k_m dominates and the rate of heat generation becomes almost independent of temperature because of the weak temperature dependence of k_m. Eq. (5) is satisfied at the points of intersection between curves Q_g with the straight lines Q_r, which can evidently lead to more than one solution. For example, when the inlet gas temperature is 280°C, Eq. (5) is satisfied for three values of T_w. As the temperature of the inlet gas is increased, the two lower intersection points approach each other and eventually both points merge. A further

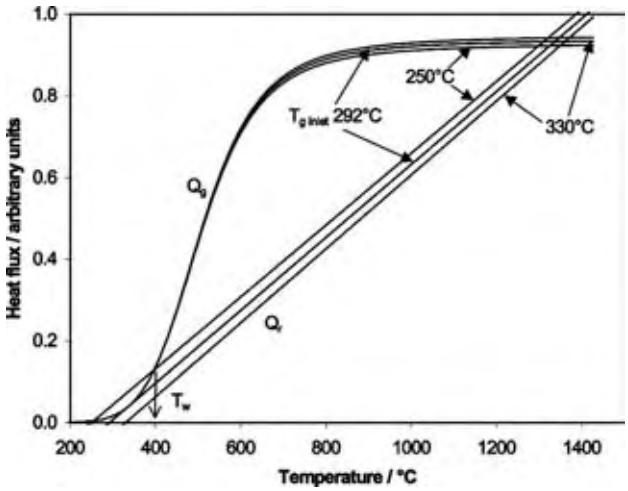

Fig. 3 Heat generated and removed at the inlet of a monolith combustor vs. temperature, calculated from Eqs. (3) and (4) for the conditions presented in Table 1. The straight lines represent the heat transfer curves in the absence of radiation losses. When the inlet gas temperature is 280°C, Eq. (5) is satisfied for three values of T_w: 297°C, 371°C, and 1326°C. As the temperature of the inlet gas is increased, the two lower intersection points approach each other and eventually both points merge at $T_w = 335$°C when the inlet gas temperature is 292°C. This is referred to as the catalytic ignition or light-off temperature. A further increase in the inlet gas temperature results in a situation where there is only one intersection point. *(View this art in color at www.dekker.com.)*

increase in the inlet gas temperature results in a situation where there is only one intersection point. The system operates then at a much higher T_w with a methane conversion nearly 100%. In practice, the inlet gas temperature should be higher than this ignition temperature to ensure that the combustor will operate with maximum conversion.

The upper branch of the sigmoidal curve corresponds to mass transfer conditions; hence, the wall temperature can be calculated by substituting Eqs. (3) and (4) in Eq. (5) and letting $k_r \to \infty$. Assuming that the resistances to heat and mass transfer can be represented by the film thickness δ_h and δ_m, respectively, we obtain, after some algebra, Eq. (6), where the Lewis number Le represents the ratio of the heat transferring capability of the gas to the rate of diffusion mass transfer. For mixtures of methane and air, $Le \sim 1$. Since $\delta_h \sim \delta_m$, the temperature of the washcoat at any point within the ignited monolith is close to the adiabatic temperature of the fuel/air mixture. For the inlet conditions in Table 1, the group $(\delta_h/\delta_m)/Le = 1.12$, and the inlet wall temperature estimated from Eq. (6) is 1371°C, as shown in Fig. 4.

$$T_w = T_g + \frac{\delta_h}{\delta_m}\frac{\Delta T_{ad}}{Le} \tag{6}$$

Table 1 Parameters used to simulate a catalytic combustor

Monolith	200 cpsi
Inlet conditions	
Pressure	12 bar
Temperature	330°C
Feed fuel/air ratio	0.0421
Adiabatic temperature rise ΔT_{ad}	933
Methane oxidation kinetics	
Activity	1740 mol/(sec cm^2 bar)
Activation energy	72 kJ/mole

Temperature and methane conversion profiles along the monolith calculated solving Eqs. (1), (2), and (5) for the conditions listed in Table 1 are also shown in Fig. 4. The washcoat temperature is highest at the inlet and then decreases slightly thereafter, asymptotically reaching the adiabatic temperature for the reactant mixture. The temperature is highest at the inlet because the concentration of methane, and hence the adiabatic temperature rise, is highest at that point. As the methane fuel is consumed, ΔT_{ad} decreases while the temperature of the gas T_g increases to become the dominant term in Eq. (8). Finally, washcoat and gas temperatures converge, reaching the adiabatic flame temperature of the fuel/air mixture after all fuel is combusted.

Fig. 4 shows that a short combustor would not lead to lower washcoat temperatures, because the washcoat reaches its maximum temperature immediately after ignition near the inlet of the channels. A short combustor would lead to incomplete methane conversion and low gas phase temperatures, both undesirable effects, without achieving the desirable effect lowering the washcoat temperature and preventing structural degradation of the catalyst. Surface temperatures reach the adiabatic temperature (~1300°C) even before detectable amounts of methane are combusted. Reducing the inlet temperature moves the ignition point farther away from the inlet, without significantly lowering washcoat temperatures (Fig. 5). A similar effect is expected from an increase in reactant flow rates.

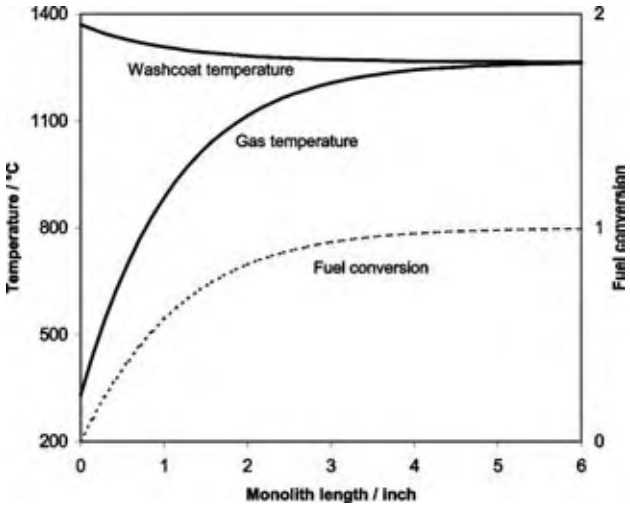

Fig. 4 Axial temperature and methane conversion distributions in a catalytic combustor calculated by solving Eqs. (1), (2), and (5) for the conditions presented in Table 1. The maximum washcoat temperature is obtained at the monolith inlet, where both gas temperature and fuel conversion are very low. Shortening the monolith would result in lower gas outlet temperatures and incomplete fuel conversion, but washcoat temperatures will remain unchanged. *(View this art in color at www.dekker.com.)*

Coupling of catalytic and noncatalytic channels by selective washcoating of a fraction of the monolith channels

An incremental improvement in the path to practical applications of catalytic combustion was disclosed by Yasuyoshi et al., who recognized the important applications of manipulating the heat balance in Eq. (5).[7] These authors coated the walls of alternate channels to have only half of the reactant flow passing through catalytic channels. For similar heat transfer coefficients in coated and uncoated channels, and assuming that there is no temperature gradient in the channel wall, the heat removal term in the heat balance is given by Eq. (7).

$$Q_r = h(T_w - T_{gcat}) + h(T_w - T_{gnoncat}) \quad (7)$$

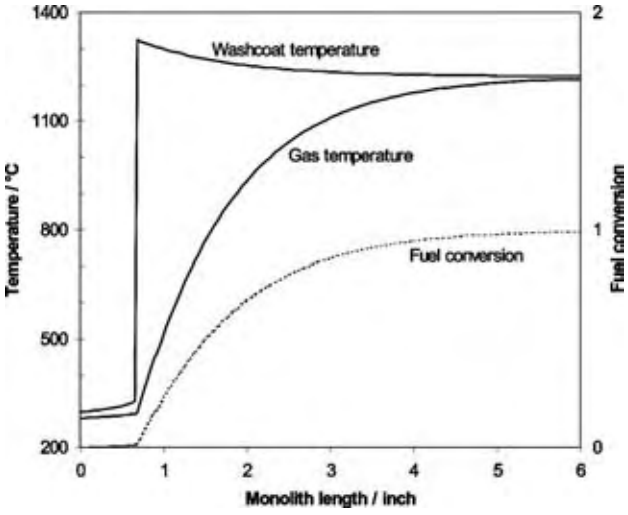

Fig. 5 Axial temperature and methane conversion distributions in a catalytic combustor. Conditions are as in Fig. 4, except that the temperature of the feed is now 280°C. The lower inlet temperature moves the ignition point downstream from the inlet of the monolith, but washcoat temperatures are not significantly reduced. *(View this art in color at www.dekker.com.)*

Because the gas flow rate is the same in both catalytic and noncatalytic channels, the gas temperatures T_{gcat} and $T_{gnoncat}$ are the same; hence, the heat removal rate is twice as fast as in the fully coated monolith. Heat and mass balances over the whole monolith show that only half the fuel fed can be consumed, even assuming full conversion in the catalytic channels. In consequence, the maximum outlet temperature of the gas phase will be the temperature for adiabatic combustion of the feed gas at 50% conversion.

Gas and wall temperature profiles and methane conversions obtained by integrating Eqs. (1), (2), and (5) after substituting Eq. (7) in the heat balance Eq. (5) are shown in Fig. 6. As for fully coated monoliths, the washcoat temperature is the highest at the inlet and decreases slightly thereafter, asymptotically merging with the gas temperature. Washcoat temperatures can be calculated from Eq. (8), which is derived by substituting Eqs. (4) and (7) in Eq. (5) and letting $k_r \rightarrow \infty$. The half-factor reflects the fact that the gas temperatures in the catalytic and noncatalytic channels are the same.

$$T_w = T_g + \frac{1}{2}\frac{\delta_h}{\delta_m}\frac{\Delta T_{ad}}{Le} \tag{8}$$

The inlet wall temperature estimated from Eq. (8) is 810°C for the conditions in Table 1, well below the value of 1371°C calculated in fully coated monoliths. The light-off temperature is 327°C, greater than the value of 292°C for the fully coated monolith, because heat transfer area is twice as large; hence, it takes a faster rate of heat generation to reach the ''runaway'' ignition conditions.

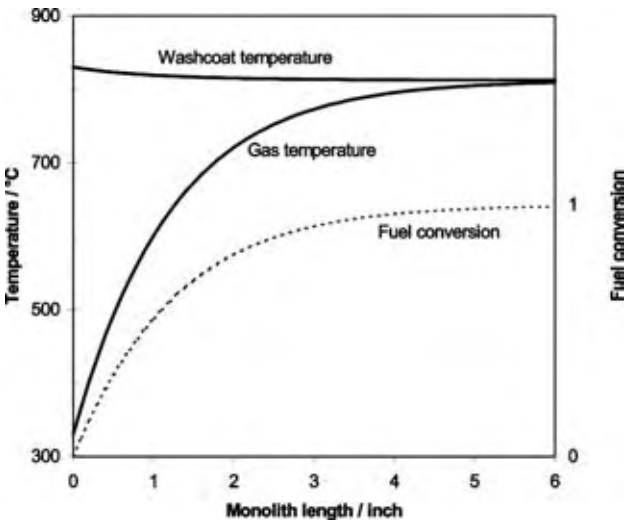

Fig. 6 Axial temperature and methane conversion distributions in a catalytic combustor with alternate channels coated. One-half of the total gas flow passes through catalytic channels. Curves are calculated solving Eqs. (1), (2), and (5) for the conditions presented in Table 1, after substituting Eq. (7) in the heat balance Eq. (5). Temperatures are much lower than in the fully coated monolith of Fig. (4). *(View this art in color at www.dekker.com.)*

Catalyst life was significantly improved by implementing the teachings of reference[7] but two problems remained.[7] First, the washcoat temperature, although much lower than in the fully coated monoliths, remained high enough to cause sintering of highly dispersed precious metals. Also, early catalytic combustors contained ceramic monoliths, which limited channel size and were easily destroyed by rapid temperature cycling. These problems were addressed in a patent application by Retallick and Alcorn, which disclosed corrugated metal foil monoliths and procedures to assemble those monoliths by coating one side of the metal foil strip and then rolling it to form a channel structure with alternating catalytic and noncatalytic channels.[5] Metal foils with chevrons or herringbone corrugations are coated with catalyst on one side, laid one on top of the other, and then rolled into a cylinder to form a monolith structure. This monolith contains alternating coated and uncoated channels with the walls of the coated channels cooled by the uncombusted fuel–air mixture flowing in the uncoated channels. The metal strips are able to expand thermally in both length and width and these metal monoliths are far more tolerant to thermal shock than ceramic structures.

Retallick and Alcorn also showed that similar structures could be built up by alternating catalyst-coated flat strips with uncoated strips having straight or other corrugations. By varying the height of the corrugations or the number of noncatalytic channels between catalytic channels it is possible to design structures where more gas would flow through noncatalytic channels than through catalytic channels. The temperature of the gas in the noncatalytic channels will then be lower than in the catalytic channels. The mixing-cup temperature of the gas leaving the monolith can be calculated from a heat balance over the volume of the monolith. For example, if the gas flow in the coated channels is 30% of the total gas flow rate, assuming full conversion in the catalytic channels the mixing-cup temperature of the outlet gas will be equal to the temperature for adiabatic combustion of the feed gas at 30% conversion.

Gas and wall temperature profiles and methane conversions, calculated integrating Eqs. (1) and (2) after substituting Eq. (7) in the heat balance Eq. (5), are shown in Fig. 7 for a monolith in which 30% of reactant inlet flow occurs in catalytic channels. As for fully coated monoliths, the washcoat temperature is highest at the channel inlet and decreases slightly thereafter, asymptotically reaching the gas temperature. Washcoat temperatures become much lower in

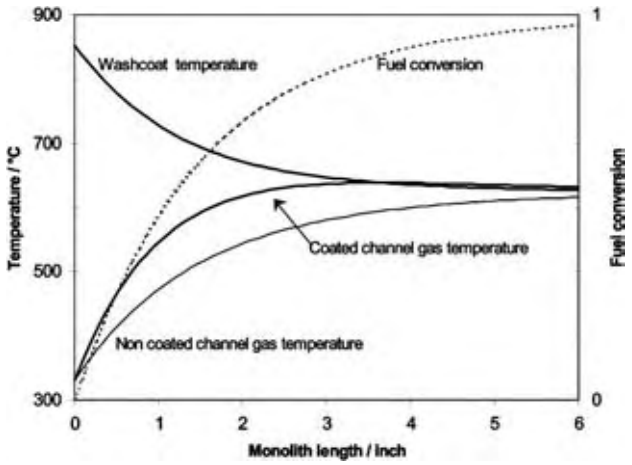

Fig. 7 Axial temperature and methane conversion distributions in a catalytic combustor with alternate channels coated. Thirty percent of the total gas flow passes through catalytic channels. Curves are calculated solving Eqs. (1), (2), and (5) for the conditions presented in Table 1, after substituting Eq. (7) in the heat balance Eq. (5). Gas and wall temperatures are considerably lower than in the case of Fig. 6 except for the inlet wall temperature, which is independent of the fraction of flow passing through catalytic channels when only one wall of the channels is coated. *(View this art in color at www.dekker.com.)*

monoliths with half of the channel coated at all points in the combustor, except at the inlet. At this point, the temperature of the gas is the same in both catalytic and noncoated channels and the washcoat temperature is governed by Eq. (8). It follows that the temperature of the washcoat at the inlet of the partially coated monolith is largely independent of the fraction of coated channels. For similar reasons, the light-off temperature at the inlet of a partially coated monolith does not change with the fraction of coated channels.

As indicated above, the inlet temperature obtained using partially coated monoliths, although substantially lower than those observed in fully coated systems, may not be low enough to prevent sintering of the highly dispersed metal catalysts. A new invention was needed to reduce the temperature of the leading edge of the monolith to allow low-temperature operation of highly active catalysts.

Partially coated monolith with diffusion barrier layer

The temperature of the leading edge of the monolith is governed by Eq. (8); hence, to lower the wall temperature (T_w) the terms in the right-hand side of the equation need to be reduced. Reducing the inlet gas temperature would require cooling down the inlet air stream, an operation that would impact on the energy efficiency of the gas turbine. Also, if the inlet gas temperature (T_g) were reduced, more active catalysts would be needed to maintain light-off at reasonable inlet temperatures. Those catalysts must be even more dispersed and, consequently, more sensitive to sintering than less active catalysts used at higher inlet temperatures. The adiabatic temperature rise ΔT_{ad} cannot be reduced, because that would decrease turbine efficiency, and the Lewis number cannot be varied because it reflects intrinsic transport properties of the fuel–air mixture. Hence, the only parameter left to change is the ratio of transport resistances δ_h/δ_m. This ratio can be manipulated by coating an inert porous layer on top of the washcoat, adding heat and mass transfer resistances in series with those of the boundary layer. In the porous layer, the resistance to mass transfer is larger and the resistance to heat transfer is smaller than in the boundary layer because mass transfers through the void fraction only, while heat transfers through gas and solid and the heat conductivity of the solid is much larger than that of the gas. The net effect of adding an inert porous layer is then to reduce the washcoat temperature by decreasing the mass flow to the catalytic washcoat without significantly changing the rate of heat transfer.

Dalla Betta et al. first proposed an inert porous layer, or diffusion barrier, to prevent temperature runaway, and loosely interpreted the effect in terms of a reduction in the rate of combustion.[8] A more rigorous interpretation of the effect of an inert porous layer on catalyst temperature was provided by McCarty et al, who also described the desired properties for diffusion layer materials, including a high thermal conductivity and low specific combustion activity.[9] These authors stated that the high washcoat temperatures found in catalytic combustion of natural gas were due to the high diffusivity of methane in air, which causes the diffusion rate to the catalyst surface to match the rate of heat dissipation by conduction to the gas phase. The diffusion barrier decreases the rate of diffusion of methane to the catalyst surface, thus reducing the catalyst temperature. Modeling work by Hayes et al. confirmed those concepts.[10]

It should be noted that the porous layer has no effect on the light-off temperature at the leading edge of the monolith. The onset of light-off occurs at low temperatures, when the reaction rate constant k_r dominates the denominator of Eq. (4). By coating a small fraction of the active channels and providing a porous layer, the temperature of the washcoat can be kept low enough to prevent from catalyst degradation while allowing light-off at compressor discharge temperature.

The effect of a diffusion barrier layer on combustor performance is evident in the model calculations shown in Fig. 8. Temperatures at the monolith inlet are dramatically lower than those presented for the

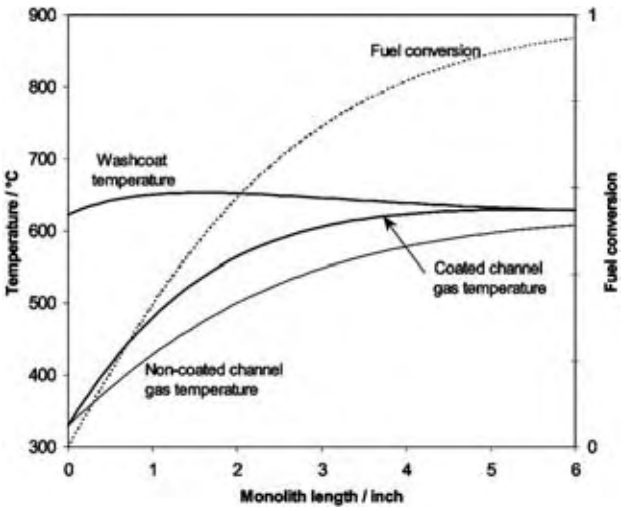

Fig. 8 Axial temperature and methane conversion distributions in a catalytic combustor with alternate channels coated and a diffusion barrier layer deposited on top of the washcoat. The thickness of the diffusion barrier layer decreases exponentially downstream from the inlet. Thirty percent of the total gas flow passes through catalytic channels. Curves are calculated solving Eqs. (1), (2), and (5) for the conditions presented in Table 1, after substituting Eq. (7) in the heat balance Eq. (5). Gas and wall temperatures are close to those in Figure 7 except for the inlet wall temperature, which is much lower now because the diffusion barrier layer limits the diffusion rate of methane to the washcoat. *(View this art in color at www.dekker.com.)*

uncoated monolith in Fig. 7, while fuel conversion and outlet gas temperatures do not change significantly.

Homogenous combustion after partially coated monoliths

Methane reactants within noncatalytic channels remain unburned and they must be combusted in a fully catalytic stage or in a homogenous flame. A fully catalytic monolith would cause the catalyst to reach adiabatic temperatures and to deactivate. Thus, the only practical option is to complete the combustion in a homogenous combustion process.

The partially combusted gases exiting the monolith will ignite after a period of time that depends on their temperature and composition at the outlet of the monolith. The temperature of the fuel–air mixture at that point must be high enough that the homogenous combustion is completed within residence times typical of turbine combustors (~20 msec). Longer residence times might result in combustors too big to fit within the space limitations of gas turbine enclosures. Homogenous kinetic simulations indicate that >300 msec residence time is required to combust the outlet gases from the monolith (Fig. 8) to CO levels below 10 ppm. Clearly, higher monolith exit temperatures are required to ensure complete homogenous combustion. One approach would be to use multiple catalytic combustor stages in which the channels in the first stage are coated with highly dispersed metal catalysts for low-temperature light-off. To protect these highly dispersed metals, the first-stage monolith should have a small fraction of coated catalysts and an inert diffusion layer, such as in the case of Fig. 8. The outlet gases from the coated and noncoated channels are mixed at the outlet of the first stage and then introduced into a second stage, in which more methane is converted and the stream temperature rises to levels required for fast homogenous ignition. The catalyst in this second stage need not be as active as in the first stage because the higher inlet temperatures allow much faster light-off along the channel. Less active catalysts are generally poorly dispersed and more tolerant of high temperatures.

A two-stage combustor operating under the inlet conditions as shown in Table 1 and using monoliths with 30% and 40% of the flow though catalytic channels in the first and second stages, respectively, will have second stage outlet gas temperature of 888°C. The time evolution of CH_4 and CO concentration and temperature in the homogenous combustion process after the second catalytic stage, calculated using the GRE-Mech kinetics, is shown in Fig. 9.[1] The sharp drop in methane concentration accompanied

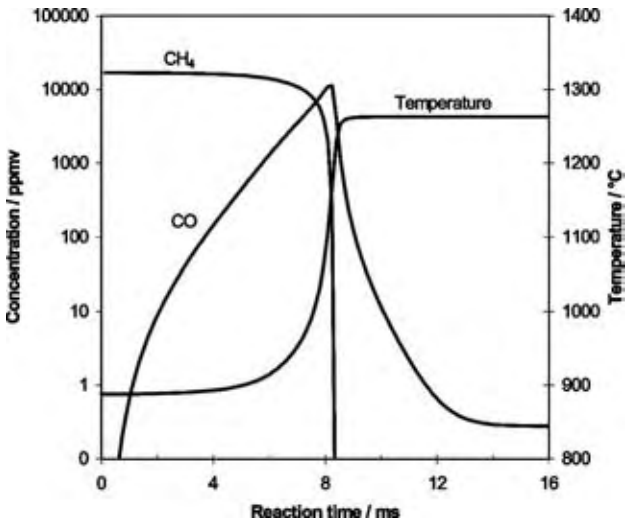

Fig. 9 The time evolution of CH_4 and CO concentration and temperature in an adiabatic flame calculated using the GRE-Mech kinetic mechanism. The flame temperature in this example is 1263°C, but this design allows for much higher flame temperatures, if needed. (From Ref.[1].) *(View this art in color at www.dekker.com.)*

by a steep rise in temperature at 8 msec denotes flame ignition. Combustion of CO to a level below 1 ppm occurs at 12 msec. Only a very small amount of CO is produced in the catalytic stages, most of the CO forms before ignition in the homogenous combustion stage.[11]

Catalytic combustion catalyst

Palladium oxide supported on metal oxides such as zirconia with various additives is the catalyst of choice for the combustion of natural gas in gas turbines because of its high activity for methane oxidation, which leads to light-off at low temperatures, and its low volatility, which minimizes sintering rates and evaporative metal losses. This catalyst presents an unusual situation in that the thermodynamically stable phase can be either Pd metal or PdO, depending on the oxygen partial pressure and the temperature. Low temperatures and high oxygen concentrations favor the oxide phase, which shows higher combustion activity than metal surfaces. Because the metal-oxide phase transition occurs under conditions of oxygen concentration and temperature found in turbine combustors, the mechanism of PdO formation and decomposition in a reaction stream containing methane and oxygen, and the kinetics of methane oxidation on both oxide and metal phases, have received considerable attention.[12] Thermodynamic calculations indicate that PdO is stable in the first-stage monolith of Fig. 6, while Pd metal is favored in the second-stage monolith. The activity of Pd metal is considerably lower than that of the oxide, but it is still high enough to allow light-off and to maintain the combustion reaction under mass-transfer control. For this reason, the peculiar behavior of the rate of methane oxidation versus temperature is largely invisible to the users of catalytic combustors.

OTHER APPLICATIONS OF CATALYTIC COMBUSTION

Catalytic combustion is used in radiant heaters for appliances such as stoves for outdoor use, that take advantage of the insensitivity of catalytic burners to windy conditions, and in industrial applications such as paint drying and plastic thermoforming, where the heat source operates in potentially explosive atmospheres. An interesting application of catalytic combustion in a consumer product is the cordless curling iron that works with a small cartridge of butane fuel. In this device, heat production and dissipation are matched to yield the desired temperature of 55°C with a fuel that could have an adiabatic flame temperature higher than 2000°C.[13] Catalytic combustion devices are also used to detect flammable gases in air. The concentration of the gas is measured through the heat released by combustion, either by placing a thermocouple on a dispersed metal catalyst or by measuring the electrical resistance of a catalytic metal wire.

Endothermic reactions, such as steam reforming, are usually carried out in long narrow tubes filled with catalysts and externally heated by flames. The heat could be provided more uniformly and more accurately at the necessary level by a combustion catalyst coated on the outside of the tubes, and heat transfer rates could be further improved by coating the endothermic reaction catalyst on the inner wall of the tube. In this way, the heat of combustion is transferred to the heat sink (the endothermic reaction) through the solid wall, avoiding solid–gas heat transfer resistances. However, the tubular geometry is not most efficient for this application because of the difficulty to coat the inside of the tubes and the need to include static mixers to facilitate mass transfer to the catalytic surfaces.

A preferred embodiment of this concept is the catalytic plate reactor, which consists of catalytically coated metal plates so that exothermic and endothermic reactions take place in alternate channels. In addition to minimizing the heat transfer resistances, this reactor facilitates mass transfer to the catalytic surface by reducing the diffusion length. Catalytic plate reactors can find applications in steam reforming, dehydrogenation, and hydrocarbon cracking which are strongly endothermic processes. In recent years those reactors have received considerable attention as steam reformers for fuel cell applications.[14]

ISSUES WITH CATALYTIC COMBUSTION

There are a few drawbacks associated with catalytic combustion. First, as noted by Pfefferle, the power density is low.[15] The volumetric heat release rates of catalytic combustors (without a homogenous flame downstream) are much lower than those found in conventional flame combustors because catalytic combustors are mass transfer limited, and mass transfer coefficients are relatively low.

Catalyst durability remains a concern, even after early problems related to thermal stability have been solved allowing turbine operation for >8000 hr.[3] Airborne impurities, such as silicones (organo-silicon compounds containing the functional group $Si(OH)_x$) can lead to stoichiometric deactivation. When a silicone molecule burns on an active site, the carbon and hydrogen atoms react to form carbon oxides and water leaving a silicon residue to deactivate the active site. Metal-containing organic molecules may cause the same effect. Rigorous filtering of the intake air is absolutely needed to ensure stable operation.

A major consideration in power generation applications is the sensitivity of the catalytic combustor to homogenous combustion in noncatalytic channels. If for some reason (for example, a momentary reduction in gas flow rate) the homogenous combustion backs up to the exit of the second-stage monolith, the gas in the uncoated channels may ignite. The adiabatic temperature of the gas at the outlet of the noncatalytic channels is the temperature of the gases at the outlet of the second stage plus the adiabatic temperature rise of the gases at the inlet of that stage. For the two-stage combustor discussed above, operating with the inlet conditions of Table 1 and using the monolith of Fig. 8 in the first stage, the adiabatic temperature rise of the feed to the second stage is 643°C. Since gas at the outlet of the second stage monolith is at 888°C, the gas in the uncoated channels will burn with an adiabatic flame temperature of 1531°C, effectively melting the metal monolith. Thus, catalytic combustion is very unforgiving of flow rate fluctuations; it takes only one accident to destroy the combustor.

This problem can be circumvented in a fuel-rich approach to catalytic combustion for gas turbines recently proposed.[12] In this method fuel is mixed with air to form a fuel-rich mixture that is reacted over the catalyst to produce both partial and total oxidation products. The reaction products are then mixed with excess air and burned in a homogenous flame. Because the gases exiting the catalyst are fuel-rich, they cannot sustain combustion in the event of a homogenous flame backup. The promise of this method needs to be confirmed in full-scale turbine tests.

CONCLUSIONS

Advances in chemical reaction engineering and catalytic materials have allowed catalytic combustion for thermal energy generation to be commercialized in consumer and industrial applications. The development of catalysts coated on one side of a metal substrate, coupled with the use of diffusion barriers, has allowed controlling the combustion temperature to suit diverse applications. Catalytic materials have been developed to remain active for thousands of hours under conditions deemed too severe just a few years ago. We may expect that the need for clean distributed power increases the demand for gas turbines fitted with catalytic combustors and promotes the development of catalytic burners to be used in fuel processors for fuel cell power systems.

Catalytic Cracking

Paul O'Connor
Akzo Nobel Catalysts, Amersfoort, The Netherlands

INTRODUCTION

Catalytic cracking is a very flexible process used to reduce the molecular weight of hydrocarbons. Today, fluid catalytic cracking (FCC) remains the dominant conversion process in petroleum refineries. Although FCC is sometimes considered to be a fully matured process, new challenges and opportunities in its application and a continuing stream of innovations in the process and catalyst field ensure that it will remain an important and dynamic process in the future of refining.

HISTORICAL PERSPECTIVE

Prior to 1925, the higher-boiling heavy crude oil molecules were chemically changed to smaller naphtha (gasoline) molecules by thermal decomposition using a process called thermal cracking. In the late 1920s, Eugene Jules Houdry demonstrated that the catalytic cracking process yields more gasoline with higher octane content. The first full-scale commercial fixed-bed catalytic cracking unit began production in 1937.

PROCESS DEVELOPMENT

During catalytic cracking, the catalysts are covered after a short time by a deactivating layer of coke. This coke can be removed and regenerated by burning, but the regeneration time is relatively long compared to the reaction time. An efficient way to solve this problem is to move the catalyst from one reactor (for hydrocarbon cracking) to another reactor (for catalyst regeneration).

The first continuous circulating catalyst process using bucket elevator thermofor catalytic cracking (TCC) was started up in Paulsboro, New Jersey, in 1941. The moving bed solved the problem of moving the catalyst between efficient contact zones. However, the catalyst beads used were still too large, limiting the regenerator temperatures to avoid intraparticle heat exchange and therefore requiring a large regenerator and catalyst holdup.[1]

Moving the solid catalyst in this way remained a challenge, which was solved by making use of the theory that it is possible to make a powder flow in a manner similar to a liquid if enough gas flows through it. This phenomenon is called fluidization, and the FCC process was introduced, which uses fine powdered catalysts that can be fluidized. The first commercial circulating fluid bed process went into production in 1942 in Baton Rouge, Louisiana.[2] By the 1970s, FCC units replaced most fixed- and moving-bed crackers.

Generally, FCC units operate in a heat-balanced mode whereby the heat generated by the burning of coke is equal to the heat needed for the vaporization of the feed plus the heat of cracking. Also, the pressure balance of an FCC unit is very important to ensure proper catalyst circulation and to prevent contact between the hydrocarbons (reactor) and air (regenerator). Overall, this makes the optimal operation of a unit a very interesting challenge.

The FCC process equipment and operations have continued to coevolve with the catalyst and the changing economical and environmental requirements. Key developments in FCC processes and machinery are:[1,3]

- Short-contact-time riser reactors.
- Feed distribution and atomization.
- Feed prevaporization or "supercritical" injection.
- Multiple feed injection.
- Quick product disengagement and separation from catalyst.
- Quick product quenching.
- More efficient stripping.
- Downer (downflow) reactors.
- Improved regenerator efficiency and lower inventory.
- Improved control of combustion (reduction in CO, CO_2, SO_x, NO_x).
- Improved air-grid designs.
- Catalyst coolers (internal and external heat removal).
- Power recovery from flue gas.
- Improved high-flux standpipes.
- High-efficiency cyclone separators.
- Cyclones without diplegs.
- Third-, fourth-, and fifth-stage particulate capture systems.
- Erosion- and high-temperature-resistant metallurgy.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007694

These developments have led to dramatic reductions in the size (elevation, volume, catalyst inventory) and, hence, costs of an FCC unit per barrel of feed charged and converted.

CHEMISTRY AND KINETICS

The catalytic cracking of hydrocarbons is a chain reaction that is believed to follow the carbonium ion theory, involving three steps: initiation, propagation, and termination. The initiation step is represented by the attack of an active site on a reactant molecule to produce the active complex that corresponds to the formation of a carbo-cation. Chain propagation is represented by the transfer of a hydride ion from a reactant molecule to an adsorbed carbonium ion. Finally, the termination step corresponds to the desorption of the adsorbed carbenium ion to give an olefin while restoring the initial active site.[4]

The carbenium-ion cracking mechanism produces a higher yield of a much more desirable gasoline than thermal cracking. While thermally cracked gasoline is quite olefinic, catalytically cracked gasoline contains a large amount of aromatics and branched compounds, which is beneficial for the gasoline's octane numbers (research octane number—RON, and motor octane number—MON). Table 1 illustrates the differences in the kinetics of thermal and catalytic cracking at about equal conversion. The data indicate that even for catalytic cracking, wide differences are possible. Only carbenium-ion cracking involving a tertiary carbenium ion produces branched compounds. A second type of cracking, protolytic[5] cracking can take place, yielding more ''radical cracking''-like products such as methane and ethane (fuel gas).

CATALYSTS

Table 2 lists the types and forms of cracking catalysts developed and used over the years. The way in which catalysts are built up from the separate components (catalyst assembly) and the form of the catalysts have a significant impact.[6]

The first FCC catalysts, super filtrols, were produced by activating clays with acid. These materials were originally used to bleach edible oils and decolorize hydrocarbons. Synthetic mixed oxide catalysts followed, some of which were two to three times more active than the activated-clay-based types. The Al_2O_3 of $SiO_2{\cdot}Al_2O_3$ was optimized by impregnating dry SiO_2 gels in the 10–25% Al_2O_3 range. The high-Al_2O_3 catalysts (25% Al_2O_3) exceeded the low-Al_2O_3 catalysts and super filtrol steamed activity level. Later on, clay was added in the preparation of synthetic $SiO_2{\cdot}Al_2O_3$ catalysts to provide additional macroporosity.

Cocurrently, microspheroidal (MS) catalysts were developed, recognizing the advantages of a catalyst with higher alumina content and improvements in impregnation efficiency with small particles compared to the traditional lumps of silica hydrogel. The original process was quite burdensome and involved an emulsion process, which was soon replaced by spray drying of the impregnated gel. Spray drying is still the way all FCC manufacturers compound and form their MS catalysts.

In the 1950s, zeolites were invented, and their potential application in catalysis received great deal of attention.[7] In the 1960s, Mobil[8] introduced zeolites into FCC catalysts, leading to very substantial increases in conversion and gasoline production, as shown in Table 3.

The first-generation zeolite catalysts were based predominantly on $SiO_2{\cdot}Al_2O_3$ gels (''matrix'') in which the zeolite was added at some point prior to spray drying. In the ''in situ'' crystallization method as applied by Engelhard, kaolin-based microspheres are prepared and calcined, after which zeolites are crystallized in the microspheres, leaving zeolite in an ''Al_2O_3-enriched matrix.''

In the early 1970s, Grace Davison introduced the use of a silica hydrosol-based binder for the incorporation of zeolites. Silica hydrosol is polymerized silica dispersed in water to form a clear continuous phase; it is a binder giving dramatic improvements in attrition resistance and density. The result is the creation of particles that are encased in a hard, resilient shell of a vitreous material. The low activity of the silica hydrosol relative to the $SiO_2{\cdot}Al_2O_3$-based systems enhanced the selectivities of nearly pure zeolite cracking, resulting in further improvements in gasoline and coke yields. Nevertheless, alternate routes for using Al_2O_3

Table 1 Catalytic vs. thermal cracking

Conversion	*i*C5/*n*C5 ratio	(C1 + C2)/*i*C4 ratio	Fuel gas (mol/mol cracked)
Thermal	0	66	2
Activated carbon	0.06	27	0.54
Alumina	0.2	14	2.72
Silica–alumina	3.8	0.6	0.41

Table 2 Early days of cracking catalysts

Year	Process	Reactor system	Catalyst type	Catalyst form
1920	McAfee	Batch	$AlCl_3$	Granulated
1939	Houdry	Fixed bed	Clay	Acid treated Granulated
1940	Suspensoid	Liquid phase	Clay	Ex-lube oil decolorizing Powdered
1942	FCC	Fluid bed	Clay	Super filtrol Acid treated Powdered
1945	TCC, Houdry flow	Moving bed	Clay	Acid treated Pellets
1942	FCC	Fluid bed	Synthetic $SiO_2{\cdot}Al_2O_3$	Ground
1946	FCC	Fluid bed	Synthetic $SiO_2{\cdot}Al_2O_3$	Microspheres
1965	FCC	Fluid bed	X, Y zeolites	Microspheres

gel and/or $SiO_2{\cdot}Al_2O_3$ gels as binders and as catalytic functional materials are still being pursued because of the significance of the porosity and permeability of the microspheres.

The importance of diffusion restrictions in FCC catalysis is often questioned. Short-contact-time pilot riser experiments confirm that combining zeolites with ''diffusion-enhancing'' matrices can result in significant product selectivity and product property improvements. The industrial benefits of a nonzeolite ''matrix'' on bottoms cracking in heavy vacuum gas oil (VGO) and resid FCC (RFCC) have also been confirmed in practice. Recently, some new methods have been used[6,11] to measure the accessibility of FCC catalysts.

Besides faujasite (Y) zeolites, today's catalysts contain several additional functional materials,[9] such as metal traps, nickel-resistant matrices, bottoms-cracking matrices, and small pore zeolites, such as, for instance, ZSM-5. These zeolites are often added as separate (additive) particles with the intention of boosting the gasoline octanes and/or the production of light olefins (propylene).

Also, separate FCC additives are produced, usually consisting of metals (Pt, Pd, Ce, V, Cu, Co, Zn) on alumina and/or alumina–magnesia supports for CO_2, CO, SO_x, and NO_x control of the regenerator off-gas[10] and for sulfur reduction of gasoline.

Table 3 Improvements in zeolite cracking catalysts

Catalyst	Conversion (vol.%)	Gasoline (vol.%)
Silica–alumina gel	56	40
REHX	68	52
REHY	75	58

Catalyst Aging and Deactivation

FCC catalysts are deactivated via several mechanisms,[11] all of which result in loss of activity and change in yield selectivity. Catalysts age, meaning they undergo change in chemical and physical structure due to the (hydro-) thermal conditions during the 10,000–50,000 reaction and regeneration cycles they endure. Catalysts can also be poisoned, whereby their active sites are covered by coke and/or polar molecules (nitrogen), which neutralize catalytic activity, or by metals (V, Ni, Na), which can destroy or alter the activity. Catalysts can also be deactivated by fouling, whereby coke and/or metals are deposited and block the catalyst pores, thereby limiting mass transfer.

Reversible deposits (nitrogen, coke) are removed during regeneration. If we assume that the poisoning effect increases with the concentration of the deposits, then the poisoning effect is inversely proportional to the catalyst-to-oil ratio, and therefore is dependent on the coke selectivity of the catalyst. Irreversible catalyst poisons (metals), on the other hand, build up and continue to interact with the catalyst.

The very detrimental effects of contaminants such as Fe and Ca on the accessibility and performance of catalysts has been reported.[6,12,13] Apparently, these contaminants can result in (liquid) eutectic melts on the surface of the catalyst particles, which can block their entrance pores and even cover the whole catalyst surface.

FEEDSTOCKS, PRODUCTS, AND THE ENVIRONMENT

To strike a balance between product demand and refinery feed composition, more residue with high

metal content and Conradson carbon residue (CCR) is being included in FCC feedstocks. Improvements in process and catalyst technology have resulted in a further opening of the feedstock processability window.

Environmental regulations are becoming a key driving force for reducing FCC process air-pollutant emissions[10] and for changing the composition of fuel products.[9] This is affecting the design and operation of FCC and is providing new opportunities for the development of catalyst and additive technology.

FUTURE ROLE OF FCC IN REFINING: FEEDSTOCK CHALLENGES

Fluid catalytic cracking is sometimes said to be an evolved process. However, new challenges and opportunities are ever-present in its application, and constant innovations ensure that it will be crucial in the future of refining.

From the beginning, FCC was employed to upgrade atmospheric (or long) residue. By distillation under vacuum, FCC feedstock (also called VGO) was separated from vacuum (or short) residue. Distillation techniques have been extended to increase the yield of FCC feedstock, and this development (revamps of vacuum units) is still taking place at various refineries. This deeper distillation does sufficiently restrict metals (Ni, V, etc.) and nonreactive and coke-producing components (CCR) in the distillate FCC feedstock. In some cases, deasphalting was and is employed to further increase the yield of acceptable FCC feedstock.

With the advent of better catalysts and effective additives, FCC feed preparation by vacuum distillation has become redundant for certain low-metal/CCR crude oils, so that the atmospheric residue can be processed in an FCC unit directly. The range of crude oils from which the atmospheric residue can be processed ''directly'' can be extended by revamping existing FCC units or building special new FCC units, RFCC units, and/or heavy-oil crackers.

The main feature of such an RFCC revamp is increasing the coke-burning capacity of the regenerator while maintaining the FCC unit in heat balance (often by incorporating catalyst coolers in the regenerator). Also, the employment of improved catalysts that reduce coke formation and enhance tolerance for metals (notably V, Fe, and Na) has enabled this development in RFCC.

In the refining world, the FCC process as a residue upgrader has to compete with other catalytic processes (such as hydrocracking) and thermal processes (such as thermal cracking, visbreaking, and coking). During the period 1983–2003, RFCC emerged from a very small base to deployment of nearly 4 million barrels a day, while several other new processes failed and passed from the scene.[14] Among the trends over the last few years are:

- Continued large increase in delayed coking capacity, particularly for processing of the lowest-quality vacuum residues.
- Significant increases in RFCC capacity in both grassroots facilities (China, India, Middle East) and FCC revamps.
- Continued growth and extension of the use of hydrodesulfurization and hydrodemetallization (HDS/HDM) processes to treat poor-quality residues for the preparation of RFCC feedstocks.
- Broader commercial application of residue hydrocracking technologies to vacuum residues, especially with ebullating bed processes.
- Continued rapid expansion of hydrogen manufacture to meet the needs of increased residue conversion capacity and to meet environmental needs for transportation fuels.
- The emergence of coproduction, via residue gasification, of hydrogen and power in refinery settings.
- A dramatic expansion of ''field'' upgrading operations in the oil sand bitumen deposits in Canada and the extra-heavy-oil Orinoco deposits in Venezuela.

An overview of the worldwide residue processing capacity is show in Table 4, taken from a recent study[14] considering the units in operation by March 2003.

An RFCC in this study is defined as an FCC that can handle feedstocks containing more than 2% CCR. For RFCC to continue to compete in this arena, the range of crude oils/residues that can be processed needs to be increased; only the crude oil/residues with the highest CCR feeds should be left for cokers.

FUTURE ROLE OF FCC IN REFINING: ADVANCED FUELS

In recent decades, product quality development has been considerable, starting with the phase-out of lead in gasoline in the last decades of the 20th century and the start of the phase-down of the sulfur level in diesel and gasoline from the 1990s. In this century, the further phase-out of sulfur in both gasoline and diesel continues. For gasoline, the main source of sulfur is FCC gasoline, and desulfurization has to be executed with care so as not to reduce octane quality. Various licensors have found commercially viable solutions. Another option that is available to refiners is the

Table 4 Worldwide residue processing capacity (million barrels per day)

Conversion technology	United States	Canada/Mexico/ Venezuela	Japan	Europe	Rest of the world	World total	% Distribution
Thermal							
Cracking/visbreaking	44	331	24	2,260	1,635	4,293	26

% of crude capacity	24	30	22	15	19	20	

use of a sulfur reduction FCC catalyst and/or additive. This option is not expected to bring down the sulfur level sufficiently, but it may be considered in a transient period and/or can serve to enhance feedstock flexibility.

A point of great concern remains the fate of light cycle oils (LCOs) in FCC refineries. These molecules are in the gasoil range, but it is increasingly difficult to blend them with the traditional, more demanding, gasoil products. Likewise, it will become more difficult to employ LCO as a diluent in the diminishing residual fuel oil pool. The necessity for inventiveness in this area should provide a fertile ground for the conception of new ideas in the catalyst field as well.

Fig. 1 illustrates the generic routes by which transportation fuels can be produced in refineries. The pure hydroconversion route 1 is usually cost prohibitive; on the other hand, the much cheaper FCC and hydrotreating route 3 is not appropriate to produce the desired fuels. Consequently, usually the thermal conversion route (e.g., delayed coking) combined with hydrotreating (route 2) is selected to improve the transportation fuels slate of a refinery.

As it stands now, FCC is not the preferred route to producing low-aromatics transportation fuels. A definite advantage of FCC is that it can produce high yields of valuable propylene and butylene, which are used as feedstock in the chemical industry or as building blocks for a very clean gasoline, i.e., alkylate, but this does not compensate enough for the poor middle distillate quality. The basic problem is that the FCC process produces a significant amount of extra aromatics (which is good for high octane gasoline), which need to be removed and/or saturated with hydrogen to produce acceptable low-aromatics diesel, advanced diesel, and/or advanced gasoline.

The challenge for FCC will be to present a ''fourth route,'' reinventing the FCC process and catalyst into a refinery solution that will give good conversion of heavy hydrocarbons to low-aromatics transportation fuels, with the option of also making light olefins from heavier residual feedstocks. The objective of this

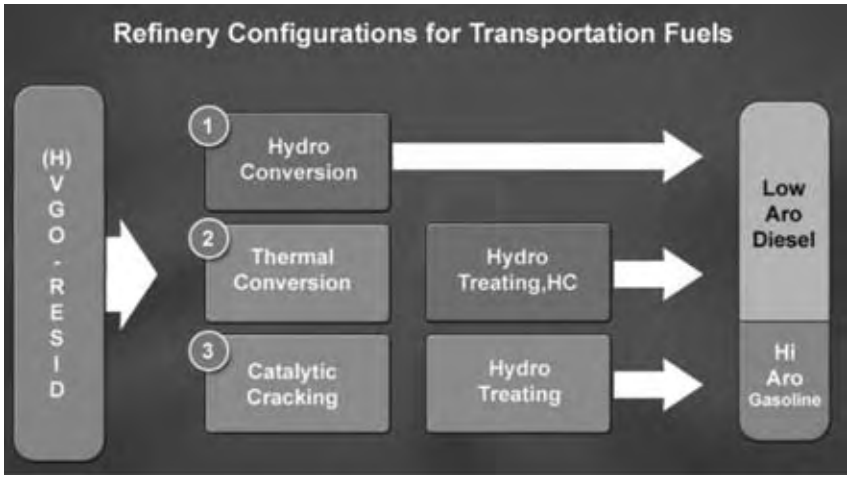

Fig. 1 Generic and simplified refinery configurations. *(View this art in color at www.dekker.com.)*

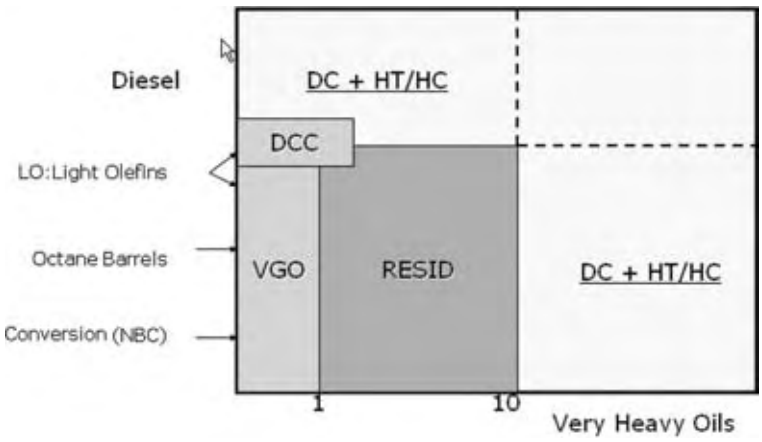

Fig. 2 Constraints on FCC technology. *(View this art in color at www.dekker.com.)*

"fourth way" will be to offer an option to the refinery industry based on the utilization of already existing FCC capacity (low investment), which will then enable the production of the advanced fuels desired in the future at low energy costs, minimum hydrogen consumption, and, hence, low extra CO_2 emissions. Preliminary scouting experiments indicate that a radical change in the FCC catalyst design strategy is possible and aromatics production can be reduced in FCC. Combining these new catalyst developments with innovations on the process side[15] opens the way to revitalizing the role of FCC in the conversion of undesirable heavy oils to clean and advanced fuels.

Also, in terms of flexibility for processing heavier oils, FCC faces tough competition from other processes. Fig. 2 illustrates how FCC technology is constrained within a box as regards product quality as well as feedstock quality. The general industry trend is towards heavier oils, which the FCC process cannot handle economically, and toward lower-aromatics transportation fuels such as diesel, which the existing FCC process cannot produce. It is very obvious that unless radical changes are made, the FCC process is approaching the end of its career as the heavy oil conversion workhorse in the refinery world.

Will the FCC process be able to compete and flourish in this difficult arena?

In a comparison of strengths and weaknesses, the FCC process competes very well with hydroconversion processes because of its simple, robust, low-pressure process configuration. On the other hand, compared to thermal conversion routes such as thermal cracking (visbreaking, deep thermal cracking) and coking, FCC runs into tough competition, especially when heavier high-metal feeds need to be processed, resulting in high catalyst consumption and hence catalyst costs. In many new refinery or refinery expansion projects, the thermal cracking option is therefore often preferred to RFCC. Here too, new breakthroughs in FCC catalyst and process technology to process the very heavy feeds will be able to change the foregoing picture.

The overall assessment, therefore, is that FCC still has a bright future ahead, albeit a future with many changes to come.

Catalytic Dehydrogenation

Bipin V. Vora
Peter R. Pujadó
UOP LLC, Des Plaines, Illinois, U.S.A.

INTRODUCTION

Dehydrogenation, in general, concerns the abstraction of hydrogen from a compound to produce a less saturated analog. Although dehydrogenation can be used on compounds that contain heteroatoms (e.g., alcohols to aldehydes), by and large, the most important reactions pertain to hydrocarbons, principally paraffins to olefins and diolefins, or alkyl aromatics to alkenyl aromatics (e.g., ethylbenzene to styrene). Dehydrogenation can be effected thermally or catalytically. Thermal dehydrogenation is best exemplified by the pyrolysis of hydrocarbons to produce olefins, usually in the presence of steam, in pyrolysis furnaces or steam crackers at elevated temperatures. By controlling temperatures and residence times, thermal pyrolysis can be surprisingly selective, as is the case, for example, in the conversion of ethane to ethylene (~80–90 wt% yields) or in the production of α-olefins by wax cracking. In general, however, thermal pyrolysis has limited selectivity patterns. Thus, for example, the thermal pyrolysis of a naphtha will typically yield only about 29–33 wt% ethylene and 14–17 wt% propylene. But these yields are a strong function of the feedstock composition, and significantly higher yields of ethylene can be obtained if the feed naphtha is rich in *n*-paraffins.

Higher selectivities can be obtained when the dehydrogenation reactions proceed catalytically, but always subject to per-pass conversion limitations imposed by thermodynamic equilibria, so that recycle of unconverted hydrocarbons is usually required. This entry concerns mostly the application of catalytic dehydrogenation. Catalytic paraffin dehydrogenation for the production of olefins has been in commercial use since the late 1930s, while catalytic paraffin oxydehydrogenation for olefin production has not yet been commercialized. However, there are some interesting recent developments worthy of further research and development. During World War II, catalytic dehydrogenation of butanes over a chromia–alumina catalyst was performed for the production of butenes, which were then dimerized to octenes and hydrogenated to octanes to yield high-octane aviation fuel. More recently, platinum or modified platinum catalysts have been used instead of chromia–alumina catalysts. Important aspects in dehydrogenation entail the approach to equilibrium or near-equilibrium conversions while minimizing side reactions and coke formation.

Commercial processes for the catalytic dehydrogenation of propane and butanes attain per-pass conversions in the range of 30–60%, while the catalytic dehydrogenation of C_{10}–C_{14} paraffins typically operates at conversion levels of 10–20%. In 2000, nearly 7 million metric tons of C_3–C_4 olefins and 2 million metric tons of C_{10}–C_{14} range olefins were produced via catalytic dehydrogenation. Oxydehydrogenation employs catalysts containing vanadium and, more recently, platinum. Oxydehydrogenation at ~1000°C and very short residence time over Pt and Pt–Sn catalysts can produce ethylene in higher yields than in steam cracking. However, there are a number of issues related to safety and process upsets that need to be addressed. Important objectives in oxydehydrogenation are attaining high selectivity to olefins with high conversion of paraffins and minimizing potentially dangerous mixtures of paraffin and oxidant. More recently, the use of carbon dioxide as an oxidant for ethane conversion to ethylene has been investigated as a potential way to reduce the negative impact of dangerous oxidant–paraffin mixtures and to achieve higher selectivity.

While catalytic dehydrogenation reflects a relatively mature and well-established technology, in many respects oxydehydrogenation can be characterized as still being in its infancy. Oxydehydrogenation, however, offers substantial thermodynamic advantages and is an area of active research on many fronts.

CATALYTIC DEHYDROGENATION OF PARAFFINS TO OLEFINS

Dehydrogenation reactions are difficult. High temperatures and low pressures are required to achieve reasonable per-pass conversions. Hydrocarbon dehydrogenation reactions are endothermic to the tune of about 30–35 kcal/mol and thus have large heat input requirements. The equilibrium constant, K_P, of a typical dehydrogenation reaction, $A \rightarrow B + aH_2$, starting with 1 mol of A, m mol of B, and n mol of an

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120016154

inert diluent (e.g., steam), can be expressed as follows:

$$K_P = P^a \frac{x}{1 - x}\left[\frac{m + ax}{1 + m + ax + n}\right]^a \quad (1)$$

where x is the equilibrium conversion of component A. This expression is needed in many dehydrogenation reactions that are conducted in the presence of hydrogen in the feed. Although hydrogen limits the extent of conversion, its use is often necessary to prevent excessive coking of the catalyst. If the reaction takes the simpler form A $\rightarrow$ B + H_2, starting with 1 mol of A and n mol of inert diluent, the expression for K_P becomes:

$$K_P = Px^2/[(1 - x)(1 + x + n)] \quad (2)$$

In these expressions, P is the total absolute pressure and $\ln(K_P) = -\Delta G/RT$, where ΔG is the change in Gibbs' free energy. Use of diluents has the effect of lowering the partial pressure and thus can lead to higher levels of conversion. Often, however, the expression can be more complex because other dehydrogenated by-products are also produced (e.g., olefins and diolefins). In the absence of any diluent, we have

$$K_P = Px^2/(1 - x^2) \quad (3)$$

$$x^2 = K_P/(K_P + P) \quad (4)$$

which allows us to quickly estimate the potential maximum conversion under a given set of conditions, T and P.

Selection of operating conditions for dehydrogenation requires a compromise. The temperature must be high enough for a favorable equilibrium and for a good reaction rate, but not so high as to cause excessive cracking or catalyst deactivation. The rate of dehydrogenation reactions diminishes as conversion increases. The ideal temperature profile in a reactor would show an increase with distance, but because dehydrogenation reactions are strongly endothermic, attainable profiles normally show a steep temperature decline or, at best, are isothermal when sufficient heat can be provided across the walls of the catalyst bed.

The reactor pressure should be as low as possible without excessive recycle costs or equipment size. Usually, it is near atmospheric, though reduced pressures (under vacuum) have been used in the Houdry butane dehydrogenation process. In any case, the catalyst bed must be designed for a low pressure drop.

Rapid preheating of the feed is desirable to minimize cracking. Rapid cooling or quenching at the exit of the reactor is sometimes necessary to prevent condensation reactions of the olefinic products. Construction materials must be resistant to attack by hydrogen, capable of prolonged operation at high temperature, and not unduly active for conversion of hydrocarbons to carbon. Alloy steels containing chromium are usually favored. Steels containing nickel are also used, but they can cause trouble from carbon formation. If steam is not present, traces of sulfur compounds may be needed to avoid carbonization. Both steam and sulfur compounds act to keep the metal walls in a passive condition.

HISTORICAL OVERVIEW AND CHROMIA–ALUMINA CATALYSTS

Paraffin dehydrogenation for the production of olefins has been in use since the late 1930s. During World War II, catalytic dehydrogenation of butanes over a chromia–alumina catalyst was done for the production of butenes that were then dimerized to octenes and hydrogenated to octanes to yield high-octane aviation fuel.

Dehydrogenation of butanes over a chromia–alumina catalyst was first developed and commercialized at Leuna in Germany and was also independently developed by UOP (then Universal Oil Products) in the United States, together with ICI in England. The first UOP-designed plant came onstream in Billingham, England, in 1940 and was soon followed by two more units in Heysham, England, in 1941.[1] The primary purpose of these butane dehydrogenation units was to produce butenes that were then dimerized to octenes using solid phosphoric acid catalysts discovered by R.E. Schaad and V.N. Ipatieff.[2]

Other companies soon followed these pioneering efforts. For example, Phillips Petroleum built a multitubular dehydrogenation reactor near Borger, TX, in 1943.[1] However, the most significant development was made by Houdry using dehydrogenation at less than atmospheric pressure for higher per-pass conversions. This process, which came onstream toward the end of World War II, was also used for the production of butenes. After the war, Houdry further developed and commercialized the chromia–alumina dehydrogenation system and extended it to the production of butadiene, in what came to be known as the Catadiene™ process.[3]

In the dehydrogenation process using chromia–alumina catalysts, the catalyst is contained in a fixed shallow bed located inside a reactor that may be either a sphere, a squat vertical cylinder, or a horizontal cylinder. The actual design reflects a compromise between gas flow distribution across a large cross-sectional area and the need to maintain a low pressure drop. A significant amount of coke is deposited on the catalyst during the dehydrogenation step; therefore, a number of reactors are used in parallel—some for dehydrogenation while the rest are being purged or regenerated.

The dehydrogenation reactions are strongly endothermic, and the heat is provided, at least in part, by the sensible heat stored in the catalyst bed during regeneration (carbon burn); additional heat is provided by direct fuel combustion and also by heat released in the chromium redox cycle. The length of the total reactor cycle is limited by the amount of heat available and can be as short as 10–20 min.

The Houdry Catadiene process was used extensively for the production of butadiene, either by itself (*n*-butane to butadiene) or in conjunction with catalytic oxydehydrogenation of *n*-butene to butadiene. The latter was commercialized by the Petro-Tex Chemical Corp. and was called the Oxo-D™ process.[3] A similar oxydehydrogenation approach for the production of butadiene was also adopted by Phillips Petroleum in their O-X-D™ process.[3]

Other companies, including Exxon (then Esso), Shell, Gulf, and Dow, also followed similar dehydrogenation technologies for the conversion of *n*-butenes to 1,3-butadiene, often in the presence of steam. Steam serves as a heat carrier, to lower the hydrocarbon partial pressure, and to minimize coke deposits on the catalyst. Catalyst compositions varied considerably. Thus, Exxon initially used a catalyst based on MgO with hourly regenerations but later changed it to a catalyst based on iron oxide with only very infrequent regenerations. Similarly, Shell's 205 catalyst (62.5% iron oxide, 2.3% chromia, and 35.3% potassium carbonate) required about 12 mol of steam per mole of feed butenes and had a butadiene selectivity of about 75–80 mol% at about 30% per-pass conversion. Dow's catalyst Type B contained Ca and Ni phosphates with a small amount of chromia and had a selectivity to butadiene of about 90 mol%, but at a higher steam ratio of about 20 mol per mole of feed butenes; hourly regenerations were still required.

Large quantities of butadiene have become available over the past 30 yr, mostly as a by-product from the thermal cracking of naphtha and other heavy hydrocarbons. This marked shift has resulted in the shutdown of all on-purpose catalytic dehydrogenation units for butadiene production in North America, Western Europe, and the Far East.

In the late 1980s, the application of chromia–alumina catalysts was extended by Houdry to the dehydrogenation of propane to propylene and isobutane to isobutylene. The new process application called Catofin™ operates on the same cyclic principle as in the former Catadiene process.[4,5] As of late 2000, a total of eight Catofin units existed for the production of isobutylene (including two converted older Catadiene units) with an aggregate capacity of about 2.8 million metric tons per annum (MTA) of isobutylene. In addition, two Catofin units were built for the production of propylene, but it is understood that only one is operational with a nameplate dehydrogenation capacity of about 250,000 MTA propylene, but usually operating only on a seasonal basis. Plans for another 450,000-MTA Catofin propane dehydrogenation unit in Saudi Arabia have also been announced. The Catofin process technology is currently owned by Süd-Chemie and is offered for license by ABB Lummus.

Around 1959, an alternative chromia–alumina catalytic dehydrogenation process was developed in the former Soviet Union. This method avoided the use of the cyclic operation by using a fluidized-bed reactor configuration similar to the fluid catalytic cracking (FCC) process used in refineries.[6] However, back mixing common to dense fluidized-bed operations results in poor selectivity and increases the formation of heavies, sometimes called ''green oils.'' A circulating regenerated catalyst is used to provide the heat of reaction in the riser, and the spent catalyst is reheated by carbon burn in the regenerator. During the 1990s, a large-scale fluid-bed isobutane dehydrogenation unit for about 450,000 MTA isobutylene was commercialized by Snamprogetti (an Italian company) in Saudi Arabia based on technology from Yarsintez in Russia.[6] Recent literature reports further improvements by Snamprogetti.[7,8]

NOBLE METAL DEHYDROGENATION CATALYSTS

A different approach to catalytic dehydrogenation was first introduced in the mid-1960s for the supply of long-chain linear olefins for the production of biodegradable detergents.

Synthetic detergents, based on the use of branched alkylbenzene sulfonates derived from propylene tetramer and benzene, had been introduced in the 1940s. By the early 1960s, however, it became apparent that branched dodecylbenzene-based detergents, though very active and offering excellent performance characteristics, did not biodegrade readily and were accumulating in the environment. The need for biodegradable detergents prompted the development of catalytic dehydrogenation of long-chain linear paraffins to linear olefins.

The work on catalytic reforming with noble metal (Pt) catalysts done in the 1940s by V. Haensel clearly demonstrated that Pt-based catalysts had high activity for the dehydrogenation of paraffins to the corresponding olefins.[9] In the 1960s, Herman Bloch further extended this thinking by developing Pt-based catalysts that could selectively dehydrogenate long-chain linear paraffins to the corresponding internal mono-olefins with high activity and stability and with minimum cracking.[10] This was the basis for the UOP Pacol™ process for the production of linear olefins for the

manufacture of biodegradable detergents.[11] In 1999, there were more than 30 commercial Pt-catalyzed dehydrogenation units in operation for the manufacture of detergent alkylate.

Long-chain paraffins are both valuable and highly prone to cracking. Therefore, to maintain high selectivity and yield, it is necessary to operate at relatively mild conditions, typically below 500°C, and at relatively low per-pass conversions. While this is economical for the production of heavy linear olefins, it is not for the production of light olefins.

Paraffin dehydrogenation is an endothermic reaction that is limited by chemical equilibrium and, according to Le Chatelier's principle, higher conversion will require either higher temperatures or lower pressures. As noted earlier, the maximum equilibrium conversion in a simplified form can be approximated as follows:

$$X_e^2 = \frac{K_P}{K_P + P} \tag{5}$$

where X_e is the equilibrium conversion, P is the total absolute pressure, and K_P is the equilibrium constant for the dehydrogenation reaction. The equilibrium constant can be easily calculated from Gibbs' free energies as tabulated in the API 44 report or in similar sources of thermodynamic data. Figs. 1 and 2 illustrate the equilibrium conversion levels that can be obtained for propane at 1 atm. abs. and at 0.23 atm. abs. (175 torr), respectively (read the respective component mole fractions as the vertical intervals between lines at a given temperature).

The equilibrium constant for paraffin dehydrogenation increases significantly as the carbon number increases. Fig. 3 shows the equilibrium constant for the dehydrogenation of *n*-paraffins ranging from ethane to pentadecane.[12]

Fig. 4 shows the temperatures required to achieve 10% and 40% equilibrium conversion based on these equilibrium constants. It indicates that the temperature required for the dehydrogenation of light paraffins is much higher than that for heavy paraffins. For example, for 40% conversion, the dehydrogenation of propane requires a temperature of at least about 580°C, while dodecane can be theoretically dehydrogenated to the same extent at only 450°C. The equilibrium conversion increases at higher temperatures, but side reactions, coke formation, and catalyst deactivation are also accelerated. Thus, extrapolation directly from heavy olefins to light olefins cannot be done without taking other factors into consideration.

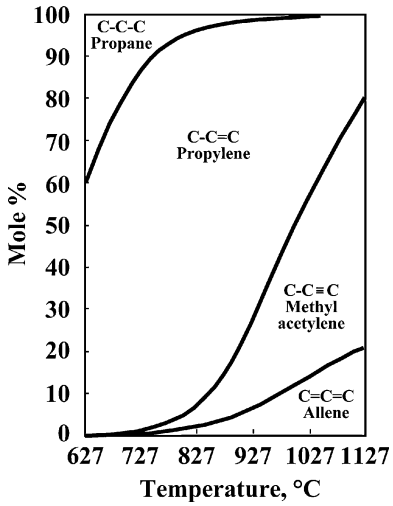

Fig. 1 Propane dehydrogenation equilibrium at 1 atm. abs. pressure.

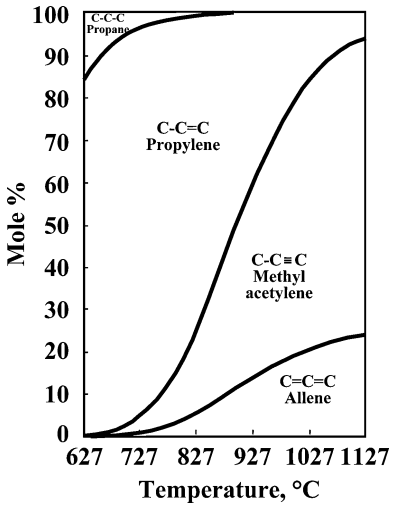

Fig. 2 Propane dehydrogenation equilibrium at 0.23 atm. abs. pressure.

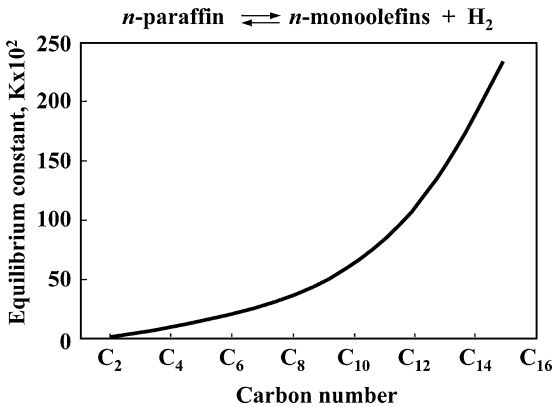

Fig. 3 Equilibrium constants for *n*-paraffin dehydrogenation at 500°C.

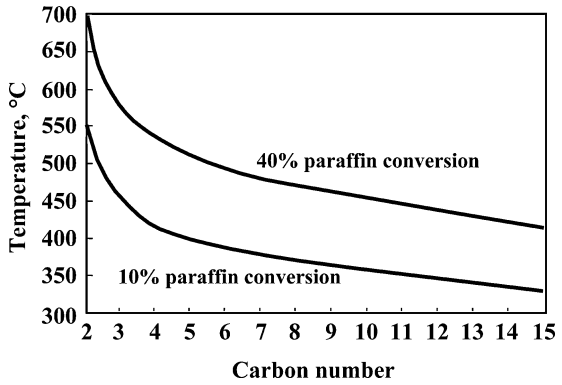

Fig. 4 Temperature required to achieve 10% and 40% conversion of C_2–C_{15} *n*-paraffins at 1 atm. abs. pressure.

Production of light olefins by the catalytic dehydrogenation of light paraffins must be able to maintain reasonable per-pass conversion levels and high olefin selectivity. Very importantly, it must be able to produce olefins in high yields over long periods of time without shutdowns.

In the early 1970s, UOP introduced continuous catalyst regeneration (CCR) technology that enabled noble metal catalysts to remain at their most desirable stable activity for several years without having to shutdown the reactor for catalyst regeneration. The combination of noble metal catalysts operating at high severity in conjunction with CCR technology made it possible to design, build, and economically operate large catalytic dehydrogenation units that can produce light olefins, in particular propylene and isobutylene, at high selectivities while still operating at superatmospheric pressures. This technology is known as the UOP Oleflex™ process. As of late 2003, there were five propane dehydrogenation units, five isobutane dehydrogenation units, and one combined propane/isobutane dehydrogenation unit of this type in commercial operation with an aggregate operating capacity of 1.3 million MTA polymer grade propylene and 2.3 million MTA isobutylene.

The world propylene production capacity based on the use of catalytic dehydrogenation of propane has increased steadily over the past 10 yr and is expected to grow even further under the right economic conditions relative to the availability and pricing of propane.[13] On the other hand, environmental concerns on the use of methyl-*tert*-butyl ether (MTBE), an oxygenated gasoline additive, are expected to adversely impact the future expansion of isobutane dehydrogenation applications.

Although production of ethylene via catalytic dehydrogenation over Pt catalysts is very selective (about 95%), extension of this dehydrogenation technology to ethane has not taken place because of the need for even more severe operating conditions: higher temperatures and lower pressures. Such conditions cause excessive coking of the catalyst or require costlier operation under vacuum.

Practically all existing catalytic dehydrogenation capacity based on Pt catalysts is based on the Oleflex process with CCR; however, there are also two smaller units for isobutane dehydrogenation for 118,000 and 13,000 MTA isobutylene, respectively, both based on the steam active reforming technology (STAR) developed by Phillips Petroleum and derived from their earlier multitubular reactor design experience. This reactor design resembles a typical steam reformer that is operated until the catalyst deactivates as a result of coke deposition; banks of tubes are sequentially taken out of service for catalyst regeneration. The STAR technology is currently owned and licensed by Krupp-Uhde.

PROCESS CHEMISTRY

The main reaction in catalytic dehydrogenation is the formation of mono-olefins from the corresponding feed paraffin. Others include consecutive and side reactions. The reaction pathways involved in heavy paraffin dehydrogenation (e.g., detergent range C_{10}–C_{14} *n*-paraffins) are more complicated than those in light paraffin dehydrogenation (e.g., propane and isobutane). The main difference in reaction pathways is that a significant amount of cyclic compounds can form via dehydrocyclization from heavy paraffins; this is not the case for light paraffins. Figs. 5 and 6 illustrate the possible reactions that take place on platinum (Pt) and acid (A) sites, respectively, in the dehydrogenation of light and heavy paraffins when the catalyst is not selective, e.g., unmodified platinum catalysts supported on alumina.

The consecutive reactions, the dehydrogenation of mono-olefins to diolefins and triolefins, are catalyzed on the same active sites as the dehydrogenation of paraffins to mono-olefins. The consecutive reactions that

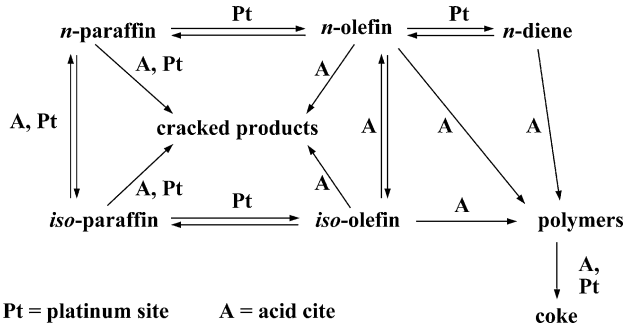

Fig. 5 Reactions in platinum and acid sites in light paraffin dehydrogenation with unmodified catalyst.

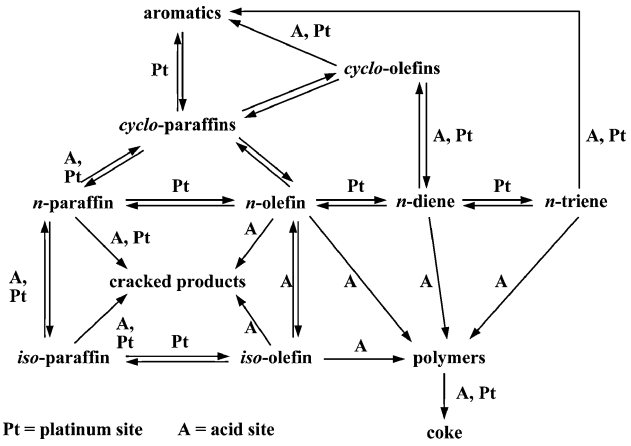

Fig. 6 Reactions in platinum and acid sites in heavy paraffin dehydrogenation with unmodified catalyst.

form triolefins, aromatics, dimers, and polymers must be suppressed kinetically or by catalyst modifications.

ROLE OF CATALYSTS AND SUPPORTS

The discussion in this section pertains to alumina-supported platinum catalysts. The work by C.P. Poole and D.S. MacIver provides an extensive review of chromia–alumina catalysts.[14,15]

The key role of dehydrogenation catalysts is to accelerate the main reaction while controlling other reactions. Unmodified alumina-supported platinum catalysts are highly active but are not selective to dehydrogenation. Various by-products, as indicated in Figs. 5 and 6, can also form. In addition, the catalyst rapidly deactivates because of fouling by heavy carbonaceous materials. Therefore, the properties of platinum and the alumina support need to be modified to suppress the formation of by-products and to increase catalytic stability.

The reaction of olefins on platinum is faster than that of paraffins because olefins interact with platinum more strongly than do paraffins. The role of platinum modifiers is to weaken the platinum–olefin interaction selectively without affecting the platinum–paraffin interaction. Among metals, arsenic, tin, germanium, lead, and bismuth are reported as platinum activity modifiers. The consecutive dehydrogenation rate of mono-olefins and diolefins is decreased by this modification without lowering the rate of paraffin dehydrogenation significantly. The modifier also improves the stability against fouling by heavy carbonaceous materials.

Platinum is a highly active catalytic element and is not required in large quantities to catalyze the reaction when it is dispersed on a high surface area support. The high dispersion is also necessary to achieve high selectivity to dehydrogenation relative to undesirable side reactions, such as cracking.

The typical high surface area alumina supports employed have acidic sites that accelerate skeletal isomerization, cracking, oligomerization, and polymerization of olefinic materials, and enhance coke formation. Alkalis or alkaline earth metals assist in the control of the acidity. Also, α-alumina supports that have essentially no acidity can be utilized; however, the challenge is to obtain high dispersion of platinum on such very low surface area supports. Therefore, acidity must be eliminated by using suitable modifiers.

Modified catalysts possess high activity and selectivity to mono-olefins. The major by-products are diolefins that can be controlled kinetically. Coke formation is also suppressed, and therefore, stability is greatly improved. Over modified catalysts, the major reaction pathways for both light and heavy paraffin dehydrogenation systems are simpler (Fig. 7).

Alumina has excellent thermal stability and mechanical strength under processing, transport, and catalyst regeneration conditions. However, the most important reason alumina is used as a support material is its superior capability to maintain a high degree of platinum dispersion, which is essential for achieving high dehydrogenation activity and selectivity.

Light paraffin dehydrogenation

Heavy paraffin dehydrogenation

Fig. 7 Paraffin dehydrogenation on modified Pt catalysts.

The catalytic reaction rate is limited by the intraparticle mass transfer rate. If the rate is relatively slow, both activity and selectivity are lowered. As a result, the support must have a low pore diffusional resistance (high effectiveness factor). For a given pore volume, the surface area and the strength of the support increase as the pore diameter decreases, and the pore diffusional resistance decreases as the pore diameter increases. Thus, an appropriate pore structure must be determined for the support to achieve optimal catalytic performance.

Selectivity decreases as the conversion increases because *n*-mono-olefins are consecutively converted into by-products. Selectivity decreases sharply as conversion approaches equilibrium because the main dehydrogenation process is limited by equilibrium, but other reactions continue to occur. Therefore, if side reactions are controlled, the selectivity is improved as the equilibrium conversion becomes higher by increasing the temperature and by decreasing the pressure and the feed ratio of hydrogen to paraffin.

The relationship between selectivity and conversion can be simulated if rate functions, relative rate constants, and equilibrium constants are known. Fig. 8 shows simulated selectivities to *n*-heptene and *n*-heptadiene for the dehydrogenation of *n*-heptane. In this simulation, the relative rate constants used are unity, which represents that the catalyst possesses perfect selectivity regarding consecutive dehydrogenation; the dehydrogenation rate of paraffin is equal to that of mono-olefin and diolefin. Experimental selectivities obtained over a UOP dehydrogenation catalyst show that the catalyst has >90% selectivity for consecutive dehydrogenation steps, as seen in Fig. 8.

The rate of light paraffin conversion over a Pt catalyst (Oleflex type process) can be expressed as a modified first-order equation according to a Langmuir–Hinshelwood mechanism. Other equations may be derived accordingly.

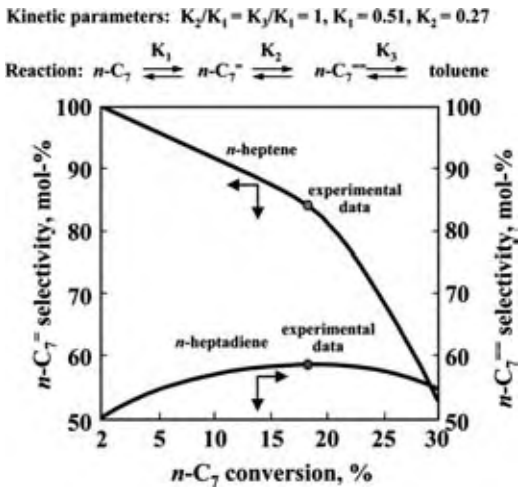

Fig. 8 Simulation of selectivity for dehydrogenation of *n*-heptane. *(View this art in color at www.dekker.com.)*

CATALYST STABILITY AND REGENERATION

The dehydrogenation of long-chain paraffins is performed under relatively mild temperature conditions of 400–500°C. Thus, the catalyst can maintain a long life even at high space velocity and catalyst productivity. Therefore, it is not economical to build facilities for catalyst regeneration.

Because of equilibrium limitations, the dehydrogenation of light paraffins requires significantly higher temperatures above 600°C to achieve economically attractive conversions. The catalyst deactivation is accelerated under high-temperature conditions, and frequent catalyst regeneration is necessary for light paraffin dehydrogenation. For the dehydrogenation of light paraffins, a number of different types of reactor-regeneration systems are commercially utilized.

- Houdry's Catofin and similar processes employ a cyclic sequence of steps—process, purge, air regeneration, purge, hydrogen reduction, and back to process.
- The Phillips STAR process also regenerates the catalyst on a cyclic basis, but while the Houdry regeneration is actually a mechanism to provide the heat for the reaction even when coke buildup is still very low, the catalyst in the isothermal STAR process is only regenerated after coke has accumulated to appreciable levels that result in low catalyst activity.
- UOP's Oleflex process uses multistage adiabatic reactors with CCR.
- Snamprogetti's dehydrogenation process consists of a fluidized-bed reactor and regeneration system. Here too, the coke buildup is very low and the ''regeneration'' loop is actually a means of supplying heat to the reactor.

HEAT OF REACTION

The heat of reaction for paraffin dehydrogenation is about 30 kcal/mol (125 kJ/mol). In a cyclic adiabatic operation (e.g., Houdry), it is provided by reheating the catalyst and the added inert materials to a high temperature during the regeneration step, so that the catalyst cools down and conversion decreases during the reaction step. Because several reactors are used in parallel, average conversion is obtained. In an isothermal process (e.g., STAR), the catalyst is loaded inside vertical tubes inside a furnace and the heat is

introduced through the tube walls. In a fluidized reactor, the temperature profile can be maintained uniformly in the back mixed zone of the bed, while heat is provided by introducing a hot regenerated catalyst. In Oleflex adiabatic reactors, a significant temperature drop occurs across the catalyst bed, which lowers the equilibrium conversion level; a multistage reactor system with interstage reheating is used for higher paraffin conversions.

Fig. 9 illustrates conversion, equilibrium conversion, and temperature along the catalyst bed in a three-stage adiabatic reactor system for the dehydrogenation of isobutane. For propane dehydrogenation, a four-stage reactor system becomes more economical because higher average temperatures are needed. A multistage reactor system also affords lower inlet temperatures, relative to a single-stage reactor system (Fig. 10). Thus, thermal cracking and catalyst deactivation, which are accelerated at higher temperatures, can be controlled to low levels.

PROCESS FLOW AND REACTOR CHARACTERISTICS

Cyclical Processes

As described earlier, the Houdry Catadiene process, the Houdry Catofin process, and other similar cyclical processes make use of parallel reactors that contain a shallow bed of chromia–alumina catalyst. Fig. 11 illustrates a schematic of such a process.

This technology has been used extensively for the production of butadiene and, in more recent years, for that of isobutylene and propylene.[16,17] The feed is preheated through a fired heater before being passed over the catalyst in the reactors. The hot reactor effluent is cooled, compressed, and sent to the product fractionation and recovery section. The dehydrogenation reactors are refractory-lined carbon steel vessels (i.e., cold wall design). To accommodate continuous flow of the main streams—hydrocarbons and regeneration air—the reactors are operated on a timing cycle that satisfies the following requirement:[1]

$$\text{Onstream time} + \text{Regeneration time} + \text{Purge time} = \text{Total cycle time} \quad (6)$$

The number of reactors in each cycle is the prorated time fraction of the total cycle time. Thus, with five reactors, two reactors can be onstream simultaneously, two on regeneration, and one on purge, evacuation, and valve changes. Fig. 12 provides a typical timing cycle for a five-reactor unit, but as many as eight reactors in parallel have been provided in some units. The total cycle time is usually in the range of 15–30 min.

The onstream period at subatmospheric pressure is followed by a purge. Next comes regeneration at essentially atmospheric pressure, followed by purge, hydrogen reduction, and evacuation to reaction pressure, after which the reactor is ready for another onstream period. Process streams enter and leave the reactors through fast-acting gate valves. The gate valves can range up to 40 in. (1 m) in diameter, are designed for high-temperature service, and are equipped with a pressurized inert seal in the bonnet to prevent leakage of air into the process gas when the valve is closed. Overall, this mechanical design has proven to be very reliable over many years of operation.

The regeneration is done with air that has been preheated through a direct fired burner or, alternatively, with the exhaust of a gas turbine. The regeneration step is intended to preheat the catalyst to the onstream temperature necessary to initiate the next process cycle and to remove coke deposits on the catalyst. Flue gas sensible heat may be recovered in a waste heat boiler. The hydrogenation step prepares the catalyst for the dehydrogenation phase and also contributes additional heat from the reduction of Cr^{6+} to Cr^{3+}.

Another cyclical process is the Phillips STAR process.[18] It uses a fixed-bed fired-tube reactor operating at a positive superatmospheric pressure. In many respects, it is similar in design to a steam reforming furnace with the heat of reaction provided by firing outside the tubes, thus operating at near-isothermal conditions. Steam is used as a diluent to lower the partial pressure of the reactants and, thus, to achieve reasonable conversion levels of about 30–40% for propane and 45–55% for butanes. It also helps slow down the deposition of carbon (coke) on the catalyst, thereby extending cycle time from minutes to hours.

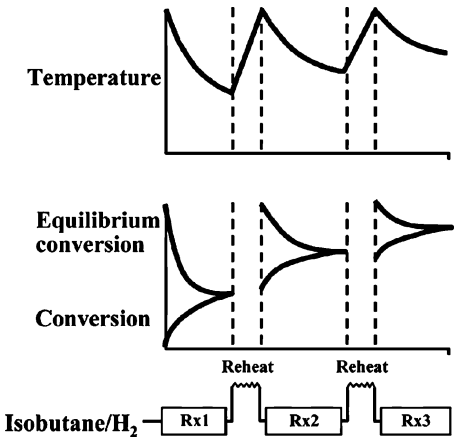

Fig. 9 Temperature profile and conversions of three-stage isobutene dehydrogenation process.

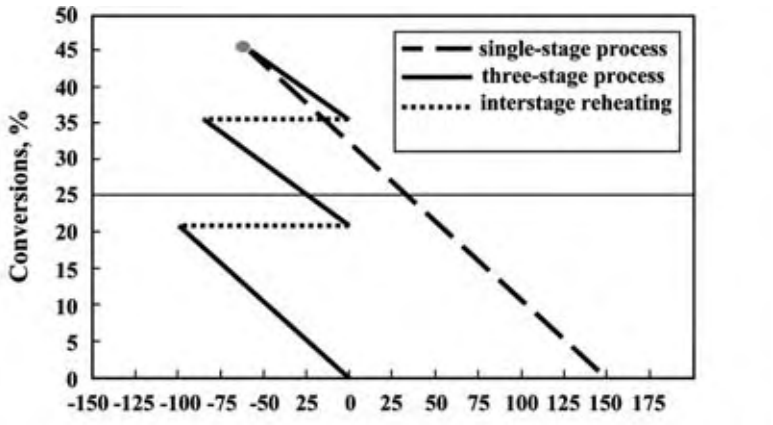

Typical temperature endotherms per stage, in °C, required to achieve about 45% isobutane conversion. In a single-stage approach the feed would have to be preheated about 150°C higher than in a three-stage process

Fig. 10 Isobutane dehydrogenation. *(View this art in color at www.dekker.com.)*

Periodic catalyst regeneration or carbon burn off is required to maintain the activity of the catalyst. Typical cycle time is reported to be at least 8 hr, with 7 hr of process time and 1 hr of regeneration time. For continuous operation, various furnace modules can be operated such that, for example, seven operate in the process mode while one is in the regeneration mode. Fig. 13 shows a schematic diagram of a STAR process unit.[18]

Continuous Processes

Snamprogetti has commercialized fluidized-bed dehydrogenation (FBD) for the catalytic dehydrogenation of light paraffins using a chromia–alumina catalyst with an alkaline promoter, which is used primarily for the dehydrogenation of isobutane to isobutylene in the manufacture of MTBE.[6–8] The catalyst is microspheroidal with an average diameter of $<100\,\mu m$ and

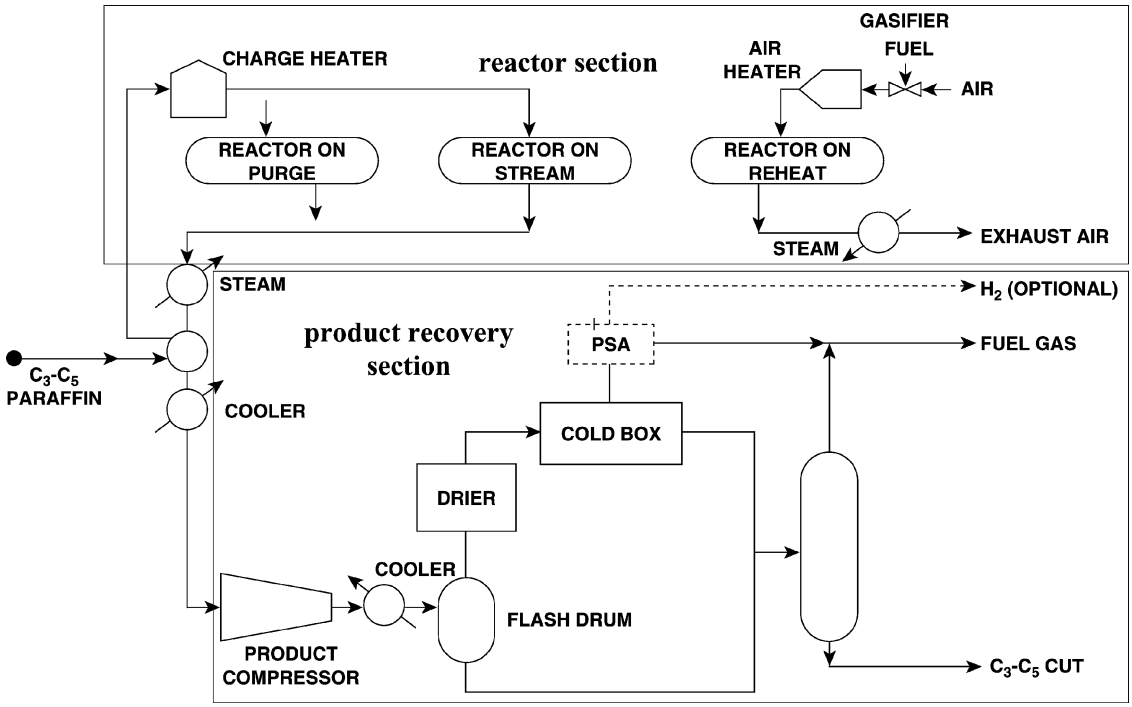

Fig. 11 Catofin process flow diagram.

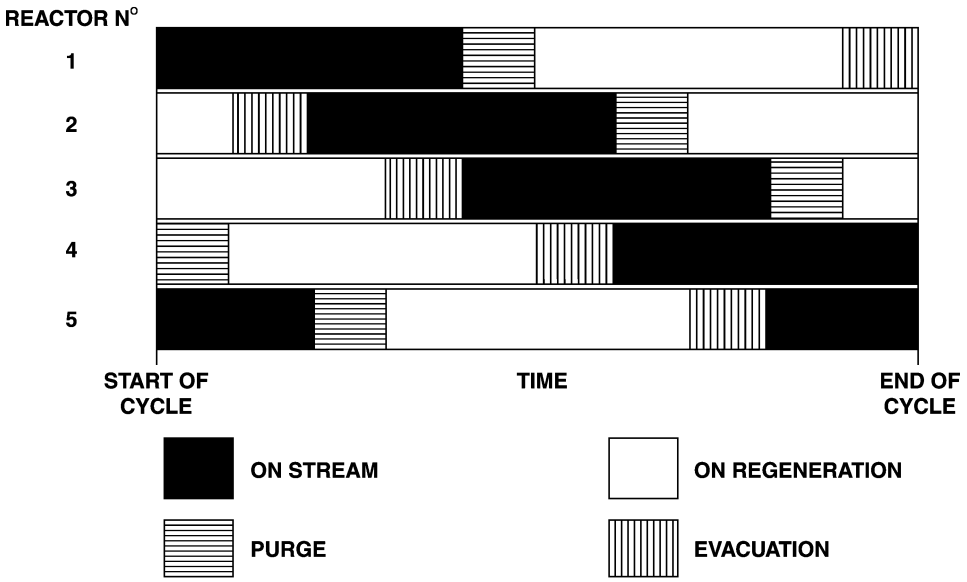

Fig. 12 Olefins from paraffins.

an apparent bulk density of $<2000\,kg/m^3$.[19] The heat of the reaction is provided by the circulating hot regenerated catalyst back to the reactor. In all concepts, the FBD process is very similar to the FCC process units commonly used in petroleum refineries. However, because back mixing has a negative effect on the yields, horizontal baffles with suitable openings are inserted within the fluidized bed to limit the backflow of solids, such that the fluidized bed is split into a series of stages, each comparable to a continuous stirred tank reactor (CSTR).[19] A typical process scheme is shown in Fig. 14.

Fresh feed is vaporized, mixed with the recycle of unconverted paraffins, and fed to the fluidized reactor through a distributor for optimal even distribution. Entrained catalyst is removed from the product off-gas by means of cyclones. The catalyst circulates continuously from the reactor to the regenerator and vice versa by means of transfer lines. Coke deposited on the catalyst is burnt off in the regenerator; however, because the amount of coke is relatively small, additional fuel must be burnt in the regenerator to satisfy the thermal requirements of the endothermic dehydrogenation reaction. However, while this approach is similar to that in the Houdry process, FBD does not have a catalyst reduction step with hydrogen before proceeding to the dehydrogenation cycle; lack of this step is believed to be somewhat detrimental to the overall performance of the process.

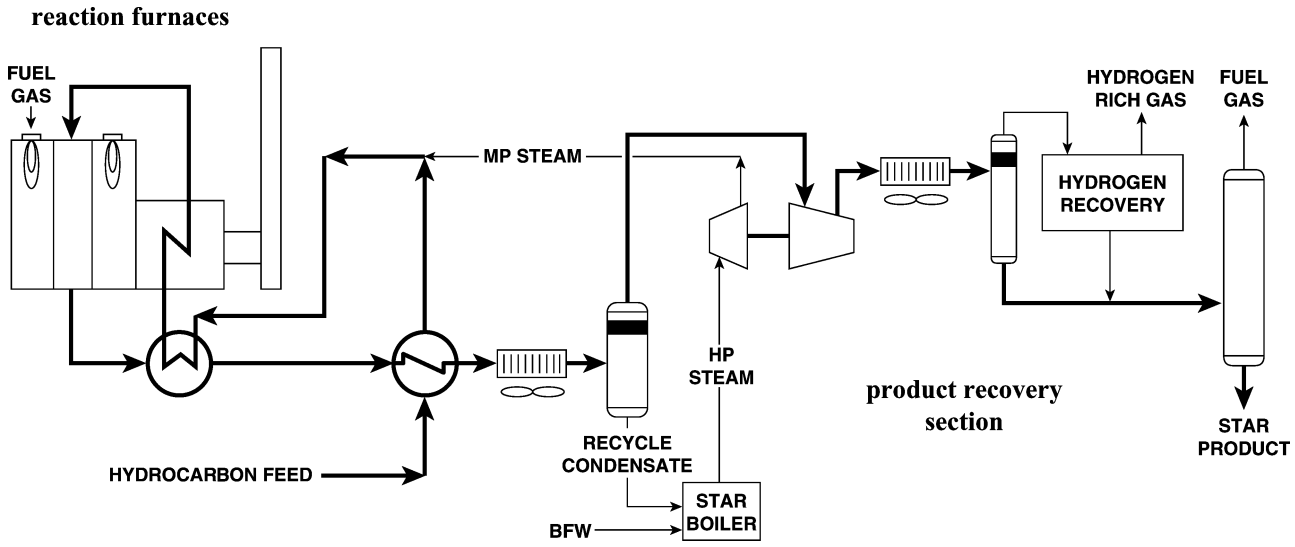

Fig. 13 Phillips Petroleum Company—STAR process.

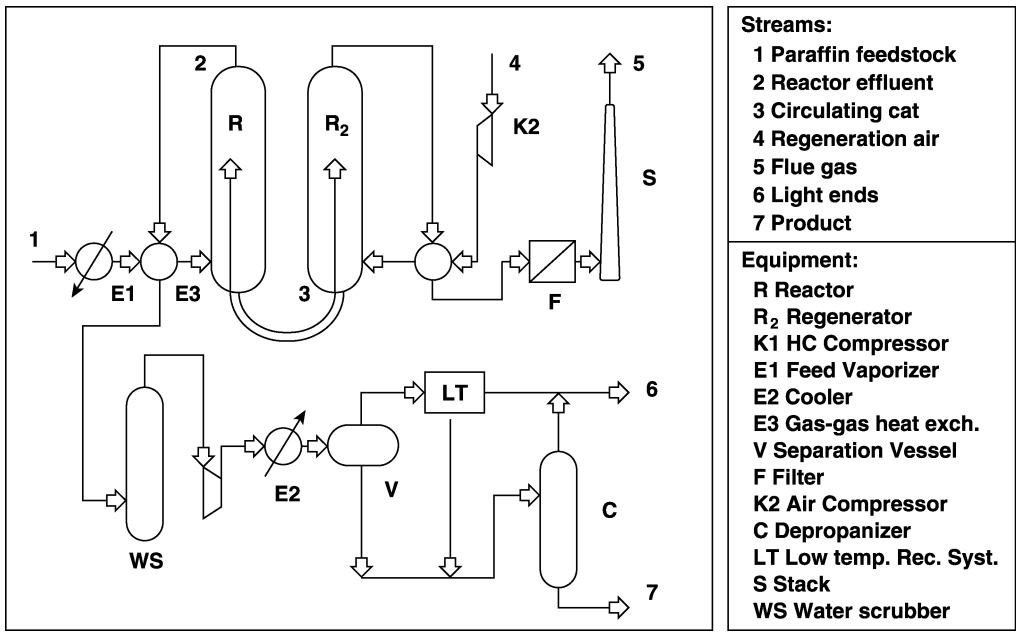

Fig. 14 Snamprogetti's FBD process scheme.

UOP's catalytic dehydrogenation processes typically make use of radial-flow adiabatic fixed-bed (or slowly moving bed) reactors with modified Pt–alumina catalysts.

The UOP Pacol process for selective long-chain paraffin dehydrogenation to produce linear mono-olefins is shown in Fig. 15 in combination with the UOP detergent alkylation process. The Pacol process consists of a radial-flow reactor and a product recovery section. Worldwide, more than 2 million metric tons per year of linear alkyl benzene is produced employing this process.[20]

The flow diagram of the UOP Oleflex process is seen in Fig. 16. The process consists of a reactor section and a product recovery section. The former consists of three or four stages of radial-flow reactors, charge and interstage heaters, reactor feed–effluent exchangers, and the CCR section (Fig. 17). As noted earlier, more than 1 million metric tons of propylene and 2 million metric tons of isobutylene are now produced via this route.[13] The performances of the Pacol and Oleflex processes are summarized in Table 1.

Use of the Oleflex process for the dehydrogenation of ethane to ethylene has also been investigated but, to date, the economics do not appear to be favorable because of the low equilibrium conversion and the need to operate at a pressure lower than atmospheric if a reasonable ethane conversion is to be expected;

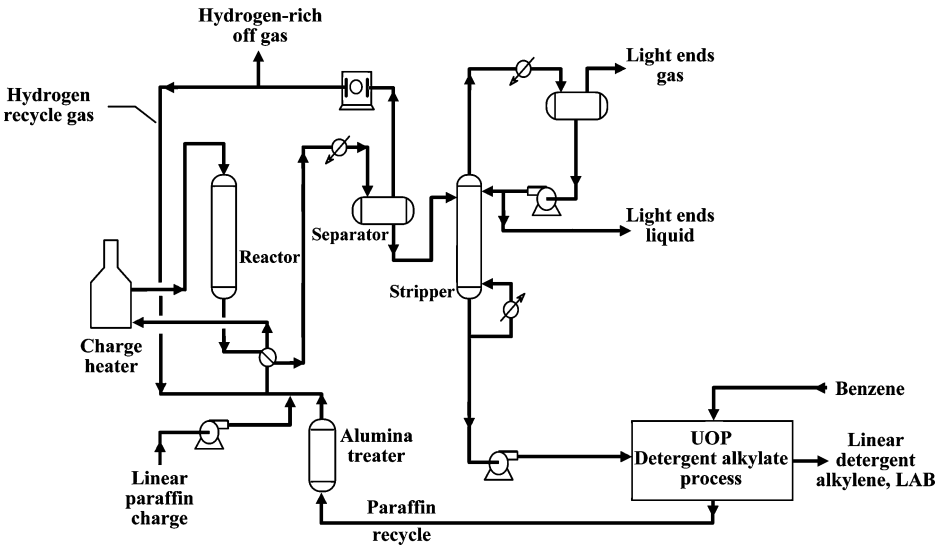

Fig. 15 UOP Pacol dehydrogenation process.

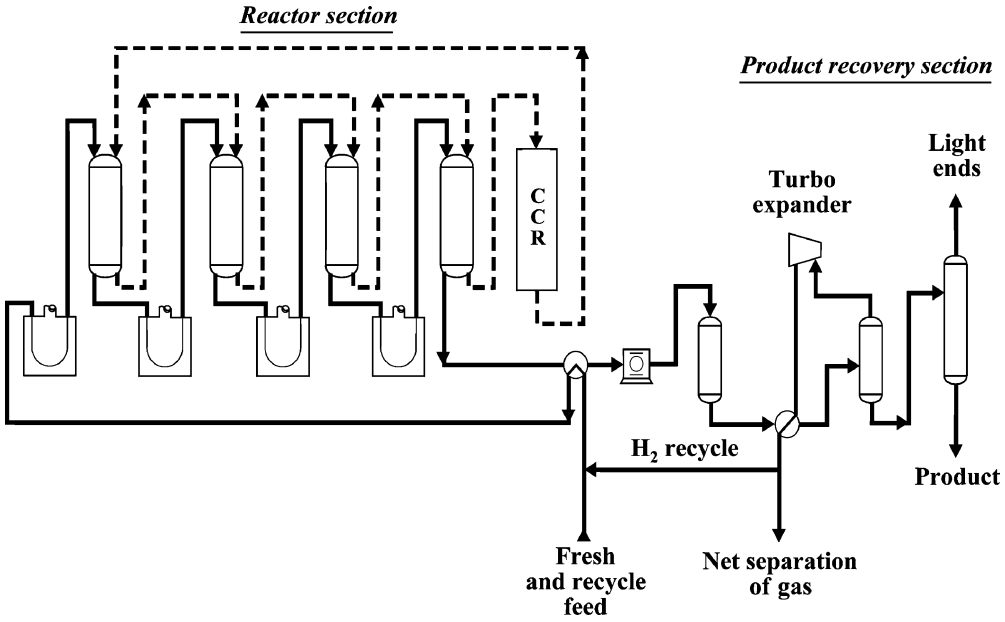

Fig. 16 UOP Oleflex process.

the cost of fractionating ethylene in an ethane–ethylene splitter is otherwise too high. Dow Chemical has recently been awarded a patent for the dehydrogenation of ethane over a metal–mordenite catalyst complex at relatively low conversions in which the product ethylene is selectively recovered from the dilute ethylene–ethane stream by alkylating it with benzene.[21]

REACTOR DESIGN OPTIONS

The choice of reactor design plays a very important role in the success of catalytic processes. The following types are commercial reactor designs for endothermic catalytic dehydrogenation processes:

- Downflow adiabatic fixed bed.
- Radial-flow fixed bed or moving bed adiabatic.
- Tubular isothermal.
- Fluidized bed.

Table 2 summarizes the main characteristics of the four reactor systems. The dot represents beneficial characteristics of each reactor type.

The choice of the right reactor depends on the catalyst and the selection of operating conditions.

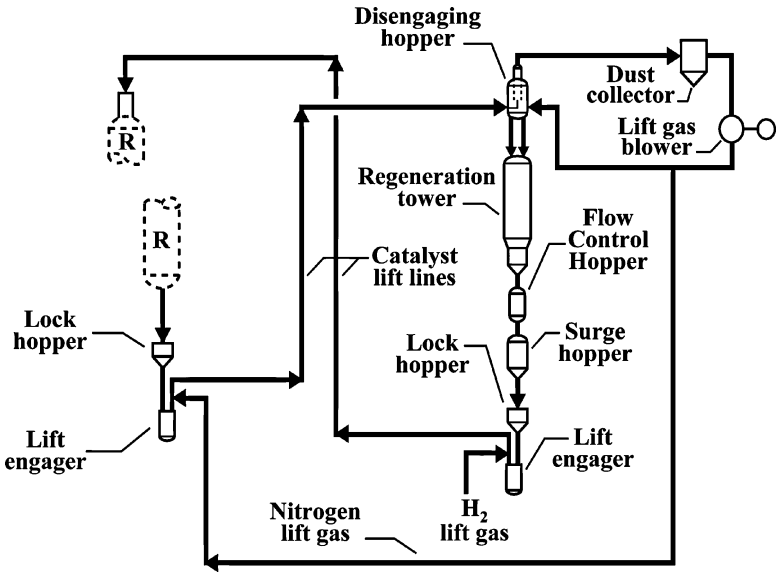

Fig. 17 Oleflex catalyst regeneration section.

Table 1 Performance of Pacol and Oleflex processes

Process	Feed	Conversion (%)	Selectivity (%)
Oleflex	Propane	40	90
	n-Butane	50	85
	Isobutane	50	92
Pacol	*n*-Heptane	20	90
	n-C_{10}–C_{13}	13	90
	n-C_{11}–C_{14}	13	90

ETHYLBENZENE DEHYDROGENATION

Although the previous discussion had centered on the catalytic dehydrogenation of paraffins, a study on the subject would not be complete without analysis of the dehydrogenation of ethylbenzene to styrene.

Styrene is an important monomer or comonomer in the manufacture of a number of polymers: polystyrene, acrylonitrile/butadiene/styrene, styrene/acrylonitrile, etc. There are two main processes for the manufacture of styrene. In one process styrene is made a coproduct with propylene oxide:

Ethylbenzene + air → ethylbenzene hydroperoxide

Ethylbenzene hydroperoxide + propylene → methyl phenyl carbynol + propylene oxide

Methyl phenyl carbynol → styrene + water

This process was originally developed and commercialized by Oxirane (a joint venture company between ARCO Chemical, now Lyondell, and Halcon) and independently by Shell Petrochemical Company. At present, this is one of the main processes for the commercial manufacture of propylene oxide (the other is a variant of the same that starts with isobutane instead of ethylbenzene, and produces propylene oxide together with *tert*-butyl alcohol, isobutylene, and ultimately MTBE, as the main coproducts); so significant amounts of styrene are obtained therefrom.

The demand for styrene, however, outstrips the supply available from its coproduction with propylene oxide; so the other major process for the production of styrene is the catalytic dehydrogenation of ethylbenzene:

Ethylbenzene → styrene + H_2

The dehydrogenation reaction proceeds over an iron or an iron–chromium catalyst that usually also contains potassium in the form of potassium carbonate, so that at elevated temperatures various complex mixed carbonates and oxides are formed, e.g., $KFeO_2$. Temperatures are elevated, in the order of 630°C, and pressures are usually subatmospheric for improved per-pass conversions. Steam dilution is performed to further lower the partial pressure of the reactants. Because the reaction is strongly endothermic, various reaction stages with interheat (and interstage addition of superheated steam) are normally employed. Fig. 18 illustrates a typical process scheme for the dehydrogenation of ethylbenzene to styrene.

Usually, two adiabatic reactors in series with interheat are used, but a third reactor may be present or added for increased capacity as shown in Fig. 19.

In an interesting variant of the conventional process, part of the hydrogen that is produced in the first stage of conversion is selectively reacted with oxygen over a separate bed of catalyst such that significant amounts of heat are released internally within the reactor system. The hydrogen oxidation catalyst is selected to ensure that there is practically no conversion or degradation of either ethylbenzene or styrene. While this process could be thought of as an oxydehydrogenation, in reality it is just a conventional dehydrogenation coupled with an oxidative reheat step. The alternative ethylbenzene dehydrogenation process, known commercially as Styrene Monomer by Advanced Reheat Technology (SMART™), was invented by Dr. Dennis J. Ward of UOP LLC in an original version called Styro-Plus demonstrated at Mitsubishi Chemicals, Kashima, Japan, and is now licensed commercially jointly by UOP LLC and ABB Lummus Global Inc. In addition to supplying the heat of reaction internally, the SMART process benefits from the equilibrium displacement that results from the selective removal of one of the reaction products, hydrogen, as illustrated in Fig. 20.

It has been shown[22] that SMART process technology is best suited for revamps of existing ethylbenzene dehydrogenation units, which in the case of the UOP/Lummus technology are called the Classic™ process. Figs. 19, 21, and 22 illustrate various modes

Table 2 Characteristics of four reactor systems

of revamping an existing ethylbenzene dehydrogenation process unit.

- In a classic revamp (Fig. 19), a new dehydrogenation reactor with its own feed reheat exchanger is inserted between the two existing dehydrogenation reactors.
- In a partial SMART revamp (Fig. 21), one SMART reactor that contains both oxidation catalyst and dehydrogenation catalyst is placed between the two existing dehydrogenation reactors. No reheat exchanger is needed for the SMART reactor.
- In a full SMART revamp (Fig. 22), an additional oxidation reactor is added after the intermediate SMART reactor and before the last conventional dehydrogenation reactor, so that no feed reheat exchanger is needed for the final stage either.

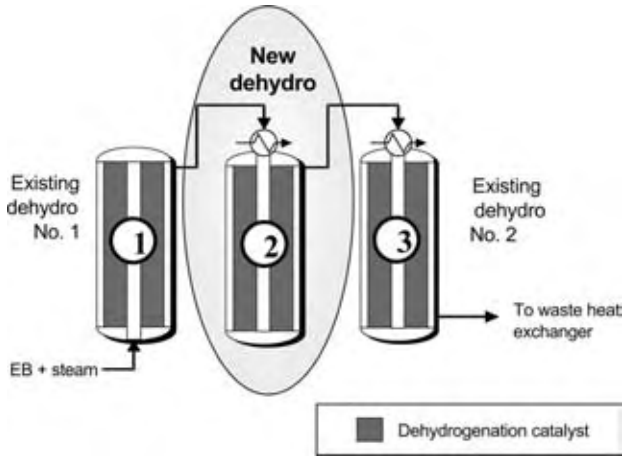

Fig. 19 Possible conventional revamp of a classic styrene monomer unit. *(View this art in color at www.dekker.com.)*

Table 3 compares the results of the various revamp options.

OTHER DEHYDROGENATION TECHNOLOGIES

The processes discussed above are for the direct catalytic dehydrogenation of paraffins to the corresponding olefins or of olefins to diolefins. Other methods have also been considered, although none has reached the level of commercialization. Some of the most notable are:

- Halogen-assisted dehydrogenation.
- Oxydehydrogenation.

Use of halogens for the dehydrogenation of paraffins has been proposed in different ways. For example, heavy paraffins were first chlorinated and then dehydrochlorinated to heavy olefins commercially in

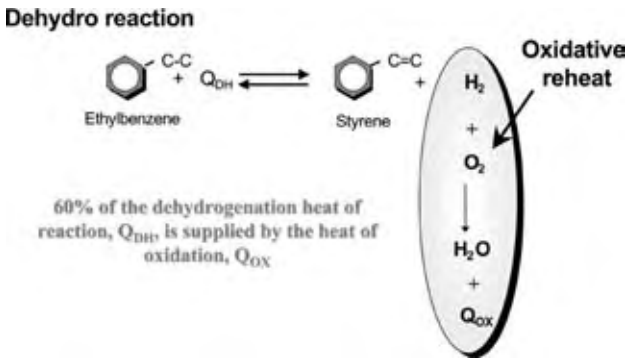

Fig. 20 Oxidative reheat mechanism. *(View this art in color at www.dekker.com.)*

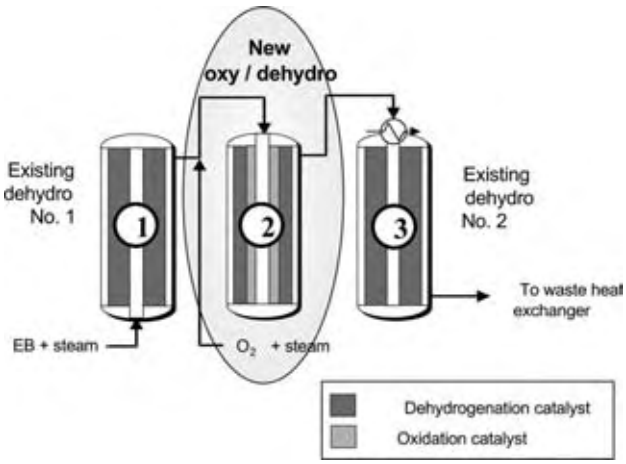

Fig. 21 Partial SMART revamp. *(View this art in color at www.dekker.com.)*

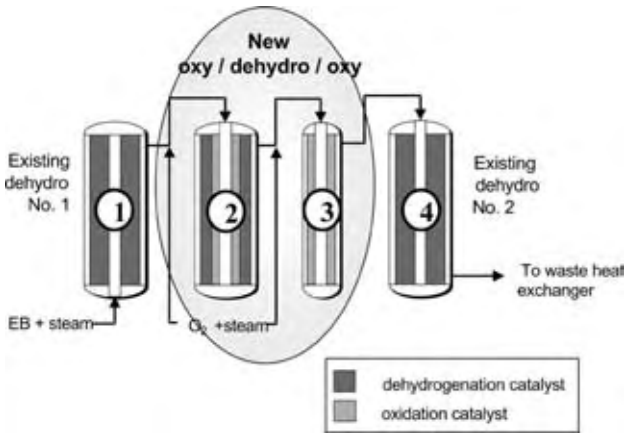

Fig. 22 Full SMART revamp. *(View this art in color at www.dekker.com.)*

the past both by Shell and Hüls, among others. Pyrolysis of methane in the presence of chlorine has been proposed by Prof. Sidney Benson for the production of acetylene and ethylene.[23] Other chlorination/dehydrochlorination cycles have been proposed for the production of ethylene from ethane. Propane dehydrogenation in the presence of iodine via a propyl iodide intermediate has also been proposed.[4,24] Apart from the apparent corrosion problems associated with the use of halogens, other difficulties readily come to mind owing to the relatively high cost of chlorine, and even more so of iodine, and the need to either dispose of or recycle vast quantities of halogens.

Oxydehydrogenation or oxidative dehydrogenation can be considered in at least two different ways.

- Use of oxygen to oxidize the hydrogen coproduct from dehydrogenation, and thus to displace the dehydrogenation equilibrium to higher conversions as discussed earlier for the dehydrogenation of ethylbenzene to styrene. Although a similar approach has been proposed for the dehydrogenation of paraffins, it has not been commercialized.[25–28]
- Direct use of oxygen as a means of dehydrogenating, for example, ethane to ethylene. Oxydehydrogenation has successful commercial applications in the conversion of *n*-butenes to butadiene (e.g., as in the Oxo-D process referred to earlier), but not yet for the production of ethylene or propylene.

Use of oxydehydrogenation relative to straight catalytic dehydrogenation must be viewed both in terms of safety issues and in an economic context.

Table 3 Results of various revamp options

	Classic revamp	Partial SMART	Full SMART
Reactor section	Add conventional dehydrogenation reactor	Add smart oxy/dehydrogenation reactor	Add smart oxy/dehydrogenation reactor and another oxydehydrogenation reactor
EB conversion (%)	70–72	74–76	80–82
Capacity increase (%)	25–30	25–40	40–50
Superheater	New heater	No change—minor modification	Minor modification
Off-gas compressor	New compressor	No change	No change
Vent-gas recovery	Bottleneck	No change	No change
Fractionation	Modification required (no major retraying required for front-end columns if there is <20% capacity increase)	Modification required (no major retraying required for front-end columns if there is <25% capacity increase)	Modification required (no major retraying required for front-end columns if there is <35% capacity increase)

On the latter, even though oxydehydrogenation offers advantages as a means of overcoming thermodynamic equilibrium limitations, it also leads to the total or partial loss of by-product hydrogen, which in some instances can have a very significant economic impact.

Although less apparent, oxydehydrogenation also plays a role in the work done by BP Amoco, Asahi, and others to extend ammoxidation to the direct conversion of propane to acrylonitrile. It is believed that the ammoxidation of propane proceeds through a transient propylene intermediate from which acrylonitrile is derived through a conventional ammoxidation pathway.[29] Similarly, the conversion of *n*-butane to maleic anhydride could also be regarded as a form of oxydehydrogenation, except that in this case it leads to the formation of a new compound that incorporates oxygen in the molecule.

CONCLUSIONS

Catalytic dehydrogenation of paraffins and of ethylbenzene is a commercial reality in numerous applications, from the production of light olefins, heavy olefins, to that of alkenylaromatics. Oxydehydrogenation, on the other hand, is still in the developmental stage, but, if successful, holds great promise on account of its potential energy savings.

Catalytic Naphtha Reforming

Abdullah M. Aitani
King Fahd University of Petroleum and Minerals, Dhahran, Saudi Arabia

INTRODUCTION

The use of catalytic naphtha reforming as a process to produce high-octane gasoline continues to be important as it has been over the 55 yr of its commercial use. The catalytic reformer occupies a key position in a refinery providing high value-added reformate for the gasoline pool, hydrogen for hydroprocessing operations, and, frequently, benzene, toluene, and xylene aromatics for petrochemical uses. The main objective of catalytic reforming is to transform paraffins and naphthenes in naphtha to aromatics-rich products with as little ring opening or cracking as possible. Aromatics have very high octane numbers (>100) and can be tolerated in gasoline up to almost 50 vol%. However, because of stringent environmental regulations, the refining industry has taken significant steps to reduce the level of aromatic compounds in gasoline by adapting its formulation. Many countries have reduced the total aromatics content in gasoline from 42–35 vol%.

Naphtha feed to the reformer contains a mixture of C_6–C_{11} paraffins, naphthenes, and aromatic hydrocarbons in the temperature range of 85–200°C. Most reformers process straight-run naphthas with qualities that vary significantly depending on the crude oil origin and boiling range.[1–3] Typical straight-run naphtha contains 65 wt% paraffins, 20 wt% naphthenes, and 15 wt% aromatics. Cracked naphthas, such as visbreaker, coker, and heavy hydrocracked, are another source of reformer feeds. In motor gasoline applications, naphtha contains the full range of C_6–C_{11} components to maximize gasoline production. In petrochemical applications, naphtha feed may be adjusted to contain a more select range of hydrocarbons to maximize the production of aromatics.

Currently, there are more than 700 commercial installations of catalytic reforming units worldwide with a total capacity of about 11.4 million barrels per day (b/d). Table 1 presents a worldwide distribution of catalytic reforming capacity.[4] About 40% of this capacity is located in North America followed by 20% each in Western Europe and Asia-Pacific region.

REFORMING CHEMISTRY

Several catalytic reactions take place during the naphtha reforming that involve the rearrangement of hydrocarbon molecules. Because naphtha contains many paraffin and naphthene isomers, multiple reforming reactions take place simultaneously in the reforming reactors. Naphthenes react rapidly and efficiently to aromatics, while paraffins react slowly and with poorer specificity. Aromatic compounds pass through the reforming unit relatively unchanged.[5] These reactions comprise the following:

- Dehydrogenation and dehydroisomerization of naphthenes to aromatics.
- Aromatization of paraffins.
- Isomerization of normal paraffins and naphthenes.
- Hydrocracking of paraffins and naphthenes to lighter saturated paraffins.
- Dealkylation of aromatics.

The above reactions take place concurrently. The first two are desirable for the production of aromatics, while the last two are generally undesirable because of the production of lower-value light products. The dehydrogenation of naphthenes proceeds rapidly and produces hydrogen as well as aromatics. The reactions take place on the surface of the catalyst and are very much dependent, among other factors, on the right combination of interactions between catalyst ingredients. Most of them are promoted by the dual metal–acid functions of the catalyst. The majority of these reactions involve the conversion of paraffins and naphthenes and result in an increase in octane number and a net production of hydrogen. The overall reactions are highly endothermic and require continuous supply of heat to maintain reaction temperature.

PROCESS CLASSIFICATION

The reforming process is generally classified into three types:

1. Semiregenerative
2. Cyclic (fully regenerative)
3. Continuous regenerative (moving bed).

This classification is based on the frequency and mode of regeneration. Table 2 presents a region-wise distribution of catalytic reforming capacity by process

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120039766

Table 1 Worldwide distribution of naphtha reforming by capacity and process type

Region	No. of refineries	Crude capacity (1000 b/d)	Reforming capacity (1000 b/d)	Reforming as % crude capacity
N. America	159	20,476	4,193	20.5

Total	675	82,409	11,347	13.8

(From Ref.[4].)

type.[4] The semiregenerative scheme dominates the reforming capacity at about 57% of the total capacity followed by continuous regenerative at 27% and cyclic at 11%. Most grassroots reformers are designed for continuous catalyst regeneration (CCR). In addition, many units that were originally built as semiregenerative units have been revamped to continuous regeneration units. The semiregenerative type requires unit shutdown for catalyst regeneration, whereas the cyclic process utilizes a swing reactor for regeneration in addition to regular reactors. The continuous process permits catalyst replacement during normal operation.

Semiregenerative Process

The semiregenerative process is characterized by continuous operation over long periods, with decreasing catalyst activity. Eventually, the reformers are shut down periodically as a result of coke deposition to regenerate the catalyst in situ. Regeneration is carried out at low pressure (approximately 8 bar) with air as the source of oxygen. The development of bimetallic and multimetallic reforming catalysts with the ability to tolerate high coke levels has allowed the semiregenerative units to operate at 14–17 bar with similar cycle lengths obtained at higher pressures. It is believed that all reforming licensors have semiregenerative process design options.[6]

The semiregenerative process is a conventional reforming process that operates continuously over a period of up to 1 year. As the catalytic activity decreases, the yield of aromatics and the purity of the by-product hydrogen drop because of increased hydrocracking. Semiregenerative reformers are generally built with three to four catalyst beds in series. The fourth reactor is usually added to some units to allow an increase in either severity or throughput while maintaining the same cycle length. The longer the required cycle length, the greater the required amount of catalyst. Conversion is maintained more or less constant by raising the reactor temperatures as catalyst activity declines. Sometimes, when the capacity of a semiregenerative reformer is expanded, two existing reactors are placed in parallel, and a new, usually smaller, reactor is added. Frequently, the parallel reactors are placed in the terminal position. When evaluating unit performance, these reactors are treated as though they are a single reactor of equivalent volume.[1,6]

Table 2 Distribution of naphtha reforming by process type

Region	Reforming capacity (1000 b/d)	Share of reforming capacity by process type (%)			
		Semiregenerative	Continuous	Cyclic	Other

(From Ref.[4].)

The research octane number (RON) that can be achieved in this process is usually in the range of 85–100, depending on an optimization between feedstock quality, gasoline qualities and quantities required, as well as the operating conditions required to achieve a certain planned cycle length (6 mo to 1 yr). The catalyst can be regenerated in situ at the end of an operating cycle. Often the catalyst inventory can be regenerated 5–10 times before its activity falls below the economic minimum, whereupon it is removed and replaced.

Cyclic (Fully Regenerative) Process

The cyclic process typically uses five or six fixed catalyst beds, similar to the semiregenerative process, with one additional swing reactor, which is a spare reactor. It can substitute any of the regular reactors in a train while the regular reactor is being regenerated. In this way, only one reactor at a time has to be taken out of operation for regeneration, while the process continues in operation. Usually, all the reactors are of the same size. In this case, the catalyst in the early stages is less utilized; therefore, it will be regenerated at much longer intervals than in the later stages. The cyclic process may be operated at a low pressure, a wide boiling range naphtha feed, and a low hydrogen-to-naphtha ratio.[6] Coke lay-down rates at these low pressures and high octane severity (RON of 100–104 range) are so high that the catalyst in individual reactors becomes exhausted in time intervals of less than 1 week to 1 mo.

The process design of the cyclic process takes advantage of low unit pressures to gain a higher C_{5+} reformate yield and hydrogen production. The overall catalyst activity, conversions, and hydrogen purity vary much less with time than in the semiregenerative process. However, a drawback of this process is that all reactors alternate frequently between a reducing atmosphere during normal operation and an oxidizing atmosphere during regeneration. This switching policy needs a complex process layout with high safety precautions and requires that all the reactors be of the same maximum size to make switches between them possible.

Continuous Regenerative Process

The CCR process is characterized by high catalyst activity with reduced catalyst requirements, more uniform reformate of higher aromatic content, and high hydrogen purity. The process can achieve and surpass reforming severities as applied in the cyclic process but avoids the drawbacks of the cyclic process. The continuous process represents a step change in reforming technology compared to the semiregenerative and cyclic processes. Since its introduction in the early 1970s, it has gained wide acceptance in refining and petrochemical industries worldwide.

In this process, small quantities of catalyst are continuously withdrawn from an operating reactor, transported to a regeneration unit, regenerated, and returned to the reactor system. In the most common moving-bed design, all the reactors are stacked on top of one another. The fourth (last) reactor may be set beside the other stacked reactors. The reactor system has a common catalyst bed that moves as a column of particles from top to bottom of the reactor section. Coked catalyst is withdrawn from the last reactor and sent to the regeneration reactor, where the catalyst is regenerated on a continuous basis. However, the final step of the regeneration, i.e., reduction of the oxidized platinum and second metal, takes place in the top of the first reactor or at the bottom of the regeneration train.

Fresh or regenerated catalyst is added to the top of the first reactor to maintain a constant quantity of catalyst. Catalyst transport through the reactors and the regenerator is by gravity flow, whereas that from the last reactor to the top of the regenerator and back to the first reactor is by the gas-lift method. Catalyst circulation rate is controlled to prevent any decline in reformate yield or hydrogen production over time onstream.

In another design, the individual reactors are placed separately, as in the semiregenerative process, with modifications for moving the catalyst from the bottom of one reactor to the top of the next reactor in line. The regenerated catalyst is added to the first reactor, and the spent catalyst is withdrawn from the last reactor and transported back to the regenerator. The continuous reforming process is capable of operation at low pressures and high severity by managing the rapid coke deposition on the catalyst at an acceptable level. Additional benefits include elimination of downtime for catalyst regeneration and steady production of hydrogen of constant purity (93% compared to 80% in the semiregenerative process). Operating pressures are in the 3.5–17 bar range and design research octane number is in the 95–108 range.

COMMERCIAL REFORMING PROCESSES

Several commercial reforming processes are available for license worldwide. A list of reforming processes with a summary of key process features is presented in Table 3. Several commercial processes are available, dominated by UOP and Axens Technologies for semiregenerative and continuous reforming. Other licensors included Houdry Division, Chevron, Engelhard, Exxon-Mobil, and Amoco, but none of them is currently

Table 3 Licensors of naphtha reforming processes

Licensor	Process name	Process type and key features	Remarks
UOP	Platforming	Semiregenerative; CCR; CycleMax regenerator; product recovery system	Over 800 units with 8 million b/d
Axens	Octanizing; Aromizing	Semiregenerative; CCR; dual forming for conventional process revamp	Over 100 licensed units
Houdry Div. of Air Products	Houdriforming	Semiregenerative; high-octane gasoline and aromatics	0.3 million b/d
Engelhard	Magnaforming	Semiregenerative or semicyclic	1.8 million b/d
ExxonMobil	Powerforming	Semiregenerative or cyclic	1.4 million b/d
Chevron	Rheniforming	Semiregenerative; low-pressure operation	1 million b/d
Amoco	Ultraforming	Semiregenerative or cyclic	0.5 million b/d

(From Ref.[6].)

actively licensing.[6] The processes differ in the type of operation (semiregenerative or CCR), catalyst type, catalyst regeneration procedure, and process engineering design.

All licensors agree on the necessity of hydrotreating the feed to lower the level of poisons for the platinum-based reforming catalyst.[2] Temporary poisons are sulfur and nitrogen, while As, Pb, and other metals are permanent poisons. Proper conditions of hydrogen, pressure, temperature, and space velocities are able to reduce these poisons to the acceptably low levels of modern catalysts. Numerous process design modifications and catalyst improvements have been made in recent years.

Platforming Process

Platforming was the first process to use platinum-on-alumina catalysts. The first UOP semiregenerative platforming unit went onstream in 1949. UOP technology is used in over 50% of all reforming installations with more than 750 units in service worldwide.[7] The platforming process has been adapted to bimetallic catalyst and to both semiregenerative and continuous operations. UOP offers semiregenerative units that use staged loading of catalyst for increased production. New catalysts are continuously aimed at maximizing hydrogen yield, increasing operating flexibility, and maximizing C_{5+} product yield.

The total capacity of the semiregenerative units exceeded 5.0 million b/d while CCR units reached 3.8 million b/d. The simultaneous use of CCR technology and bimetallic catalysts has given UOP a unique position in the field of catalytic reformer process licensing. Recent catalyst formulations have improved both aromatic and reformate yields. UOP has improved the performance of the conventional platforming process by incorporating a CCR system. The process uses stacked radial-flow reactors and a CCR section to maintain a steady-state reforming operation at optimum process conditions: fresh catalyst performance, low reactor pressure, and minimum recycled gas circulation. The flow pattern through the platforming unit with CCR is essentially the same as with conventional fixed-bed units. The effluent from the last reactor is heat exchanged against combined feed, cooled, and phase split into vapor and liquid products in a separator. A schematic flow diagram of the CCR platforming process is presented in Fig. 1.

Catalyst flows vertically by gravity down the stack, while the feed flows radially across the annular catalyst bed. The predominant reactions are endothermic; hence, an interheater is used between each reactor to reheat the charge to reaction temperature. The catalyst is continuously withdrawn from the last reactor and transferred to the regenerator. The withdrawn catalyst flows down through the regenerator where the accumulated carbon is burned off. The regenerated catalyst is purged and then hydrogen is lifted to the top of the reactor stack, maintaining nearly fresh catalyst quality. Because the reactor and regenerator sections are separate, each operates at its own optimum conditions.

Typical operating conditions for the current design of the UOP CCR process are: reactor pressure 6.8 bar; liquid hourly space velocity (LHSV) 1.6 per hour; H_2/hydrocarbon (HC) molar ratio 2 : 3; and RON-clear 100–107. The CCR unit operates at higher severity and lower reactor catalyst inventory. In addition, the CCR unit runs continuously compared to 12 mo semiregenerative cycle lengths. Typical product yields for the CCR and semiregenerative platforming units operating at the same conditions are presented in Table 4.[8] Many of the benefits of CCR include higher hydrogen yield and purity as well as higher octane barrels.

One recent development in CCR technology is second-generation CCR platforming with several modifications in the reactor and regenerator sections.

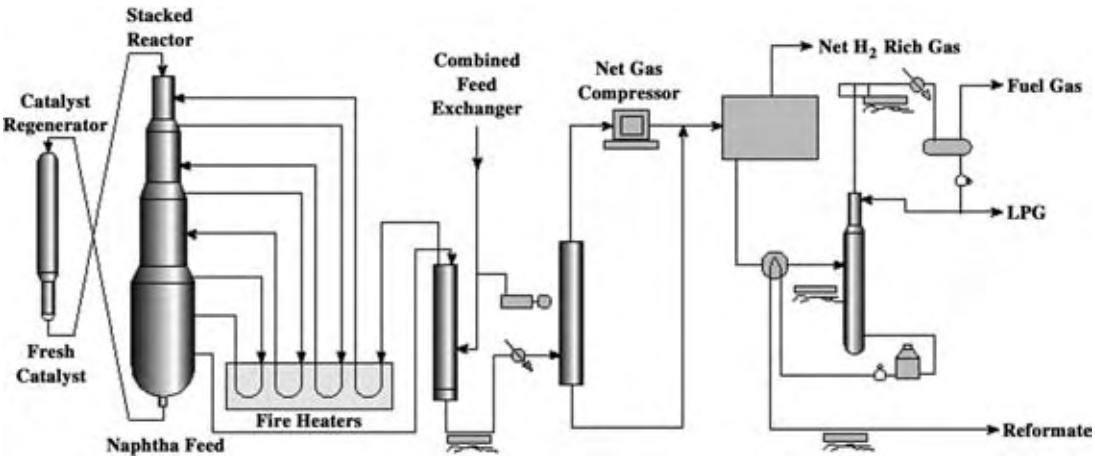

Fig. 1 Schematic of UOP CCR platforming process.

The high-efficiency regenerator design resulted in an increased coke-burning capacity with reduced regeneration severity and complexity. CycleMax regenerator provided easier operation and enhanced performance over other regenerator designs. The operation at ultra-low pressure (3.4 bar) and the use of low-platinum catalyst ensured the highest yield of the reformate and aromatic product with more cost-effective process operation. The net gas recovery schemes maximized the yields of reformate and hydrogen. Moreover, the new regenerator allowed higher regeneration rates to support the coke generation of the low-pressure operation and high conversion levels.

UOP has developed the RZ platforming process for high aromatics selectivity, in the range of 80% or higher. The selectivity of conventional reforming for benzene and toluene is significantly lower than for the C_8 aromatics. Although UOP CCR platforming is the most efficient means for producing xylenes from heavy naphtha fractions, its conversion of C_6 and C_7 paraffins to aromatics is normally below 50%, even at low pressure. In general, RZ platforming configuration is consistent with other UOP platforming systems. The process employs adiabatic, radial-flow reactors that are arranged in a conventional side-by-side pattern. Interheater is used between each reactor to reheat the charge to reaction temperature. Treated naphtha feed is combined with recycled hydrogen and sent to the reactor section. The effluent from the last reactor is heat exchanged against combined feed, cooled, and phase split into vapor and liquid products in a separator. The liquid from the recovery section is sent to a stabilizer where light saturates are removed from the C_{6+} aromatic product. Typical cycle lengths are 8–10 mo and the units are designed for efficient in situ catalyst regeneration.

Table 4 Typical yields of UOP semiregenerative and CCR units for a Middle East naphtha feed

Parameter	Semiregenerative	CCR
Catalyst type	R-72	R-274
Stream factor (day/yr)	330	360
Pressure (kPa)	1380	345
Yield		
Hydrogen (scfd)	1270	1690
C_{5+} (wt%)	85.3	91.6
RON-clear	100	100

(From Ref.[8].)

Octanizing Process

The Axens octanizing reforming technology is based on Institut Français du Pétrole (IFP) and Procatalyse's reforming expertise for the upgrade of various types of naphtha to produce high-octane reformate, BTX, and LPG. The reforming process can be supplied in either semiregenerative or continuous operation.[9–11] The Axens semiregenerative version is a conventional reforming process in which the catalyst is regenerated in situ at the end of each cycle. The operating pressure of this process is in the range of 12–25 bar with low-pressure drop in the hydrogen loop. The product RON-clear is in the range 90–100. Trimetallic catalyst formulations for semiregenerative applications offer higher selectivity and stability.

The decrease in the reformate yield during the run of the semiregenerative version (in spite of improved catalyst stability) has led Axens to develop a catalyst moving-bed system that allows continuous regeneration of the catalyst. The octanizing process is an advanced design that reflects the results of several decades of research and development efforts. The heart of the technology lies in its original catalyst circulation and CCR systems. A schematic flow diagram of the

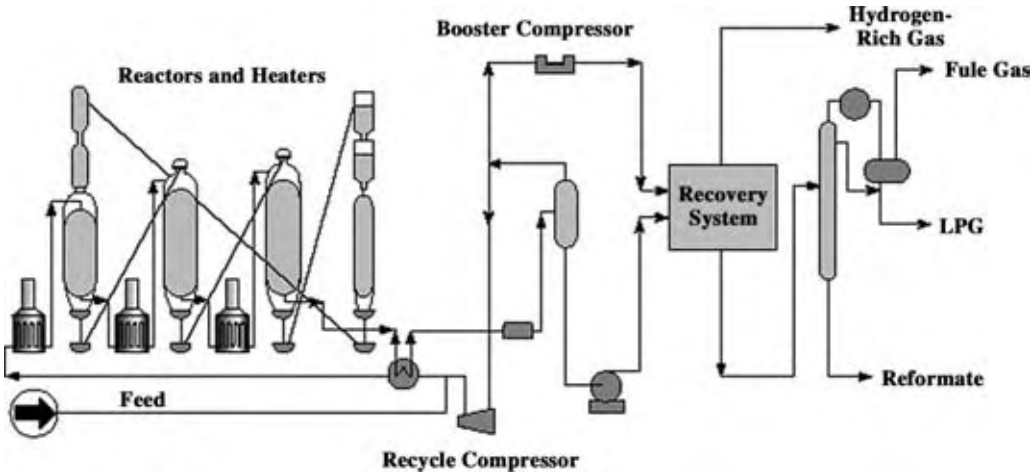

Fig. 2 Schematic of Axens octanizing process.

octanizing process is presented in Fig. 2.[12] The overall process comprises the following:

- A conventional reaction system consisting of a series of four radial-flow reactors using a highly stable and selective catalyst suitable for continuous regeneration.
- A catalyst transfer system using gas lift to carry the catalyst from one reactor to the next and finally to the regenerator.
- A catalyst regeneration section, which includes a purge to remove combustible gases, followed by catalyst regeneration.

The octanizing process features high onstream efficiency, flexibility, and reliability. Major improvements, compared with previous designs, are the development of catalysts of increased activity, selectivity, and hydrothermal stability along with substantial increases in the yields of C_{5+} reformate and hydrogen. Table 5 presents typical yields of the Axens conventional and regenerative process.

Aromizing is Axens CCR reforming process for the selective production of aromatics. It is the petrochemical complement to the octanizing process. The technology employs an advanced catalyst formulation to achieve high BTX aromatics yield and offers high aromatics yields, low investment and operating costs, and high onstream factor. In the octanizing or aromizing process, treated naphtha is mixed with recycled hydrogen, preheated, and passed through a series of adiabatic reactors and heaters, where it is converted to aromatics-rich stream and hydrogen. The effluent is cooled by heat exchange, and the liquid product is separated from recycled and hydrogen gases. Axens regenerative technology has been improved to allow faster circulation of the catalyst and, as a consequence, increased regeneration frequency as required by the more severe operating conditions (low pressure, low H_2/HC ratio).

Table 5 Typical yields of Axens semiregenerative and octanizing processes for a 90–165°C cut light Arabian feedstock

Parameter	Semiregenerative	Octanizing process
Pressure (kg/cm^2)	10–15	<5
Yield (wt%)		
Hydrogen	2.7	3.8
C_{5+}	83	88
RON-clear	100	102
MON-clear	89	90.5

(From Ref.[9].)

Houdriforming Process

The houdriforming process was licensed by the Houdry Division of Air Products and Chemicals, Inc. It can be used to upgrade various naphtha to aviation blending stocks, aromatics, and high-octane gasoline in the range of 80–100 RON-clear. The process operates in a conventional semiregenerative mode with four reactors in series for BTX production, compared with three for gasoline. The catalyst used is usually Pt/Al_2O_3 or a bimetallic. A small ''guard case'' hydrogenation pretreater can be used to prevent catalyst poisons in the naphtha feedstock from reaching the catalyst in the reforming reactors. The guard case is filled with the usual reforming catalyst but is operated at a lower temperature. It is constructed as an integral stage of the houdriforming operation when required for the feedstock.

At moderate severity, the process may be operated continuously for either high-octane gasoline or

aromatics, without provision for catalyst regeneration. However, operation at high severity requires frequent in situ catalyst regeneration. Typical operating conditions are: temperature 755–810 K, pressure 10–27 bar, LHSV 1–4 per hour, and H_2/HC ratio 3 : 6. The total capacity of houdriforming units is about 250,000 b/d.

Magnaforming Process

The magnaforming process, which was licensed by Engelhard Corporation, can be used to upgrade low-octane naphtha to high-octane reformate. The product is a premium blending component or aromatic hydrocarbon source. The feature that most distinguishes the magnaforming process from other reforming processes is its use of a split hydrogen recycle stream to increase liquid yields and improve operating performance. About half of the recycled gas is compressed and recycled to the first two reactors, which are operated under mild conditions. The greater portion of the recycled gas is returned to the terminal reactors that operate under severe conditions. It is believed that substantial compressor power savings can be achieved by splitting the recycle. It is also claimed[3] that the lower H_2/HC ratio in the first two reactors benefits naphthene dehydrogenation, while the higher ratio in the latter reactors provides improved catalyst stability.

Engelhard does not offer a continuous design, but it did provide a semiregenerative design and a combination of semiregenerative and cyclic regeneration. The combination design is made by supplementing the terminal reactors by a swing reactor that can alternate with the terminal reactors. It can also operate in parallel with the terminal reactors, permitting these reactors to be regenerated without unit shutdown. Smaller magnaforming units use a conventional three-reactor system, compared with four reactors in large units.

The process was initially designed to operate with established monometallic platinum catalysts but was adapted to include the newer platinum–rhenium-based catalyst of the E600 and E800 series. The catalysts provide greater activity and stability, enabling use in units where high-severity operation and long cycle lengths are required. A wide range of catalysts have been used in the magnaforming process to optimize operating performance and to produce the desired product specifications. Many units incorporate sulfur guard technology to reduce sulfur in reformer feed to ultralow levels. There are approximately 150 units totaling 1.8 million b/d using the Engelhard reforming technology.

Powerforming Process

Powerforming is offered by ExxonMobil to produce gasoline blending stocks from low-octane naphthas. Alternatively, the process may be operated to give high yields of benzene or other aromatics, or to produce aviation blending stocks. It also produces large quantities of hydrogen that can be used to hydrotreat or improve other products. The process features a semiregenerative or cyclic configuration and proprietary catalyst system tailored to the client's specific needs. Advantages include cost-competitive installations for units less than 12,000 b/d, 98 RON products achievable, mild severity operations, and long cycle lengths.

The staged catalyst system has high stability, good selectivity and selectivity maintenance. It uses the high-activity catalyst with very high stability and benzene/toluene yields. KX-130 is an excellent debottlenecking catalyst or BTX-producing catalyst. The dual catalyst system offers high-activity catalyst, high benzene/toluene yields, and a C_{5+} yield advantage. ExxonMobil's catalyst management techniques for hot flue gas regeneration in cyclic units, onstream chlorination, and analytical tools for monitoring the catalyst help enhance the unit's performance.

Cyclic powerformers are designed to operate at low pressure, with a wide range of feed boiling point and low hydrogen-to-feed ratio. The unit has four reactors in series plus a swing reactor. The use of the swing reactor allows any of the onstream reactors to be taken out of service for regeneration while maintaining continuous operation of the unit. The frequency of regeneration can be varied to meet changing process objectives as well as to operate under high-severity, low-pressure conditions, as coke deposition is maintained at low levels. Regeneration is generally performed on a predetermined schedule to avoid having two or more reactors regenerated at the same time. Usually, the terminal reactors are scheduled for more frequent regenerations than the early-stage reactors. Run lengths of up to 6 yr between shutdowns could be achieved. Powerforming has a wide range of potential refining applications and has been commercially applied in nearly 50 semiregenerative units and over 30 cyclic units ranging from 1000 b/d to 65,000 b/d.

Rheniforming Process

The rheniforming process can be used to convert naphthas to high-octane gasoline blendstock or aromatics plant feedstock. The process gained wide acceptance when Chevron patented the bimetallic Pt/Re catalyst in 1968. Rheniforming is basically a semiregenerative process comprising a sulfur sorber, three radial-flow reactors in series, a separator, and a stabilizer. The process is characterized by the sulfur control sorber, which reduces sulfur to 0.2 ppm in the reformer feed. A new rheniforming catalyst system has been used, which permits low-pressure operation. The high

resistance to fouling of the catalyst system increases the yields of aromatic naphtha product and hydrogen due to the long cycle lengths, which reach 6 mo or more. Optimized operating techniques permit maintenance of high catalyst activity throughout each cycle and return to fresh activity after each regeneration.

The increased resistance to fouling also provides for expansion of existing plants by using higher space velocities, lower recycle ratios, or increased product octane. Converted units operate with H_2/HC ratios of 2.5 : 3.5 and long cycles between regeneration. It is believed that a total of 73 rheniformers are onstream with a total capacity of more than 1 million b/d.

Ultraforming Process

The Amoco's ultraforming process (now BP's) can be used to upgrade low-octane naphthas to high-octane blending stocks and aromatics. The process is a fixed-bed cyclic system with a swing reactor incorporated in the reaction section that is usually specified for aromatic (BTX) production. The system can be adapted to semiregenerative operation with the conventional three radial-flow reactors in series. The process uses rugged, proprietary catalysts, permitting frequent regeneration and high-severity operations at low pressures. The catalyst system has a relatively low precious metals' content, and its estimated life is perhaps 4 yr for cyclic operation vs. 8 yr for semiregenerative operation. The swing reactor in cyclic operation replaces any reactor while the catalyst bed in this reactor is being regenerated. Normally, the reactors are of the same size; however, the first reactor is loaded with half the usual amount of catalyst.

Ultraformers may be designed to produce high-purity xylenes and toluene, which can be separated by straight distillation before the extraction step. The benzene fraction can be recovered by extractive distillation. High yields of C_{5+} reformate and hydrogen have been reported for the ultraforming process. The total capacity of ultraforming is over 530,000 b/d for 39 commercial units worldwide. However, no new ultraformers have been licensed in recent years.

Zeoforming Process

The zeoforming process is a new reforming technology for high-octane gasoline production from hydrocarbon raw material of various origins (straight-run naphtha of gas condensates and crude oils, condensates of accompanying gases, olefin-containing gases, secondary hydrocarbon fractions of refinery and petrochemical plants), boiling up to 200–250°C. The process has been developed by the SEC Zeosit Center of the Siberian Branch of the Russian Academy of Sciences. A special highly stable and selective IC-30-type catalyst based on modified pentasil zeolite is used in the process.[13]

Because of the acid–base shape-selective mechanism of the hydrocarbon conversion in the zeoforming process, the gasoline product has a lower aromatics content compared to the reformate with the same octane number. Reactions proceeding under zeoforming process conditions allow benzene concentration to decrease below 1 vol% and to produce gasoline with low sulfur content without naphtha hydrotreating owing to insensibility of the catalyst to sulfuric compounds in the feedstocks. The process is based on the catalytic conversion of linear paraffins and naphthenes into iso-paraffins and aromatics over zeolite-containing catalysts, which allows the motor octane number (MON) of naphtha to increase from 45–60 up to 80–85.

Stepanov et al.[13] reported that a small-scale plant of 120 b/d of naphtha was operated successfully in the north of Siberia, Russia in 1992. Catalyst life reached more than 1.5 yr. A new industrial plant based on zeoforming process of 1000 b/d capacity has been in operation at Glimar Refinery in Poland since 1997.

COMMERCIAL REFORMING CATALYSTS

In the 1950s, naphtha-reforming catalysts were essentially heterogeneous and monometallic and composed of a base support material (usually chlorided alumina) on which platinum metal was placed. These catalysts were capable of producing high-octane products; however, because of quick deactivation as a result of coke formation, they required high-pressure, low-octane operations. Typically, the time between regenerations is a year or more.

In the early 1970s, bimetallic catalysts were introduced to meet the increasing severity requirements. Platinum and another metal (often rhenium, tin, or iridium) account for most commercial bimetallic reforming catalysts. The Pt–Re catalyst has proven to be reliable and easily regenerable, making it the primary catalyst in use today in semiregenerative units.[14] The catalyst is most often presented as 1/16, 1/8, or 1/4 in. Al_2O_3 cylindrical extrudates or beads into which Pt and other metals have been deposited.

In commercial catalysts, platinum concentration ranges between 0.3% and 0.7% and chloride is added (0.1–1.0%) to the alumina support (eta or gamma) to provide acidity. Those of CCR are mainly bimetallic Pt–Sn on chlorided alumina in a spherical form. The advantages include increased activity and selectivity during paraffin aromatization and decreased rate of catalyst deactivation.

At present, there are six international vendors of reforming catalysts producing more than 80 different types of catalysts suitable for different applications

and for a variety of feedstocks. The current demand for reforming catalysts is mainly a replacement market with about 75–80% of it as bimetallics. Reforming catalyst vendors continue to develop new catalyst formulations designed to meet a wide array of challenges. Many of these challenges involve environmental regulations that refiners have been, and will be, required to meet during the coming few years. Table 6 presents a compilation of commercial reforming catalysts that are available by sale or license to refiners.[15] The list provides information on catalyst supplier, catalyst type, and other selected catalyst properties.

CONCLUSIONS

Catalytic reforming remains the primary process in the refinery for producing high-octane gasoline to be blended into the gasoline pool. As the needs for gasoline have risen, the demands on the reformer have also increased. The catalytic reformer is one of the few units to provide hydrogen in the refinery to meet clean fuel requirements. Reforming is also a major source of aromatics for petrochemical production. Nowadays, the catalytic reformer produces more hydrogen by increasing the severity of operation or by improving selectivity to aromatics. New reforming technology, in the form of new catalysts or minimal revamp process improvements, has improved the operation of the catalytic reformer.

Centrifuges

Alan G. Letki
Alfa Laval Inc., Warminster, Pennsylvania, U.S.A.

INTRODUCTION

Centrifuges are a means of mechanical separation. They can be used to separate insoluble solids and liquids mechanically based on particle size and/or density, or immiscible liquids based on density. Most commonly, the solids have a higher density than the liquid(s) from which they are separated. Centrifuges occupy two separate branches of the mechanical separation tree (Table 1), as they are of value in enhancing both sedimentation-based and filtration-based separations.[1] Their design has evolved since the time when Swedish engineer Gustaf de Laval in 1878 patented the first successful industrial centrifuge—a cream separator. Operating in batch, batch automatic, or continuous modes, centrifuges are now used by process industries to perform many separation duties. These include clarification, classification, dewatering, extraction, purification/concentration, rinsing, washing, and thickening. The aim of this entry is to describe general operating characteristics. More theoretical issues are discussed elsewhere.[2]

SEPARATION DUTIES

Each separation duty and its function is described below.

Clarification is the separation of insoluble particles from a liquid. The goal is to maximize the clarity of a single liquid phase via solid removal.

Classification splits a slurry into two streams. The aim is to achieve the separation of solids based on particle size and/or density differences.

Dewatering is the removal of the vast majority of solids from a slurry to produce a cake that has body and integrity. The objective is to produce a conveyable/truckable cake, increase the fuel value, or reduce the processing cost of the feed solids by removing the liquid, which is usually water.

Extraction involves the mixing of a liquid, typically an immiscible organic liquid with an aqueous slurry. The purpose is to transfer the solute from the aqueous to the organic phase and recover the organic phase.

Purification and concentration describe the separation of two immiscible liquids, with or without the presence of insoluble solids. The former process aims to produce a very clean light-phase liquid, whereas the latter seeks to yield a very clean heavy-phase liquid.

Rinsing is the removal of mother liquor from suspended solids after separation but before they are removed from the centrifuge. The intent is to produce a less contaminated solid.

Washing is the countercurrent or cross-current cleaning performed by dissolving impurities in suspensions or crystal/amorphous solid slurries. The objective is to use a series of centrifuges to enhance the purity of the solids or to minimize the amount of wash liquid.

Thickening is the removal of the vast majority of suspended solids from a liquid to produce a fluid solid stream of acceptable viscosity. The usual aim is to reduce the liquid content and maintain a pumpable/mixable solid slurry.

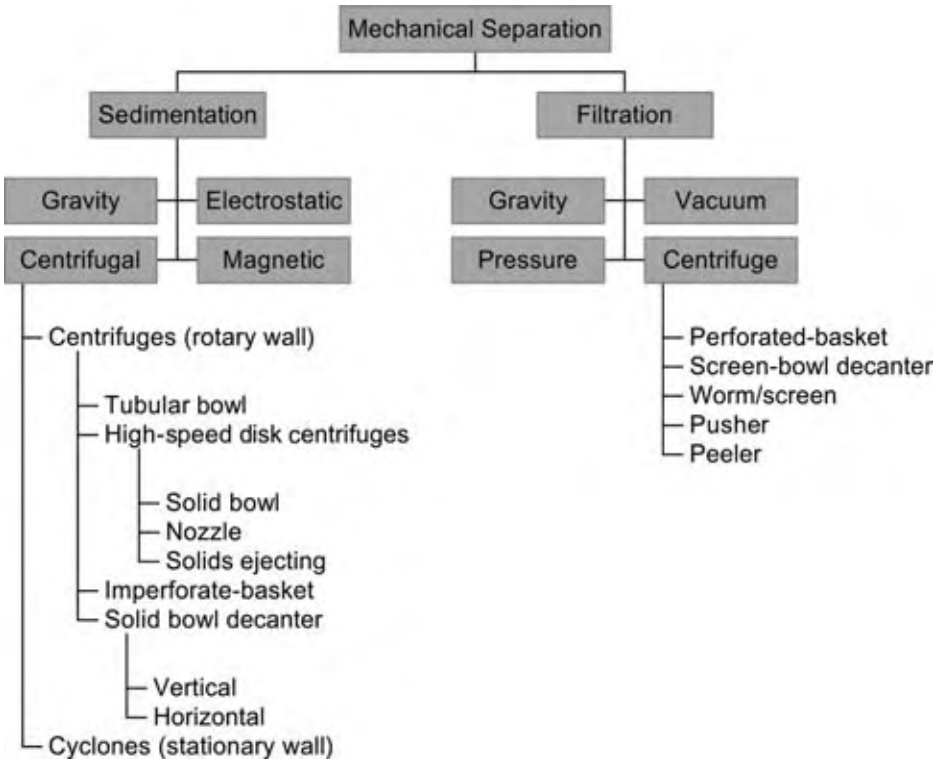
SEDIMENTATION VS. FILTRATION

The basic difference between filtration and sedimentation is media dependence. Filtration removes solids from a liquid by directing the stream at the media. It succeeds by collecting the solids on, or within the thickness of, the media, while allowing the liquid to pass through. The process is usually used for materials that form incompressible (rigid) cakes, especially if rinsing is required. Premixing of the slurry with additives (filter aid) is done sometimes to provide the necessary cake consistency. At other times, a precoat layer, normally in conjunction with cloth, may be used to enhance filtration. Sedimentation is employed on materials that form compressible cakes, especially soft, slimy, gelatinous materials, or on those materials with particle sizes too small to be efficiently collected by filter media. Whether a cake acts compressibly or incompressibly may vary with particle size distribution and the shapes of the mixture of particles, and may be affected by the G-level applied.

While most solids have a higher gravity than the liquor from which they are separated, floating solids that are usually not captured in ordinary sedimenting centrifuge may well be collected in filtering centrifuges if the particles are large enough.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120006800

Table 1 Mechanical separation tree



MECHANICAL COMMONALITY

Centrifuges consist of the following common mechanical parts: a bowl that generally rotates on either a horizontal or a vertical axis in which the separation takes place, a casing that collects the solids or liquids discharged from the bowl and diverts them in different streams away from the bowl, a frame that supports the casing and bowl, and a drive mechanism to supply power for turning the bowl. Some method of feed input/distribution into the bowl as well as a means of discharging solids and/or liquids from the bowl is also required. Sedimenting centrifuges have mostly solid or imperforate bowls, while perforate ones are used to support the media, usually screens or cloths of filtering centrifuges.

THE ROTATING BOWL

The fundamental mechanical component of a centrifuge is a rotating bowl. When properly designed and utilized, it augments separation. The magnitude of the enhancement is based both on the radius of the bowl and on the speed of rotation, and is sometimes incorrectly described as G-force. The relative centrifugal force or G-level is not a force—it is the ratio of the acceleration of the centrifugal field to the acceleration caused by the earth's gravity, which is a dimensionless number:

$$G_s = \omega^2 r/g \text{ dimensionally } (1/\text{time}^2 \times \text{distance})/(\text{distance}/\text{time}^2) \text{ dimensionless} \quad (1)$$

This ratio or level may reach 60,000 on small laboratory units, 20,000 on small industrial scale units, or may be limited to a few hundreds on large industrial centrifuges. Although the level tends to decrease as the size of the rotor increases, it is normally large enough so that a rotor rotating horizontally is considered to have the same separating capacity as it would have if it rotated vertically, i.e., the influence of the earth's gravitational field is negligible while the rotor is spinning. The choice of a vertical or horizontal centrifuge is therefore based on other factors than the effect of the earth's gravitational pull on the material being centrifuged.

The rotation of the bowl results in power being consumed and stresses being placed on the rotating bowl shell.[3]

SEDIMENTATION

Starting with Newton, when a force is applied to a particle, it is accelerated:

$$F = ma \quad (2)$$

In a static settling tank under the influence of the earth's gravity, the particle settles along the radius of the earth. When g is the gravitational constant,

$$F = mg \quad (3)$$

In a centrifugal field, the acceleration, $\omega^2 r$, results in a force that acts normal to the axis of rotation:

$$F = m\omega^2 r \quad (4)$$

In a sedimenting centrifuge, a continuous liquid phase moves through the rotor. To accomplish a useful separation, the discontinuous phase, either the insoluble solids or the immiscible liquid drops (or both), must move in a direction different from the flow of the continuous liquid. Stokes' law is usually applied to describe this relationship. The effective force accelerating the particle in a centrifugal field is then given as:

$$F_p = (m_p - m_l)\omega^2 r \quad (5)$$

where m_p is the mass of the particle and m_l is the mass of the liquid displaced by the particle. If we define $\Delta\rho = (\rho_p - \rho_l)$, the difference in the density between the particle and the continuous liquid phase, then for a spherical particle of diameter D:

$$F_p = (\Pi/6)\Delta\rho D^3\omega^2 r \quad (6)$$

If the diameter is small or the viscosity is high, the particle moves at a velocity below the turbulent range and Stokes' law defines the force of the liquid phase resisting the particle as:

$$F_l = 3\Pi\eta D v_s \quad (7)$$

If the particle settles long enough (reaches equilibrium), then

$$F_l = F_p \quad (8)$$

Then, in a centrifugal field:

$$v_s = (\Delta\rho D^2\omega^2 r)/18\eta \quad (9)$$

In the earth's gravitational field:

$$v_g = (\Delta\rho D^2 g)/18\eta \quad (10)$$

The difference between the velocity in the centrifugal field (v_s) and in the earth's gravitational field (v_g) is an essential reason for utilizing sedimenting centrifuges. In a centrifuge, as in a gravity thickening device, the diameter of the particle, the difference in density between the particle and the continuous-phase liquid, as well as the viscosity of the liquid, are important process parameters.

From an operational standpoint, it may be useful to consider that in the earth's gravitational field, if the center of the earth were viewed as "downhill"—the direction in which movement usually occurs—the direction in a centrifuge corresponding to this downhill movement would be away from the center of rotation, i.e., from smaller to larger radius.

SIGMA THEORY

A method of sizing/scaling centrifuges called the sigma theory had been developed by Ambler over half a century ago.[4] Ambler recognized that there are two sets of factors influencing separation performance: those that are characteristic of the feed and others that are typical of the centrifuge. The former include particle size, densities, and viscosity and the latter include bowl speed and bowl dimensions. The theory calculates the equivalent area of a centrifuge so that the feed rate to the centrifuge divided by the sigma factor yields a clarification capacity in units of mass/area/time. Other slightly different factors have been advanced over the years.[5]

INLETS AND OUTLETS

Considerable engineering effort is typically expended in the design of inlets and outlets. In selecting the correct bowl type and operating speed, it is important to ensure that the advantages achieved not be diminished by either the inlet or the outlet chosen for the desired application.

If, as discussed, the square of particle diameter is related to settling velocity, it is obvious that separation may be enhanced by not reducing the diameter of the particle in the inlet to the centrifuge. It is perhaps less obvious that the type of discharge/outlet may reduce particle size and be detrimental to further downstream processing.

The inlet, including the feed pipe, serves several purposes and should therefore exhibit various properties. One among them is that it should be free from plugging. To achieve this, grinders may be used (especially on waste applications). When feed pipe nozzles are used, screens may be employed ahead of the centrifuge to remove oversized materials and prevent plugging. In addition to carrying feed slurry into the centrifuge, concentrically designed tubes may also be used to transport a second or even a third fluid into

the centrifuge. In horizontal decanters, the inlet may convey a flocculent that is added internally to flocculate shear-sensitive materials. In screen bowls, separate rinse liquor for distribution as screen rinse may also be transported. A similar function is also observed with cleaning solutions, especially on hygienic applications. The inlet also helps determine the characteristics of the feed system. It may be a single open pipe discharge as in the case of horizontal decanters or disk centrifuges that would have a fairly low pressure drop associated with them. It could be a nozzle to jet the feed into the bowl as is typical of the tubular bowls and vertical decanters that would require higher pressure. In the case of some hermetic disk centrifuges, the feed system is used to cause flow through the entire centrifuge. With high solid slurries or particles that tend to settle quickly, the feed pipe may have several discharge points to evenly distribute solids, especially in large basket centrifuges, and may be fed from a circulating loop to prevent settling of the feed slurry.

Outlets of both solids and liquids, if not properly chosen, may adversely affect separation to the extent that it may even be impossible to effect separation in the bowl. Because choosing the correct outlet size can be critical, most sedimenting centrifuges are designed so that at least the liquid outlet radius can be changed relatively easily. Selecting the appropriate outlet radius is particularly important in separating immiscible liquids because two must be chosen.[6]

Open discharges, i.e., the simple flow of liquid phase over the bowl weir of sedimenting centrifuges, if properly designed, tend to consume less energy but require more space in the casing. The absence of adequate casing space may promote remixing of discharged components in, or while being discharged from, the casing. Paring disks or skimmer tubes, while consuming power, may be used not only to carry isolated liquid away from the unit, but may also be critical in minimizing air entrainment or foam production on some materials. Although an overwhelming number of materials are acceptably processed, when cake discharge causes unacceptable degradation of some of them, they can be removed from batch operations by completely stopping the centrifuge and hand scooping the material or by manually removing bags or liners designed to fit in the centrifuge rotor.

SEDIMENTING CENTRIFUGES

Sedimenting centrifuges use a solid/imperforate bowl to enhance sedimentation. The most common sedimenting centrifuges listed in the order of decreasing G-level, are as follows: tubular bowl, disk stack separator, decanter, and imperforate baskets.

Several tables are provided to show the 40-fold difference in diameter and the 300-fold difference in attainable G-level. Table 2 lists the separation duties normally associated with the centrifuge type, while Table 3 shows the type of separation and the mode of operation when solids are present in the feed. The typical feed solids and particle sizes associated with the centrifuges are shown in Table 4. Table 5 provides the common feed rate ranges and solid concentrations achieved. Solids in Tables 4 and 5 are given in typical %vol/vol and in typical %wt/wt (insoluble or suspended solids) because the preference for volume or weight measurements varies by application. Tubular bowls (Fig. 1) use a small diameter to allow operation at an extremely high G-level and a relatively high length to diameter ratio. The small diameter limits the stress on the bowl shell allowing relatively common materials such as stainless steel to be utilized in bowl construction. To allow reliable operation, the rotor is vertically mounted and acts as a pendulum. The small diameter and high-speed rotation preclude using a solid-discharge mechanism. Hence, solid–liquid separations require manual solid removal.

Disk stack separators are vertical bowl centrifuges that are characterized by the presence of a nested conical stack of disks. The centrifuges are usually categorized by the method of solid removal from the bowl and include solids-retaining, solids-ejecting, and nozzle-discharge units. The feed enters the bowl at

the center of rotation, is distributed across the bottom of the bowl, and then flows up through a disk stack. The solids that are more dense than the liquid travel radially outward. Those that enter the disk stack are forced to the underside of the conical-shaped disk, and then along the disk surface to the periphery of the bowl. The lighter liquid moves radially inward and up the stack. In the case of two immiscible liquids, the heavier (more dense) one forms an intermediate position between the light phase and the heavier solids. The presence of the heavy liquid requires the presence of a special top disk and a provision for keeping the liquids separate while exiting the bowl and casing. The settling distance is limited by the spacing between the disks. Because the distance that the particles or immiscible droplets have to settle is considerably shortened, settling capacity is significantly increased. This makes these units the most efficient of clarifiers, purifiers, or concentrators per unit of floor space.

Solids-retaining separators (Fig. 2) are batch centrifuges. They are generally larger in diameter than tubular bowls. Therefore, they are large enough to contain a disk stack but are dependent on at least partial disassembly for manual removal of solids. The larger diameter means that even though they operate at high G-levels, the G-level is somewhat lower than that of a tubular bowl. It also indicates that they have higher solids-holding capacity than the tubular bowl. The bowl shown in this figure is equipped for a liquid–liquid separation. The outlet dams would be adjusted to devote the majority of the disk stacks to the phase requiring greater purity. In the purification process, which aims at producing a clean light phase, the interface (e-line) would be moved outward. On the other hand, in the concentration process, which seeks to yield a clean heavy phase, the e-line would be moved inward. The feed would normally be introduced near the e-line.

Solids-ejecting separators (Fig. 3) are designed for continuous processing with intermittent discharge of solids. The bowl consists of a sliding bottom and a top or hood. At its widest part, the body has a series of discharge openings. In normal operation, the bottom is held against the hood, closing off these openings. When the bottom drops to its lower position, the space between the it and the hood exposes the discharge ports. Accumulated solids are ejected or shot through the ports and into the collecting cover. In the

bowl shown here, an operating fluid and springs control the opening and closing of the bowl. Numerous variations in discharge methods have been employed. It is generally considered that the faster the shot, the greater the potential for a drier cake.

Nozzle-discharge separators (Fig. 4) consist of a solid bowl that has a double cone shape. In place of discharge ports that are intermittently open, it contains nozzles that are usually along the periphery. As solids flow toward the nozzle, they are concentrated before being continuously discharged. The bowl shown here has been modified and can introduce rinse water or recycled nozzle flow between the disk stack and the nozzle. With the introduction of rinse, the solids are forced through the layer of rinse before being discharged through the nozzle. At least some portion of the rinse liquor tends to travel inward and be discharged through the stack. It cannot be discharged separately from the centrate unless it is immiscible and provision is made for liquid–liquid discharge. The recycling of nozzle flow would allow the use of larger nozzles to produce the same nozzle concentration,

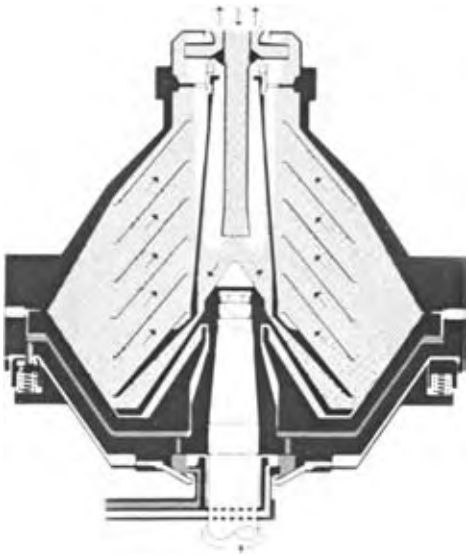

Fig. 3 Solids-ejecting disk stack separator. *(View this art in color at www.dekker.com.)*

or may permit the concentration to be controlled externally via the recycle rate.

Solid bowl decanters (Fig. 5) are characterized by the presence of a screw concentrically located within the rotating bowl, a bowl that is cylindrical with a conical beach extension, and the use of a gear reducer to establish a differential speed between the conveyor and the bowl. The feed material is introduced through a feed tube at the center of rotation. It is discharged inside the conveyor hub and accelerated through feed ports into the bowl. This means that the energy to accelerate the feed is provided by the centrifuge driver—usually an electric motor—and not by the feed pump. In the bowl, the solids are continuously separated from the liquid. Being denser than the liquid, they settle against the bowl wall. The liquid or the

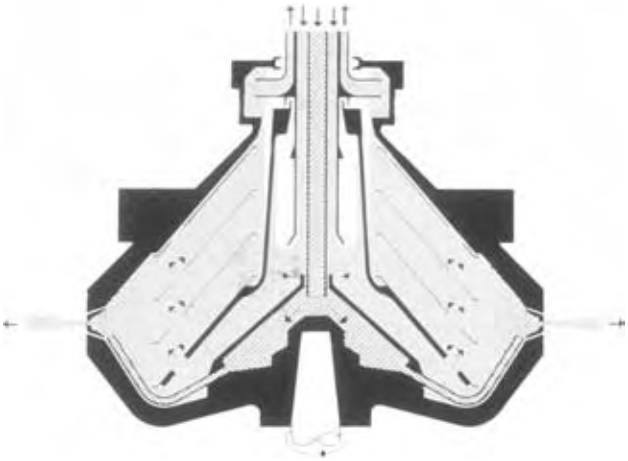

Fig. 4 Nozzle-discharge disk stack separator. *(View this art in color at www.dekker.com.)*

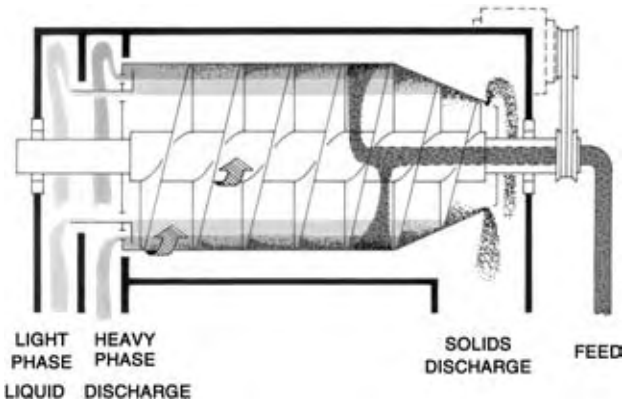

Fig. 5 Solid bowl decanter centrifuge. *(View this art in color at www.dekker.com.)*

two immiscible liquids are decanted over adjustable weirs, usually on the large (cylindrical end) side of the bowl. The conveyor moves at a speed slightly different from the bowl because of the gear reducer, which is often augmented by a variable speed driver—usually electric or hydraulic. This differential speed conveys the solids along the cylindrical portion of the bowl and up the conical beach, discharging them at the opposite end of the bowl from the liquid. If the electric or hydraulic drive is infinitely variable, then the bowl conveyor differential is also infinitely variable over its operating range. The unit can be used on solid–liquid or solid–liquid–liquid separations. By installing nozzles above the beach and using a concentric feed tube, with the inner tube transporting feed slurry and the outer tube carrying rinse liquor, it is possible to do some rinsing in this unit. If the rinse is added on the beach, it must ultimately find its way to the centrate end and be commingled with the centrate before discharge from the bowl.

Solid bowl scroll decanter centrifuges have also been built vertically. The pendulum-type construction allows the bowl to expand more easily when operating at higher temperatures and makes mechanical sealing for elevated pressures less cumbersome. Although these units have been designed for operation up to 10 bars, they often operate at 5 bars or less.

Imperforate basket centrifuges are vertical baskets that make up a relatively small portion of those sold. They are most often used to collect fine or amorphous solids, especially slimy or sticky ones. The solids are fed into the basket and those that are heavier than the liquid accumulate on the wall, much as they do in the tubular bowl. Because the diameter of the basket is at least an order of magnitude larger than that of the tubular bowl, there is usually space for a discharge mechanism inside the basket. Imperforate bowls often have two instruments: a skimmer for liquids and a plow for solids. The clear, less dense liquid supernates

and is discharged over a top ring or is removed through a skimmer tube. After the liquid is removed, the plow is inserted and the solids usually drop out through the bottom. As the diameter becomes larger than 4–5 ft, the G-level drops to a few hundred times *g*. As the unit is batch operated, the spin times can be increased, which sometimes compensates for the decreased G-level.

THE BATCH CYCLE

Centrifuges may be batch, batch automatic, or continuous. Handling of the separated solids is the primary reason for the difference in operating modes. Therefore, a centrifuge type may be a batch operation when separating solids from liquids, but a continuous one when separating two immiscible liquids.

Although from an economic and production standpoint the batch cycle analysis certainly applies to the tubular bowl and the solids-retaining disk stack centrifuge, the batch cycle (Fig. 6) is most often considered when operating basket centrifuges. The cycle as shown is most often associated with a filtering centrifuge. The feeding, spinning, and rinsing can be individually varied to optimize process performance. Likewise, the bowl speed for spinning and discharge is sometimes altered for optimal performance, usually to avoid compression or to minimize particle breakage. Vertical baskets or pendulum-type units are usually operated at variable basket speeds to allow higher G-levels for dewatering and lower levels to minimize particle breakage on discharge. The peeler is typically a horizontal basket that plows the cake for discharge at high speeds to minimize the cycle time. For vertical baskets, the cycle and its component times are usually measured in minutes, and in extreme cases, in hours, while the corresponding cycle component times in peelers may be measured in seconds. In lieu of accelerating and decelerating times, the peeler may have an additional rinsing time after the solids are discharged. The residual solids on the screen may be dissolved on an intermittent basis. This conditioning of the screen can be programmed into the batch cycle to maintain drain rates and cycle times.

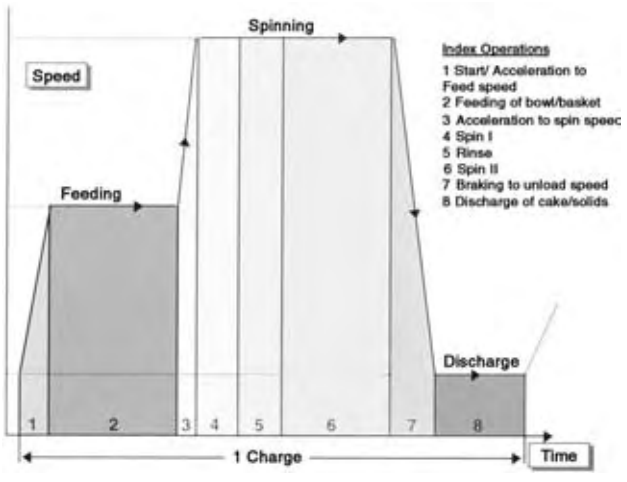

Fig. 6 Batch cycle diagram. *(View this art in color at www.dekker.com.)*

The batch cycle with respect to imperforate bowls would most often substitute skimming for rinsing. As the solids settle against the bowl wall, there may be a clean liquid layer in the basket above the settled solids. To maximize cake dryness, the clear layer is taken off through a skimmer tube. There may be one or more feed and skim cycles before the cake solids are plowed out for discharge.

FILTERING CENTRIFUGE

While the tendency is to consider hydraulic rates on sedimenting centrifuges, filtering units are commonly considered in terms of tonnages. High tonnages are often achieved, not by processing high liquid rates, but by processing high to extremely high slurry solid concentrations. Mechanical comparisons are often made on filtering area or volume per batch/tonnage per cycle. Cake thickness is an important consideration as is rinse efficiency.

The screen bowl decanter (Fig. 7) can be thought of as a horizontal solid bowl decanter with a cylindrical screen inserted between the top of the conical beach and the bowl discharge. The screen opening is of the order of 150 mesh. In addition to having the ability to segregate the rinse liquid from other centrifuge discharges, the decanter allows cake rinsing to be much more comparable to other filtering centrifuges than to the solid bowl. Alternately, it can provide a clean centrate and a more uniform crystal size at the cake discharge by allowing the fine particles to pass through the screen and be isolated for processing separately from the cake and centrate discharges.

The vertical or pendulum perforate basket (Fig. 8) is perhaps the most commonly used centrifuge. The perforated basket in its simplest form is lined with a cloth, wire mesh, or a bag that accumulates solids as the liquid passes through. When the solid space is filled, feeding is discontinued and the relevant portion of the batch cycle is continued. In smaller units, the bowl may simply spin down to a complete stop for manual removal of the cake or replacement of the bag. At higher G-levels or in larger diameter units, wire mesh or screen is added to support the filter media. Slowing the unit and plowing the solids out at low speed complete the batch cycle. Rinse can be isolated

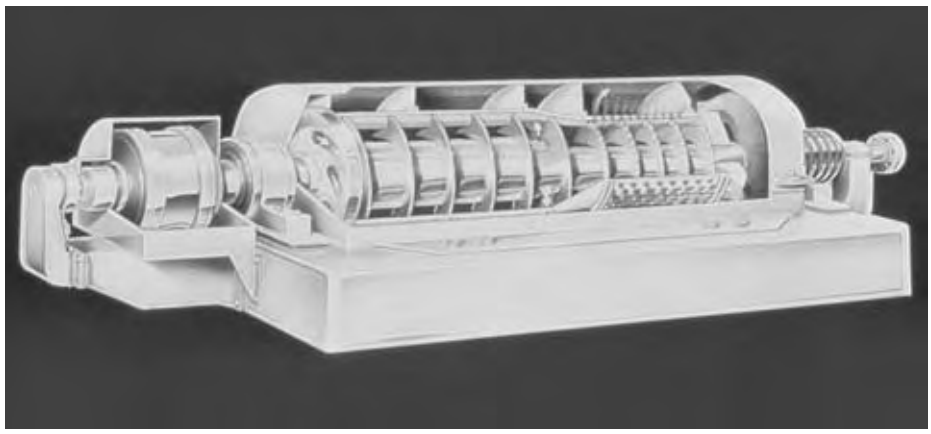

Fig. 7 Screen bowl decanter centrifuge. *(View this art in color at www.dekker.com.)*

from centrate by diverting the liquid discharge at the appropriate time.

Major types of horizontal perforate basket centrifuges are peelers, pushers, and worm/screen centrifuges. The fundamental purpose of the horizontal operation is to keep the operating mechanisms, including drives, isolated from the process streams. The variation in size, G-level, and application is not nearly as high as it is with the sedimenting centrifuges. The fundamental concern is the processing of crystals, with emphasis on throughput, dryness, particle integrity, and purity.

Peelers are characterized by conical baskets (Fig. 9) that are fitted with a heavy-duty plow mechanism that ''peels'' the cake away from the bowl for discharging at operating speed. This minimizes the batch cycle time and is normally used to process more rugged crystals. Peelers may provide cake rinse and may be equipped to dissolve the residual heel cake on line, promote drainage, and maintain short cycle times.

Cylindrical screen sections over which solids are ''pushed'' by the reciprocating action of a piston characterize pushers. They may consist of one, two, or multiple stages. The cake may receive one or more rinses, if required.

A conical screen with an internal screw or ''worm'' characterizes the worm/screen. Because the crystals are

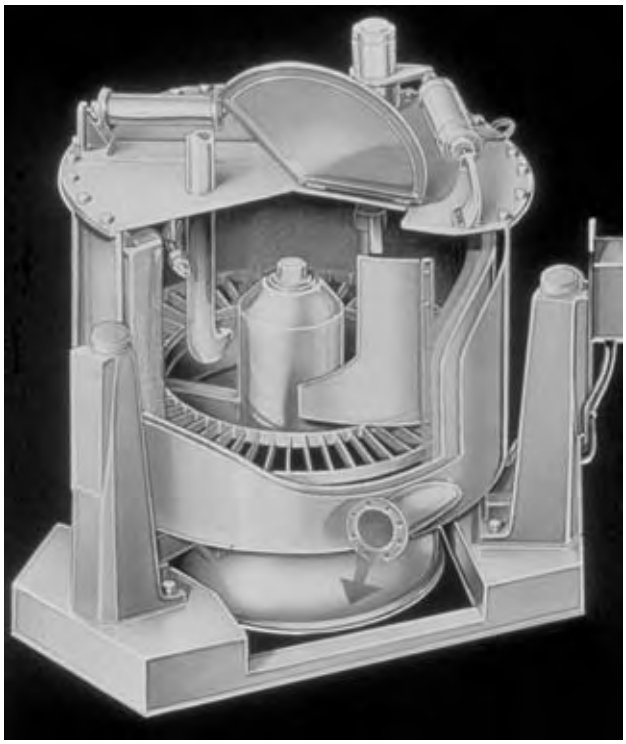

Fig. 8 Vertical perforate basket centrifuge. *(View this art in color at www.dekker.com.)*

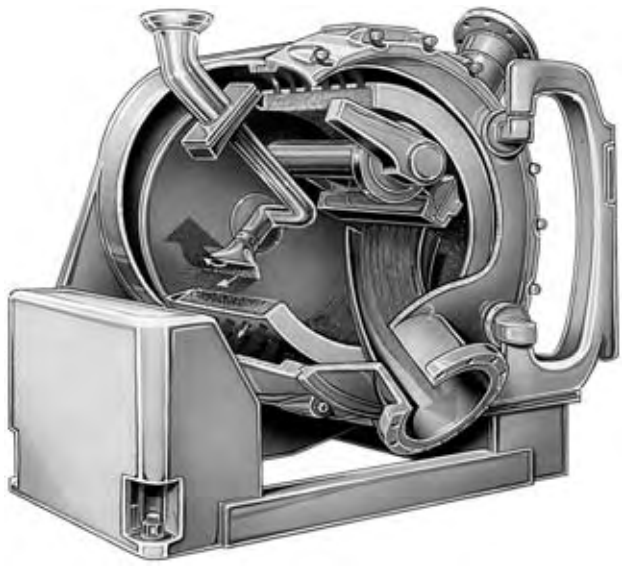

Fig. 9 Peeler centrifuge. *(View this art in color at www.dekker.com.)*

fed at the small end of the cone, the internal screw helps control the rate at which the crystal travels down the screen to discharge. The differential speed between the screw and the screen is sometimes externally adjustable. Multiple rinses may be employed and are sometimes kept separate from each other.

CONCLUSIONS

This entry has presented a brief description of sedimenting and filtering centrifuges. The types of separation, separation duties, and modes of operation have been discussed. The basic common and distinct mechanical elements have also been dealt with. References are included for those readers seeking a more in-depth historical, theoretical, as well as practical background on the subject.

Ceramics

Stephen J. Lombardo
Department of Chemical Engineering, University of Missouri–Columbia, Columbia, Missouri, U.S.A.

INTRODUCTION

This entry will be divided into sections covering the classification of ceramics, a brief history of ceramics, raw materials for ceramics, properties and applications of ceramics, processing of ceramics, and a brief commentary on future trends. The field of ceramics is very broad and encompasses not only well-known, conventionally used materials and technology but also much newer compositions, processing methods, and applications. More detailed information on all of these sections is available in printed format[1–9] and on the web.[10–14]

CLASSIFICATION

Ceramics, which come from the Greek words *keramikos* and *keramos* for pottery or potter's clay, are defined as inorganic nonmetallic solids and are a separate class of materials as compared to metals or organic solids such as polymers and plastics. This simple definition, which encompasses many materials, can be divided into broad application categories as whiteware, structural clay, refractory, glass, abrasive, advanced, and other (see Fig. 1). These groups can be further divided into more specific market segments. The last heading in Fig. 1 of "Other" contains cement, diamond, graphite, and silicon. Although these materials do not completely fit the definition of ceramic materials, they also do not fully meet the criteria to be classified solely as organic or metallic solids either. They are thus often included with the more conventional ceramics in Fig. 1 because of similarity in properties, application, or processing.

In addition to grouping ceramics by general application as in Fig. 1, alternative taxonomic schemes are possible. Table 1 indicates ways that ceramics can be classified according to application, composition, crystal structure, forming method, microstructure, and synthesis method. The subheadings in each category are often combined in conversational usage so that one may refer to "ferroelectric electronic ceramics," "chemical vapor deposited oxide films," "single crystal sensors," or "monolithic ceramics for wear applications."

BRIEF HISTORY

In the social, cultural, and technological evolution of mankind, ceramic materials have played a significant role. The earliest man-made ceramics, which were figurines, were produced around 24,000 B.C. By 10,000 B.C., vessels fabricated from ceramic materials were in use. By 5000 B.C., a number of cultures worldwide used ceramics in basic functions such as storage vessels for food and drink, and as cookware; ceramics also served as decorative, ornamental, and possibly symbolic functions in different cultures as well. By 1500 B.C., glass products were produced in many areas of the world. These early developments of ceramic technology, which postdate the Stone Age and predate metal processing, are exemplary of mankind's creativity whereby common raw materials are transformed by sequential processing steps into value-added, often highly functional products. In fact, the basis for many aspects of modern ceramic processing can be found in technologies developed hundreds or thousands of years ago.

Today, ceramic materials find widespread applications in both the consumer and industrial market segments. In the home, ceramics are commonly used in kitchens and bathrooms and for decoration and ornamentation. As construction materials, ceramics are widely used as bricks, tiles, and concrete sidewalks.

Although many of the common uses of ceramics listed above are well known, the foundation role that ceramic materials have played in technology development and in modern society is often less widely appreciated. Ceramic materials are technology enablers for the processing of a variety of commodity and advanced materials. For example, the inertness of ceramic crucibles and refractory bricks enables the high-temperature processing of metal alloys and glass. Ceramic and glass materials support silicon wafers in many of the processing steps used to manufacture integrated circuits. Ceramic coatings on gas turbine blades allow for operation at higher temperature, which leads to more efficient energy generation.

In addition to their role as technology enablers, ceramic components find widespread use today in electronics, wireless communications, fiber optic cables, lasers, digital data storage, and capacitors. Emerging technologies in which ceramics play a key role include

RAW MATERIALS FOR CERAMICS

Ceramic materials of the clay family occur widely in nature, and the many different forms of clay differ in both their composition and crystal structure. In general, the structure of clay is noted for its layered arrangement of aluminosilicate sheets. Upon addition of water, the clay–water mixture responds plastically, which aids in the ability to form complex shapes. Two examples of clay compositions are kaolinite [$Al_2(Si_2O_5)(OH)_4$] and montmorillonite [$(Al_{2-y}X_y)(Si_2O_5)_2(OH)_2$, where X is Na or Mg and y is 0.33].

Nonclay minerals also widely used as ceramic raw materials are silica (SiO_2, obtained from quartzite, sandstone, and sand), lime (CaO, derived from limestone, $CaCO_3$), talc ($Mg_3Si_4O_{10}(OH)_2$), and feldspar (aluminosilicates containing oxides of sodium, potassium, and calcium). Other ceramic materials are derived from naturally occurring minerals. Alumina (Al_2O_3) is obtained from the mineral bauxite, which is a mixture of gibbsite [$Al(OH)_3$] and diaspore ($HAlO_2$). Zirconia (ZrO_2) is found as the mineral baddeleyite or is derived from zircon ($ZrSiO_4$). Titania (TiO_2) is found as the minerals rutile and anatase. Many of the ceramic raw materials found in nature may need to undergo powder beneficiation prior to being further processed for specific applications.

Some ceramic materials are not found widely or at all in nature, and thus are synthesized for use. To prepare more complex ceramic compositions such as perovskites of general structural formula ABO_3, and ferrites, of formula MFe_2O_4, the individual oxides or salts of the cations A, B, and M are often combined as powders and then reacted at high temperature by a solid-state diffusion mechanism. Silicon nitride (Si_3N_4) can be manufactured from either the nitridation of silicon metal or from the reaction of silicon tetrachloride with ammonia. Silicon carbide (SiC) is obtained from the reduction of silica with a carbon containing source.

Other synthesis methods have also been developed but may not be practiced on a large commercial scale as compared to those indicated above. Examples of syntheses that begin from liquid phase precursors include the sol–gel, hydrothermal, and Pechini methods. In the course of these reaction schemes, polycondensation or precipitation occurs, and the volatile components are removed, often by thermal methods. Other synthesis routes to ceramic materials include the nitridation of metals to form metal nitrides and the carbothermal reduction of oxides to form carbides and borides.

PROPERTIES AND APPLICATIONS

Ceramic materials have a number of properties that make them useful in a wide variety of applications. Although from a fundamental viewpoint material properties can be classified as equilibrium (e.g., stress–strain), transport (e.g., thermal conductivity), hysteretic (e.g., ferromagnetization), and irreversible (e.g., hardness), a more conventional grouping is used here. Some of the main physical, chemical, mechanical,

thermal, electrical, magnetic, and optical properties of ceramics are listed in Table 2.

The properties of ceramics are related to the type of bonding in the material and whether the material is amorphous or crystalline. Glasses are a common example of amorphous materials in which the atoms comprising the material do not exhibit a highly regular long-range arrangement of atoms in space.

The crystal structure of ceramics, i.e., the periodic arrangement of atoms in space, ranges from simple to complex. The complexity arises from the occurrence of both covalent and ionic bonding and from the diverse compositions of ceramics, especially when multiple cations or anions are present. In order of decreasing symmetry, seven crystal systems exist (cubic, tetragonal, orthorhombic, monoclinic, rhombohedral, hexagonal, and triclinic); ceramics are found in all these crystalline forms. The crystal structure of a ceramic material can be the determining factor whether certain mechanical, electrical, and magnetic properties exist.

Physical Properties

One primary physical property is density, and as a class of materials, the density of ceramics (2–7 g/cm^3) is intermediate between the densities of polymers (0.4–2 g/cm^3) and metals (>7 g/cm^3, with the exception of alloys of aluminum, magnesium, and titanium). Thus, ceramics are attractive materials when compared to many metals, when a reduction in weight per unit volume is desired.

Another physical property is melting point. Many ceramics have melting points above 500°C; many oxide, carbide, and nitride ceramics, however, have melting points (or decompose) near or well above 1500°C. These values far exceed those of polymers, which generally melt or begin to decompose below 400°C. Metals, on the other hand, often possess melting points between 500 and 1500°C; exceptions to this are refractory metals such as tungsten and molybdenum, which melt above 2500°C, but these two materials are restricted to use at elevated temperature in high vacuum or reducing environments. As a consequence of their high melting points, ceramics are often used in high-temperature applications. Some ceramics, especially the nonoxides, do not exhibit a true melting point but rather decompose or dissociate at elevated temperature.

Chemical Properties

One important chemical property of ceramics is resistance to chemical corrosion at both room and elevated temperatures. In fact, the inertness of some ceramic materials, combined with high melting point and the retention of at least modest mechanical strength, allows them to be widely used in the high-temperature processing of other materials such as molten metals and glasses. Quartz, for example, is the crucible material in the Czochralski process for growing single crystal silicon. Refractory bricks, which are used in furnace construction, glass melting, and steel making, are made from compositions mainly consisting of alumina, silica, and magnesia (MgO). Clay-based filters are employed in the filtering of molten metals before they are cast into molds. Silicon carbide, quartz, and other ceramic materials are holders for silicon wafers in the fabrication of integrated circuits.

Some ceramics exhibit biocompatibility in the human body. Alumina and zirconia are employed as the ball for hip replacements. Hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$) is used as bone replacements, as ocular implants, and as a coating for metallic implants. Ceramics also find application in dentistry for restorative work.

The adsorption properties of ceramics for liquids and gases also make them widely used for separations based on chemical affinity; silica, alumina, and zeolites (aluminosilicates with highly regular microporous intracrystalline pores) are widely used as adsorbents in the chemical process industries. Inorganic membranes based on silica, alumina, titania, and zeolites are also emerging; in these applications, their surface properties and highly tailored pore size are used to effect gas and liquid separations. Ceramic membranes, as compared to polymeric membranes, can also operate in aggressive (highly basic or acidic) chemical environments and at high temperature.

Mechanical Properties

The mechanical properties of interest for ceramics include tensile strength, strain at failure, compressive strength, modulus of elasticity, hardness, and fracture toughness. Of all materials, ceramics have some of the highest values of compressive strength, modulus of elasticity, and hardness. These attributes, alone or in combination, often make ceramics suitable for applications wherever wear resistance is important. Silicon nitride, for example, is used to make ceramic ball bearings. Alumina is used for femoral hip replacements. Silicon carbide is used as water pump seals in automobile engines and alumina is used as seals in water faucets. Abrasive grains of alumina, silicon carbide, boron carbide (B_4C), silica, cubic boron nitride (BN), and diamond (C) are used in grinding, lapping, and polishing operations. Silicon nitride is used in high performance cutting tools and is being considered for use as engine valves in diesel and internal combustion engines. Concrete, which contains cement, is used as a durable and inexpensive road and sidewalk material.

For tensile strength and fracture toughness, lower values, as compared to advanced metal alloys are often realized for ceramics. This arises, to a certain extent, from flaws that arise in the material during processing. To extend the range of application of ceramic materials, much current process development, compositional development, and microstructure engineering are aimed at improving the tensile strength and fracture toughness.

Many applications of ceramics rely on their mechanical properties at high temperature. This advantage of ceramics is realized because of their high melting points and because of the inertness of the materials to chemical reaction, which can include resistance to oxidation, reduction, and chemical corrosion. In combination, these properties often lead to superior creep and fatigue resistance of ceramic materials. Thus, many ceramics find their application as high-temperature barrier materials in the form of tiles, bricks, crucibles, and supports for silicon wafers in the semiconductor industry. For silicon nitride, the retention of high-temperature mechanical properties in extreme environments has led to the use of this material in gas turbines and automobile turborotors.

Thermal Properties

The thermal properties of interest for ceramics are thermal expansion, thermal conductivity, specific heat, and emissivity. The thermal expansion of ceramics tends to be lower than that of metals and this has both positive and negative consequences. Because of the low thermal expansion coefficient of some ceramics, they tend to withstand thermal shock, and thus can be subjected to temperature cycling. This same low thermal expansion, however, leads to strain mismatch when ceramic components, such as turborotors, are joined to metallic parts, such as the turborotor shaft.

The thermal conductivity of ceramics can span a range of values and, for a given material, can also be adjusted by addition of second phases, including air (pores), dopants, and by grain boundary engineering. To lower the thermal conductivity of ceramics, porosity is often designed into the microstructure of the materials. This can be accomplished by incomplete sintering, by preparing ceramic foams, and by preparing fibrous materials. The low thermal conductivity of these materials, along with high melting points, makes them extremely useful for thermal insulation as tiles, heat shields, and as fibrous insulation. Fiberglass insulation is one such example; a second is the tile for the space shuttle, which is mainly fibrous silica containing approximately 90% porosity. In addition to dissipating heat, the shuttle tiles can also withstand the extreme thermal shock associated with exposure to shaded and sunlit regions of outer space.

Electrical Properties

The electrical properties of interest for ceramics include conductivity, resistivity, dielectric breakdown strength, dielectric constant, loss factor, and electromechanical coupling. Most ceramics do not have high electrical conductivity, and thus ceramics have found application as electrical insulators for many years. The electrical insulating capability of some ceramics is also retained under high electric field; this is referred to as high dielectric breakdown strength

and is important in electricity transmission and in other high voltage applications.

Although the vast majority of ceramic materials are electrical insulators because of their high band gap, some ceramics, such as silicon carbide, strontium titanate, and silicon, are semiconducting. The semiconducting behavior of these materials is often modified by the incorporation of impurities or dopants into the material: n-type dopants lead to semiconduction whereby electrons (negative particles) are the predominant charge carriers. Conversely, p-type dopants lead to semiconduction whereby holes (positive particles) are the predominant charge carries. Doping is widely used to tailor the semiconducting properties of silicon in integrated circuits.

Another type of electrical conductivity observed in ceramics is ionic conductivity, which often occurs appreciably at elevated temperature; a widely used material exhibiting this behavior is zirconia doped with other oxides such as calcia (CaO) or yttria (Y_2O_3). For this material, atomic oxygen is the mobile ionic species. Doped zirconia finds widespread use as oxygen sensors, especially as part of automobile emission control systems, where the oxygen content of the exhaust gas is monitored to control the air-to-fuel ratio. Other applications of ionic conducting ceramics are as the electrolyte phases in solid-oxide fuel cells and in sodium–sulfur batteries.

Ceramic compositions also exhibit superconductivity, and what is notable is that they become superconducting at much higher temperatures as compared to other metallic and intermetallic compositions. The oxide composition $YBa_2Cu_3O_7$ is superconducting near 90 K, which is above the temperature of liquid nitrogen. Other ceramic oxide compositions containing bismuth, strontium, barium, calcium, and copper are superconducting at temperatures between 100 and 150 K.

Ceramics can possess a wide range of dielectric constants from 2 to 10,000, and thus find use as capacitors for charge storage and electronic filtering. Ceramic dielectrics include porcelain materials and many titania- or titanate-based compositions. In electrical applications involving alternating current, the dielectric loss factor is important for determining how efficiently electrical energy is utilized.

Selected classes of asymmetric crystal structures exhibit the property of piezoelectricity. With the application of a mechanical strain, piezoelectric materials develop an electrical potential difference across them; conversely, when a potential difference is applied to these materials, a displacement occurs. The efficiency of the conversion between mechanical energy and electrical energy is described by the electromechanical coupling constant, which practically ranges to values as high as 0.7; a value of 1 would imply complete conversion between mechanical and electrical energy. The piezoelectric behavior of ceramics is used widely. The conversion of electrical energy to displacement underlies the applications of ultrasonic mixing, sound wave generation from ultrasonic transducers, and precision-controlled positioning devices. The conversion of strain to an electrical signal is the basis of operation for ultrasonic sensors, accelerometers, strain gauges, and sound generation from phonograph recordings. Ferroelectric materials that find widespread use in these applications are barium titanate ($BaTiO_3$), lead titanate ($PbTiO_3$), and lead zirconate ($PbZrO_3$). Because the response of piezoelectric devices is very sensitive to aspects of ceramic processing and microstructure, additives are often used with the primary compositions to fine-tune the performance. Such fine-tuning may lead to improved coupling constants and better mechanical, temperature, and frequency performance.

Magnetic Properties

Ceramic materials also exhibit magnetic behavior, which is described in terms of the magnetic permeability or the magnetic susceptibility. Magnetic ceramics find application as permanent magnets, as circuit elements in electronic devices, and as digital information storage media in the form of coatings on recording tape and on disk substrates. Many magnetic ceramics are of the ferrite composition and have the general chemical formula of MFe_2O_4, where M is a divalent cation such as iron, nickel, copper, manganese, or magnesium. More than one of the divalent cations is often included in ferrite compositions to fine-tune the magnetic properties. Other ceramics that exhibit magnetic behavior include the rare earth garnets, orthoferrites, ilmenites, and hexagonal ferrites.

Optical Properties

The optical properties of ceramics are useful in the ultraviolet, visible, and infrared ranges of the electromagnetic spectrum, and one key quantity used to describe the optical property of a material is the refractive index, which is a function of the frequency of the electromagnetic radiation. Other quantities used to characterize optical performance are absorption, transmission, and reflection; these three properties sum to unity and are also frequency dependent. The last three properties govern many aspects of how light interacts with materials in windows, lenses, mirrors, and filters. In many consumer, decorative, and ornamental applications, the esthetic qualities of the ceramic, such as color, surface texture, gloss, opacity, and translucency, depend critically on how light interacts with the material.

In addition to the well-known optical uses listed above, the behavior of light with ceramic materials

is used to advantage in a number of advanced applications. Fiber optic glass cables exhibit nearly 100% total internal reflectance and are used to transmit both light images and digital information. Glass beads can exhibit directional reflectance and are used as additives in paint to improve the light reflectivity of signage and pavement lines. Solid-state lasers from ruby and yttrium aluminum garnet (YAG) are also widely fabricated from ceramic materials. Windows for gas lasers are often fabricated from ceramics materials; the ceramic used depends on its ability to transmit light at the frequency of interest.

PROCESSING

The majority of ceramic components are derived from powder processing routes, which are in contrast to the casting or molding of metals, polymers, and glass. The difficulty in casting ceramic shapes arises because of the high melting points of ceramic materials. In addition, because of their brittleness, it is not possible to stamp or forge ceramic shapes either. For applications requiring thin cross-sectional area, ceramics are prepared as coatings and as thin films.

Powder Processing

A generic processing route to fabricate a ceramic component from a powder raw material is contained in Fig. 2, and the individual processing steps are described in more detail below. Myriad variations of this processing scheme are possible, but in general, the manufacture of any ceramic component by a powder processing route will contain a number of steps of the type and in the order indicated below.

Powder beneficiation

As received, ceramic powders often need to be modified before they can be used to manufacture a component. Such powder beneficiation includes changing the particle size, shape, surface area, particle size distribution, and purity. Reduction of the particle size is generally accomplished by milling (particle size comminution). Although ball milling has been widely used to modify the particle size, shape, and size distribution, higher energy methods, such as jet milling, attrition milling, and vibratory milling, are also available and can lead to finer particle sizes. Jet milling is accomplished by impinging a high velocity stream of particles onto itself; the energy of the impacts causes particle fracture and hence size reduction. Attrition and vibratory milling often use relatively small milling media, as compared to ball milling, but rely on increased frequency of impacts between the milling media and the powder particles for size reduction.

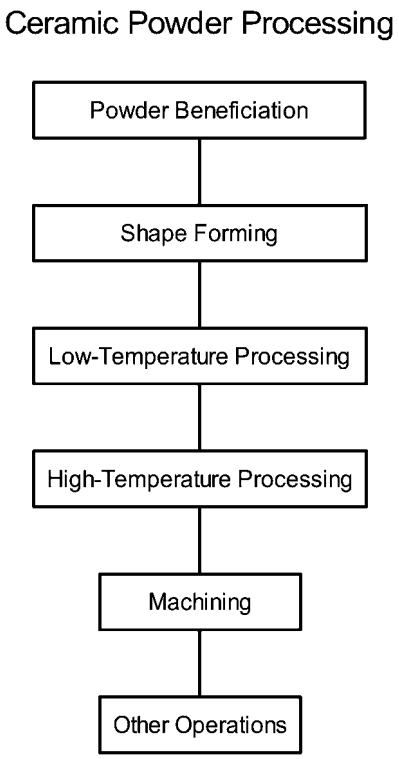

Fig. 2 Example of a process flow diagram for preparing a ceramic component by a powder processing route.

As part of powder beneficiation, compositional modification may also be performed by the addition of second phases, dopants, etc. These changes may be required to influence the sintering behavior of the ceramic powders or to tailor the structural, thermal, electrical, and optical properties of the ceramic products. The source of these additives may be from powders such as oxides, glasses, or salts. To remove unwanted impurities, second phases, surface contaminants, or other by-products, powders may beneficiated by washing, sedimentation, filtration, and magnetic separation.

In the processing of some ceramic powders, enlargement of the size of the solid particulates is required. Granulation and spray drying are two process operations that convert small particles that do not readily flow, into flowable solids; this facilitates the forming of shapes. Granulation is accomplished by agitating solid particulates against each other in drums or by forcing particles between plates, blades, narrow gaps, or rollers. Spray drying is performed by atomizing a slurry that contains ceramic particles, a carrier fluid—often water or a solvent—and organic phases such as dispersants and binders. As the slurry is atomized from a nozzle into a heated chamber, droplets form and dry into spherically shaped solid particulates.

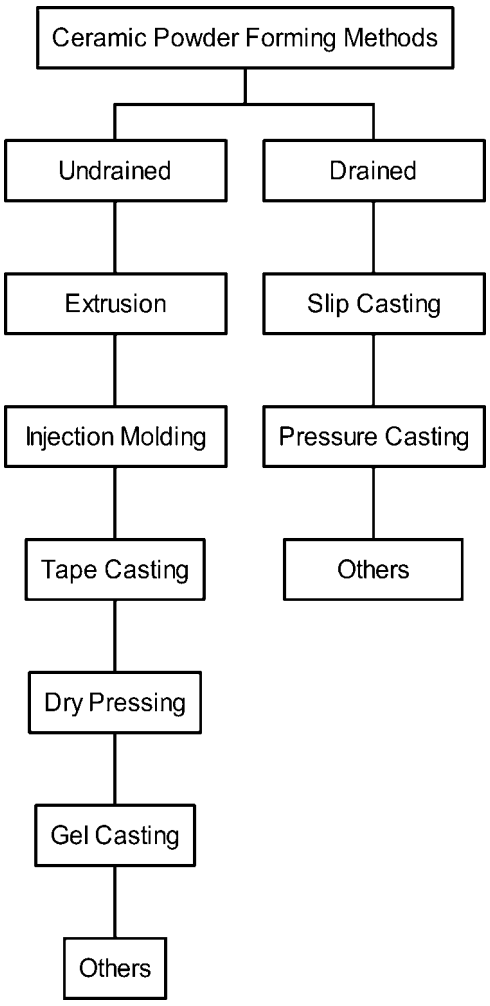

Fig. 3 Classification of powder-based forming methods used to make ceramic shapes.

Shape forming

Many shape forming techniques based on powder processing exist for ceramics, and some of the main types are listed in Fig. 3. These fabrication techniques can be grouped into drained and undrained methods; these techniques differ in the degree of dimensional tolerance that can be achieved. In general, net-shape forming methods are preferred, but in the fabrication of ceramics, only near-net shape is often realized.

In drained forming, the carrier fluid that is used to facilitate the motion of the ceramic particles is removed as the shape is formed. Slip casting (see Fig. 4) and pressure casting are examples of drained methods. Because in drained forming the carrier fluid is removed as the particles pack into a shape, the green density of the formed components is higher than the density of particles in solution, and in fact, drained forming can lead to very high green densities, as compared to undrained methods.

Undrained forming methods are those in which the carrier fluid used to facilitate the motion of particles is not removed as the shape is made. The carrier fluid thus remains in the formed shape and must be removed prior to high-temperature processing of the component. Extrusion, injection molding, tape casting, and gel casting are all undrained methods. For extrusion and injection molding (see Fig. 5), the carrier fluids are often mixtures of organic species, which collectively is referred to as binder. For tape casting (see Fig. 6), the carrier fluid is predominantly either solvents or water; binders are again used to impart plasticity to the tapes. For gel casting, the carrier fluids contain monomeric species and initiators that cause polymerization directly in the mold. Because in undrained forming methods the carrier fluid remains in the mold, the green density, i.e., the bulk density of the particulate body, is often close to the density of the particles in the carrier fluid.

Another widely used method for forming simple ceramic shapes is dry pressing (see Fig. 7). If for dry pressing, the carrier fluid is viewed as the particle phase itself which flows under the influence of gravity, then dry pressing can be included as an undrained forming method. The other fluid phase present during dry pressing is air, a compressible fluid, which neither imparts much flow to the particles, nor does it impede particle packing in the mold.

Low-temperature processing

After the powder is formed into a shape, the resulting component, termed the green body, is subjected to processing operations at low temperature to remove the carrier fluid, which may consist of one or more of solvents, water, dispersants, and binders, depending on which forming method is used. Solvents and water removal may be accomplished initially at temperatures below 100°C whereas binders are removed at temperatures of 100–800°C. Although most binders are mainly decomposed below 500°C, higher temperatures are sometimes used to remove any trace carbon from the material. For bodies moderately to highly loaded with organic phases, such as those obtained by injection molding, extrusion, and tape casting, the removal of binder can be a very slow process and can take days to avoid forming defects in the body.

After drying and binder removal, the powder particles are often not strongly adherent to each other, and because of this, the body is sometimes presintered, or bisque fired, to improve the mechanical strength for handling. Presintering may be performed at temperatures of 800–1500°C, depending on the ceramic. Because the low-temperature furnace operations span a range of temperatures, each step may be performed in separate ovens or furnaces or the steps may be combined into one or more heating units, where the

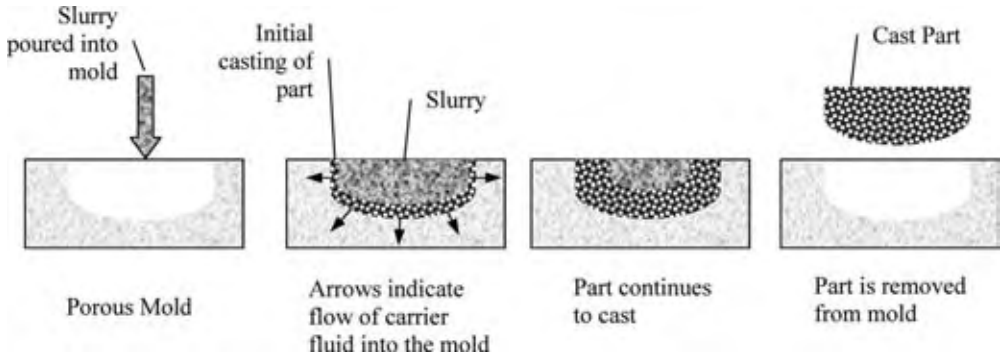

Fig. 4 Schematic of the slip casting process for a ceramic shape. A slurry of ceramic particles and a carrier fluid is poured into a porous mold. The carrier fluid flows into the pores of the mold, and the ceramic particles remain behind and build up a solid cake in the mold. After the fluid has drained from the part, the cast shape can be removed from the mold.

time–temperature profile is tailored to meet the different processing objectives.

High-temperature processing

After the porous green body has been dried and the organic phases have been removed, the component is sintered at elevated temperature below the melting point of the material. This process step is generally one of the most important, whereby the microstructure of the material is tailored to meet specific, end-use properties.

During sintering, the amount of porosity and the surface area decrease, and the pore size, grain size, and density all increase. The sintering process is generally divided into three stages: initial, intermediate, and final. During the initial stage of sintering, necks or bridges form between particles, and a small amount of particle rearrangement takes place. Generally, the amount of shrinkage is small during this stage of sintering. The most dramatic changes in the microstructure occur during the intermediate stage of sintering. A substantial reduction in the total porosity, surface area, and number of pores takes place; the pore size, however, increases. In the final stage of sintering, the most important processes are the final elimination of porosity and the growth of grains. A scanning electron micrograph of a sintered, nearly dense microstructure is shown in Fig. 8. The elimination of porosity that occurs during sintering may be performed by different transport mechanisms including vapor phase transport, solid-state diffusion, and liquid phase dissolution and reprecipitation.

After sintering, a final process step at elevated temperature may be performed to impart specific properties to the component. This may include fine-tuning of the crystallinity, porosity, grain size, stress, and electrical and magnetic properties of the material.

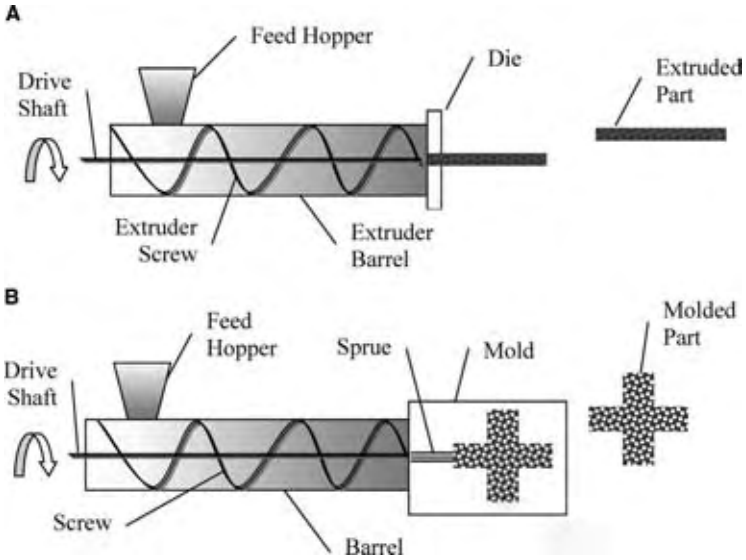

Fig. 5 (A) Schematic of screw extrusion of a ceramic shape. The ceramic feed material dispersed in a binder flows from the hopper into the barrel where the rotating screw transports the material through the die opening. (B) Schematic of injection molding of a ceramic shape. The ceramic feed material dispersed in a binder flows from the hopper into the barrel where the rotating screw transports the material through the sprue into a closed mold. After the mold is opened, the part is ejected.

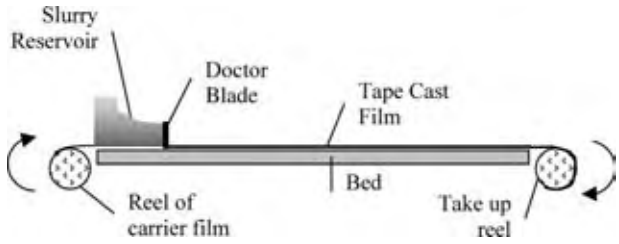

Fig. 6 Schematic of a tape casting process used to form thin sheets of ceramic material. The slurry of ceramic particles and carrier fluid flows beneath the doctor blade onto a moving carrier film. As the tape moves down the bed, it dries and is then spooled on a take up reel.

Machining

After the processing operations at high temperature, machining of the component may be performed to meet the final product specifications for shape, dimensions, and surface finish. For ceramics, this requires expensive diamond tooling such as slicing and grinding wheels and lapping and polishing media. Alternative methods to machining with diamond tooling are electric discharge, ultrasonic, laser, and abrasive flow machining.

Machining may also be performed at other points in the process flow schematic in Fig. 2, such as after the drying step or after presintering. These are the likely process points because the green bodies may then have sufficient strength to withstand the contact stresses of the tooling with the component.

Other operations

Before the manufacturing process for a ceramic is complete, other processing operations may be performed which are specific to an application. These may include applying a coating, metallization, characterization, proof testing, inspection, and packaging.

Glass Processing

Because glasses can be melted at relatively low temperatures, alternative methods to powder-based forming are primarily used to shape glass components. One technique is pressing, in which force is applied to a viscous gob of glass so that it adopts the shape of a mold. Pressing is used to form glass components with thick cross sections such as dishes, lenses, and plates and is also used to fabricate preforms for later processing operations such as blowing. Glass blowing is used to manufacture thin-walled shapes such as light bulbs, glass containers, and art objects. Drawing is used to form long highly symmetric shapes such as sheets, rods, and tubes. Fiberglass reinforcing filaments, fiber optic cables, and thermal insulation are all made by drawing operations. For very thin fibers used in mat or wool form, as is found in thermal insulation, fibers are produced in large quantities by a spinning operation, in which molten glass flows through a multiholed device called a spinneret. It can be mentioned here that there is a special class of ceramics referred to as glass ceramics. Components from these materials are formed from the melt obtained by glass processing methods. They then undergo crystallization. The advantage of this processing route is that the large shrinkage that occurs during sintering is avoided.

Coatings and Thin Film Processing

Coatings or thin films of ceramics can be prepared on a wide variety of substrates for a wide range of applications. The benefits derived from coatings can be

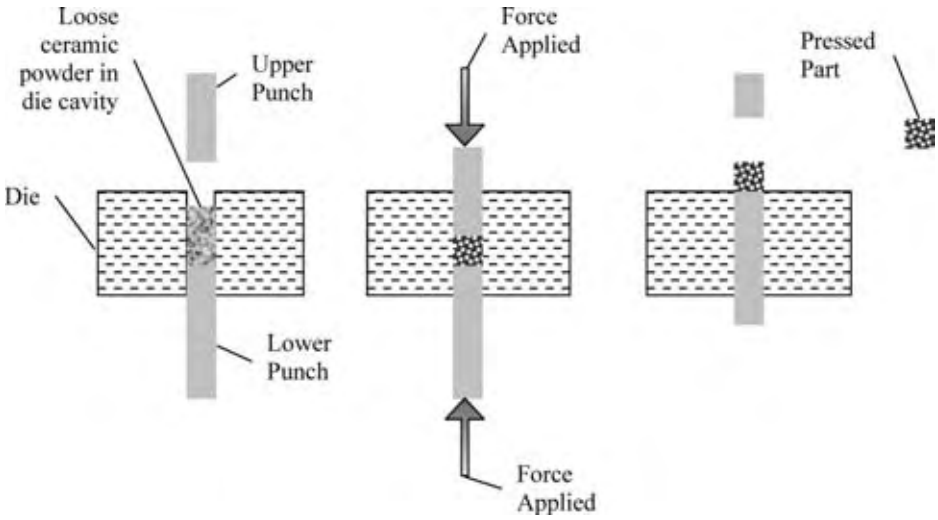

Fig. 7 Schematic of dry pressing of a ceramic shape. The ceramic particle feed flows into the die cavity. Force is applied to one or both punches and the powder is pressed into shape. The part is then ejected from the die cavity.

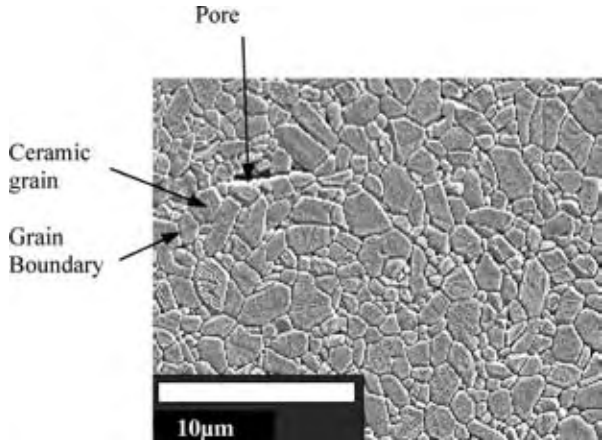

Fig. 8 The microstructure of alumina sintered at 1450°C for 3 hr. The micrograph was taken by a scanning electron microscope. Grains, grain boundaries, and pores are evident in the nearly dense microstructure. The magnification bar is 10 μm, or about one-tenth the width of a human hair.

improved wear-, thermal-, and corrosion resistance. Thin films are also widely used in the fabrication of integrated circuits in which different regions of the substrate have different compositions with highly tailored electrical properties.

Coating and thin films can be applied by a number of methods. In thermal or plasma spraying, a ceramic feedstock, either a powder or a rod, is fed to a gun from which it is sprayed onto a substrate. For the process of physical vapor deposition (PVD), which is conducted inside an enclosed chamber, a condensed phase is introduced into the gas phase by either evaporation or by sputtering. It then deposits by condensation or reaction onto a substrate. A plasma environment is sometimes used in conjunction with PVD to accelerate the deposition process or to improve the properties of the film. For coatings or films made by chemical vapor deposition (CVD), gas phase chemicals in an appropriate ratio inside a chamber are exposed to a solid surface at high temperature; when the gaseous species strike the hot surface, they react to form the desired ceramic material. CVD-type reactions are also used to infiltrate porous substrates [chemical vapor infiltration (CVI)]. For some applications, the CVD reactions take place in a plasma environment to improve the deposition rate or the film properties.

CONCLUSIONS

Ceramic materials have played a key role in the economic, societal, cultural, and technological development of mankind and will continue to do so. For many commodity and advanced applications, ceramic materials, as compared to metals and polymers, are the only suitable options either as technology enablers or in end-use products. For many of the most demanding advanced applications relying on electrical, magnetic, optical, wear, hardness, strength, and thermal properties, new or improved ceramic materials are the likely candidates. This will require continued investment in the research and development of new ceramic materials, new processing methods, and new characterization tools. In addition to the key role ceramics play in the world today, they will continue to do so in the future in science, medicine, communication, transportation, core industrial infrastructure, environmental remediation, energy efficiency, and in the chemical process industries.

INTRODUCTION

The use of semiconductors has become a common occurrence in everyday life. Desktop and laptop computers, automobiles, medical devices, cellular phones, and all entertainment electronic gadgetry including toys, game boys, and television sets, etc., use semiconductors. For all these applications, miniaturization and fast speed of the gadgetry have become a desirable marketing tool that device and electronic manufacturers utilize to lure customers. The manufacture of integrated circuits, which are the essential building blocks for semiconductors, has continued to grow in complexity. Miniaturization requires that millions of these integrated circuits be built on a single chip. The ability to deliver multiple functions to the customer with this single chip has resulted in increased sophistication in their production.

In integrated circuit manufacturing, there are multiple processing steps, from the fabrication of the silicon wafer starting with a cylindrical silicon ingot to packaging of the chip as an end product to deliver to device and electronic manufacturers. Chemical mechanical planarization (CMP) is one of the back-end processing steps used in multibillion dollar manufacturing complexes known as fabs to fabricate these integrated chips. The history of CMP has been well documented elsewhere.[1,2] Ever since the early 1980s with its discovery and application by International Business Machines (IBM) and other companies, such as Motorola, CMP has become an essential step in the manufacture of all integrated circuits in the semiconductor industry. As microprocessor, logic, and wireless device dimensions have continued to scale down to meet high-performance requirements, CMP has become the enabling technology for planarizing metal and dielectric layers. Planarization is needed to lay down multiple layers of metal to build the circuitry, with millions of chips being packed into smaller areas of the wafer. Table 1 shows the National Technology road map for semiconductors, indicating the increased interconnectivity and metal levels that are being incorporated into current and future semiconductor devices.[2]

As technology continues to evolve and as integrated circuits become more sophisticated, integrated device manufacturers such as Intel, Motorola, IBM, Micron, Texas Instruments, and others in Europe and Asia have continued to work in instituting improvements to reduce the cost of ownership of integrated process manufacturing technologies, while continuing to seek an edge in device fabricating methods.[3] Chemical mechanical planarization, as one of the critical process technologies in this fabrication, is considered to be an enabling technology in the manufacture of leading edge devices. In this article, fundamental aspects of CMP will be discussed. Applications of CMP in front-end manufacturing such as in building shallow trench isolation (STI) layers that are used in the front end to isolate devices on a silicon chip, and back-end manufacturing methods such as copper (Cu) CMP that are used to build the electrical interconnectivity of the chip to the outside world will be discussed.

THE CMP SYSTEM

Fig. 1 shows a schematic representation of a CMP system with a rotating polishing table, a wafer carrier where the pressure or down force is applied, a pad conditioner, a stacked polish pad, and a slurry delivery tube, which delivers slurry to the polishing table. The pad typically consists of a hard pad (made of a material such as polyurethane). Fig. 2 shows a scanning electron microscopy (SEM) of the surface of a used polyurethane (IC1000 pad from Rodel) polishing pad. The open voids in the subsurface are clearly shown in the SEM. The pad is a closed cell, void filled polyurethane foam. As can be seen, the top of the pad surface is rough (with voids in the subsurface in the range of 20–100 μm), compared with the scale of typical local wafer features (smallest features for current and future technologies are <0.1 μm).

Polishing pad structure and material pad properties are important determinants in the polish rate and planarization in a CMP process. The impact of pad properties on rate, uniformity, and planarization is still not well understood. However, pad properties that are

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120008022

Table 1 National Technology road map for semiconductors

	Year				
Technology characteristics	**1998**	**2001**	**2004**	**2007**	**2010**

Interlevel dielectric constant	<3	<2.5	<2	1–2	1–2

considered to be important determinants of polishing performance include specific gravity (a measure of porosity), hardness, and compressibility. It has been shown that harder pads with lower compressibility provide better planarization.[2]

As the pad is used, or as it ages, the pad starts losing its roughness and porosity, resulting in lower removal rates. More pad ''glazing'' occurs with a subsequent loss in surface roughness or porosity. To maintain the porosity, a process known as pad conditioning, which involves utilizing diamond conditioner grit moving across the diameter of the pad in a programmed sequence to provide maximum conditioning, is used. Fig. 3 shows the surface height probability density function (PDF) for an IC1000 pad.[4] It shows that above a certain height (mean surface) on the pad, the polishing behavior of the pad is influenced by conditioning and abrasive wear. With optimized pad conditioning, pad life can be extended by as much as 100 times in terms of the numbers of wafers polished on that pad.

As shown in Fig. 1, down-force or pressure is applied on the wafer through a wafer carrier. The wafer carrier plays an important role in polishing nonuniformity. Tool manufacturers have designed wafer carriers with flexible membranes in the center and retaining rings on the edges of the wafer.[5] Utilizing backside pressures to the membranes, differential pressures can be applied across the wafer starting from the edge to the center of the wafer. If faster edge removal is desired, for instance, to account for the higher deposition profile on the edge of the wafer, a higher pressure through multizone control will be applied at the edge of the wafer (on the retaining ring) vis-à-vis the center of the wafer (on the membrane) to provide the faster edge removal rate.[6] Also, it has been shown that matching the carrier and platen angular velocities while rotating is essential to achieving uniform removal rate across the wafer.

Fig. 4 shows a multistep chemical mechanical polishing (CMP) tool utilized in current production. The tool consists of three polishing platens with each platen having all the features that have been discussed previously. As processing is completed on the first polishing platen, the wafer can be transferred to the next polishing platen for the next stage of processing.

For example, for a typical metal stack such as 6 kA Cu/400 kA tantalum (Ta)/2.5 kA TEOS on top of a

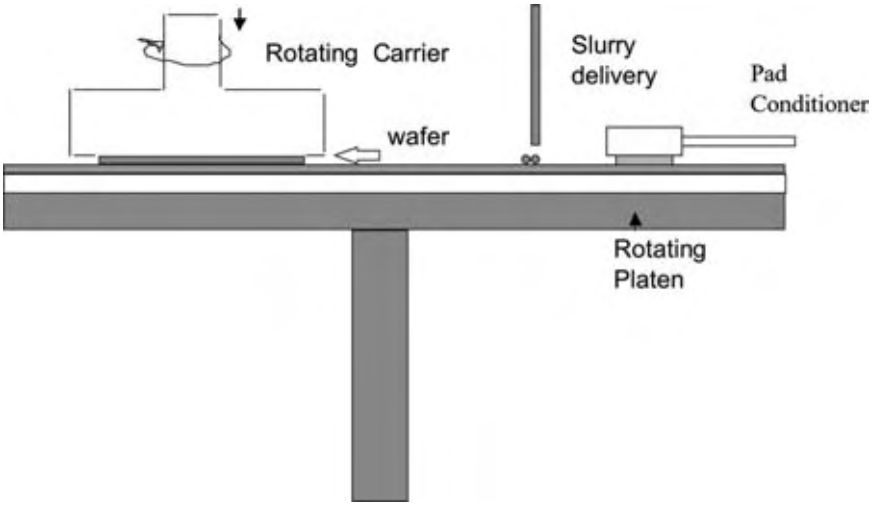

Fig. 1 Schematic of the CMP system. *(View this art in color at www.dekker.com.)*

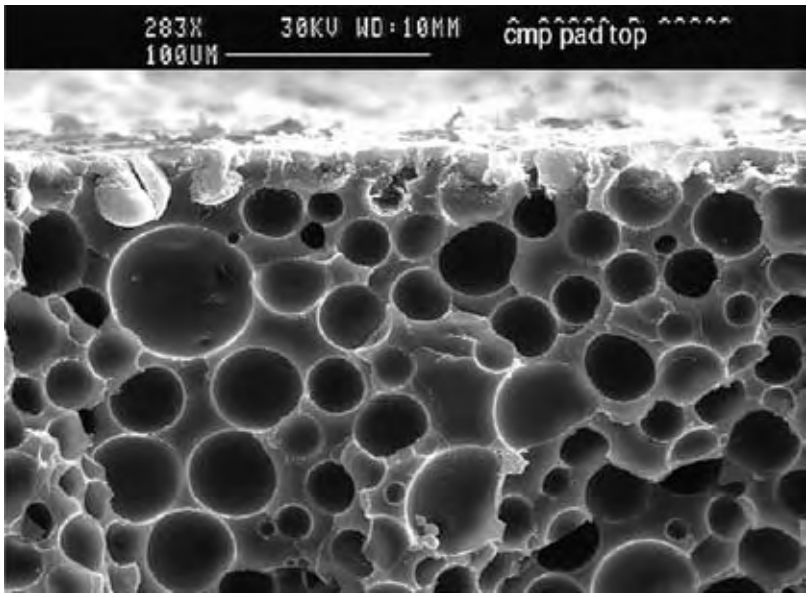

Fig. 2 Cross-section of a Rodel IC1000 polishing pad.

blanket silicon wafer, the bulk Cu will be polished on the first platen to remove most of the 6 kA thickness of Cu. The wafer will then be transferred to the second platen to polish the remaining Cu film, which has been reduced to <6 kA thickness and the process on this platen will then transit to an overpolished step after the end point has been triggered by the polishing tool with the detection of the 400 kA Ta barrier film. The wafer is transferred to a third platen to remove the remaining Ta film and also polish the oxide to buff the oxide layer. For selectivity purposes, the first two platens could use different slurry chemistries to polish the Cu, while the third platen will also use an entirely different slurry, also to polish the oxide film. The multistep tool provides the versatility to handle multiple slurries for different polishing steps and films. After the wafers are polished, the wafers are transferred to a cleaner, which serves the purpose of removing any remaining slurry particles. In the cleaner, removal of slurry postpolish and wafer drying is done. Slurry and other particulate defects are removed from the wafer surface through a combination of chemical and mechanical action.[7] For most scrubbers, a polyvinyl alcohol brush is used to provide mechanical action. Chemical is added through the brushes. The cleaning chemical is selected based on pH to give like charges to the particles, wafer surface, and brush. This selection prevents brush loading and defect redeposition

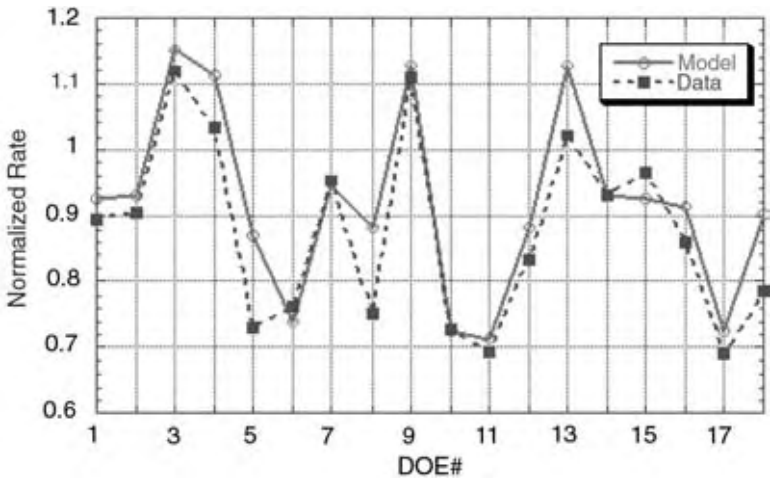

Fig. 4 Fit of Preston's model to experimental data for W CMP design of experiment. *(View this art in color at www.dekker.com.)*

on the wafer. A fundamental understanding of zeta potential effects is needed to enable cleaning chemistry to remove slurry particles from the wafer surface. For most applications, oxide CMP does not require any chemical to be applied in the scrubber to remove the slurry particles, while for metal applications, specifically tungsten (W) and Cu CMP, high- and low-pH chemistries such as NH_4OH and citric acid, respectively, are needed at different stages of cleaning, for effective removal of abrasive slurry particles.[2,8]

Most typical slurries consist of at least two components. The first component is the slurry abrasive, which typically provides the mechanical shear force that is needed to remove the oxide or metal films from the wafer. Most abrasive particles are in the range of 40–150 nm in size. The slurry will also have an oxidizer component such as H_2O_2 to provide the right chemical environment or chemical forces for the oxidation of the metal layer. For oxide polishing, mechanical forces predominate. Typical oxide slurries such as SC112 (KOH based slurry with silica abrasive from Cabot) do not have any oxidizer component. For metal polishing, it is theorized that the metal film has to go through a transformation of forming the oxide, which in most cases is fairly soluble and can easily be removed by mechanical action on the wafer surface.

PRESTON'S EQUATION

Chemical mechanical planarization is the selective planarization of a wafer by mechanical or chemical removal of material. The removal of material is governed by the Preston equation:[2,9]

$$\text{Removal rate} = \Delta H/\Delta t = KP^m V^n \tag{1}$$

where ΔH is the change in the thickness of the material that is being removed from the wafer, Δt is the elapsed time, K is Preston's coefficient, P is the pressure, and V is the relative velocity of the wafer carrier with respect to the polish pad. Both P and V could be a function of the position of the wafer to explain the variation of the polish rate across the wafer. K is dependent on process and consumable variables such as slurry concentration and pad properties, and m and n are constants. Typically, a value of 1 has been used for both m and n for oxide polishing; however, values ranging from $-4/3$ to $4/3$ have been reported in the literature based on slurry particle and pad properties.[2,9] Preston's equation has been found to be reasonably accurate for oxide, W and Cu CMP processes, although the dependence of K on slurry and pad properties is still not well understood and is still being investigated.[2] Both mechanical and chemical forces are important parameters and are expressed through the constant K. For example, in oxide polish, mechanical forces dominate and K can be expressed in terms of the mechanical properties of the film being polished.[2] K can be expressed in terms of Young's modulus:

$$K = (1/2)E \tag{2}$$

where E is Young's modulus of the film being polished. Thus, in cases where polishing is dominated by mechanical forces, Preston's equation is:

$$\text{Removal rate} = \Delta H/\Delta t = ((1/2)E)P^m V \tag{3}$$

Further attempts to elucidate the factors incorporated in this equation are given elsewhere.[2]

For metal polish, chemical effects can be explicitly delineated from Preston's coefficient Eq. (1):[9]

$$\text{Removal rate} = k^1 C_{ox} P^m V^n \tag{4}$$

where $K = k^1 C_{ox}$, and C_{ox} is the concentration of the oxidant in the slurry. All the other material properties are expressed through k^1. All pad and slurry properties

are expressed through the constant k^1. The chemical Preston's model [Eq. (4)] predicts that the polish rate will be directly proportional to the concentration of the slurry, and the oxidizer concentration (C_{ox}) in particular. Using experimental data at different pressure and velocity settings, best fit values for the parameters in Eq. (4) can be generated from a design of experiments (DOE).[4]

Table 2 shows a summary of DOE data for normalized values of P [represented by the down-force variable, and relative velocity V between the platen and carrier (represented by the variables, the platen speed, and the wafer carrier speed)], with the corresponding normalized removal rate for the W CMP process. Fig. 5 shows a good fit between Preston's model for the process and empirical data with normalized polish rate for each of the values shown in Table 2.

Also, the pressure P can be written as:

$$P = F/A \tag{5}$$

where F = force and A = area. Planarization is the process of removing up-areas at a faster rate than down-areas on a wafer.[2] From Eq. (5), since the pressure P is dependent on the force applied and the surface area of the features being polished on the wafer, dense areas and large features will polish slower than isolated or smaller features. Thus, removal rates and planarization are pattern dependent, as predicted by Preston's equation. We will now discuss the individual CMP processing steps that are typically used to build a device.

SHALLOW TRENCH ISOLATION CMP

For sub-0.5 μm devices, shallow trenches are used to isolate active areas in CMOS circuits. Fig. 6 is a simplified schematic showing a three-level metal device on top of a silicon wafer with the shallow trench in the front end near the devices, and the dielectric and metal layers in the back end to provide the interconnectivity. The trench elements are used to isolate the device elements. Due to the fact that these isolation areas are closest to the device areas and to the silicon substrate, care must be taken to ensure that all processes to form these elements have low defectivity and good selectivity to enable the process to stop at an oxide or nitride layer without processing through to the silicon substrate. Fig. 7 shows the processing steps in STI CMP process starting from photopatterning with photoresist to forming the device. Prior to STI CMP, etching through the nitride and oxide forms a trench using oxidizing gases after photopatterning. The trench is filled with SiO_2 using chemical vapor deposition. The interlevel dielectric (ILD), which in this case is SiO_2, is then planarized. It is critical to completely clear the SiO_2 and stop at the nitride layer during CMP. Thus, having a good consumable set of pads and slurries that will enable high polish rate of uniformity with good stop features at nitride, while exhibiting low defectivity, is desirable.

Typical slurries for polishing SiO_2 are KOH or NH_4OH based at high pH (10–12) with equal or slightly harder material such as silica. Careful particle size control of the slurry using filtration is required to minimize defects such as micro scratches and gouging.[10]

INTERLEVEL DIELECTRIC CMP

Dielectric CMP is used to planarize intermetal dielectrics (IMD) (represented by ILD1, ILD2, or ILD3) and premetal dielectrics (represented by ILD0). The slurry typically used in this process is at high pH (10–12), KOH or NH_4OH based and silica abrasive. The hydroxide ion is needed to hydrolyze the substrate, which in this case is SiO_2.

The planarization and uniformity resulting from ILD CMP improve the depth of focus for photolithography by reducing the variation at the top of the ILD or oxide layer and also enable reduction of the metal step coverage at that step and future steps. Fig. 8 shows the topography associated with an underlying structure, which contains a metal feature, prior to undergoing CMP processing. Fig. 9 shows the processing steps needed to planarize the feature and build the device and the interconnecting structure. Several ILD or IMD steps have to be conducted to provide the planarity to build the devices, the metal contacts, and interconnecting vias. As previously discussed, removal rate and planarization in ILD CMP are pattern-dependent and could be determined by consumable factors such the compressibility of the pad, how the pad is conditioned, and slurry properties such as the size of the abrasive particles. Further, these slurry properties could also play another important role in ILD CMP in determining the level of defectivity.

Both the defectivity and the removal rate can be determined during ILD polish by making measurements using stand-alone or integrated metrology tools.[11,12] For rate determination, thickness measurements can be determined by stand-alone metrology spectrophotometric tools or by tools that are fully integrated into the polisher for in situ measurements, which can provide a closed loop feedback system for measuring thickness while polishing.[13]

TUNGSTEN CMP

The first metal CMP application to be used in the industry was W CMP. Tungsten CMP slurries typically

consist of an oxidizer to provide the chemical and abrasive material to provide the mechanical component of the polish. Typical oxidizers include low-pH strong oxidizers such as H_2O_2, $FeNO_3$, and KIO_4. The abrasives are typically composed of Al_2O_3 or SiO_2.

It has been discussed widely in the literature that the mechanism for W CMP consists at the beginning of the polish, the formation and removal of a surface layer of WO_3 that forms naturally on the W surface that is being polished:[2]

$$W + (OX)^{n-} + nH_2O \rightarrow WO_3 + (OX)^{(n+1)-} + 2nH^+ \quad (6)$$

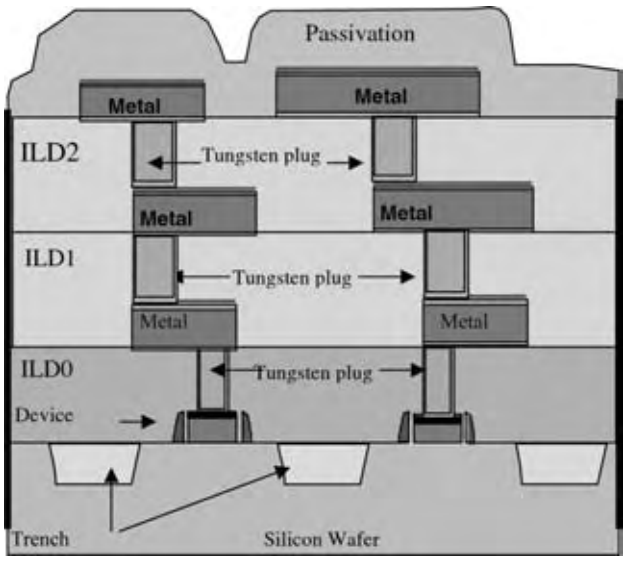

Fig. 6 Cross-section of a three-level metal device showing the trench isolation, W plugs, metal, and interlevel dielectric layers. *(View this art in color at www.dekker.com.)*

WO_3 is a surface oxide that prevents further oxidation and dissolution of the underlying W by the slurry once it is formed. In the high surface areas where the pad contacts the surface, mechanical abrasion of the abrasive in the slurry removes the surface layer and exposes W, while in the low area where the pad does not contact the surface (and abrasion does not exist with no pad to wafer contact), the W film remains intact due to the presence of the oxide layer. Once both the high- and the low-surface areas of the wafer are planarized and are fully in contact with the pad, mechanical abrasion of the underlying film takes place.

Fig. 10 shows the W deposition, W CMP, aluminum (Al) physical vapor deposition, and patterning processes that are used to form the contact plug. These processes are repeated at each metal level as shown earlier in Fig. 6. In order to maintain the planarity of the W plugs with the surrounding oxide layers, dishing of the metal plugs and erosion of the oxide must be minimized. Schematic definitions of dishing and erosion are shown in Fig. 11. Dishing occurs primarily because of pad bending into the plugs to remove metal. Erosion is the thinning of the ILD layer. Interlevel dielectric erosion is defined as the difference in the ILD thickness before and after the polish step. Both dishing and erosion occur during the overpolish step and are highly pattern dependent.[2] The wider the metal lines, the more likely it is that a pad will exert more pressure to remove the material within the plug or recess, increasing the likelihood of dishing. As metal pattern density increases, oxide erosion increases. Also, both pad and slurry properties (such as W: oxide selectivity of the slurry), in addition to pattern density, will affect dishing and erosion.[2] Further detailed discussions of W CMP are given elsewhere.[2]

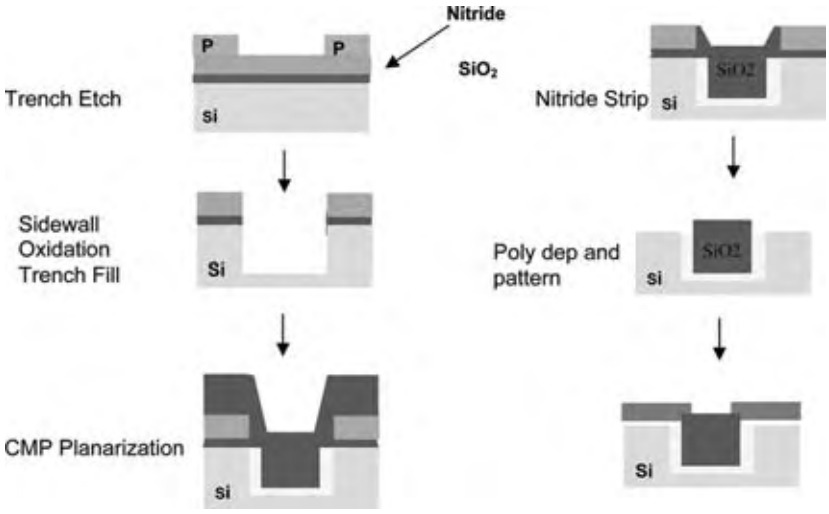

Fig. 7 Shallow trench isolation processing. *(View this art in color at www.dekker.com.)*

COPPER CMP

As device features diminish in size, Cu CMP has become the dominant CMP process for processing this device in the back end. Cu has several attributes that make it attractive as an interconnect material for such devices.[14] Electrochemically, Cu is noble compared to W and Al. Its hardness falls between W and Al and will not scratch as easily as Al. It has higher electromigration resistance than W or Al/Cu, which has been conventionally used as the interconnect metal in current devices.

One of the parameters for measuring device performance is interconnect delay or the time constant.[2]

The interconnect delay is due to the capacitance C and resistance R associated with metal lines. The resistance of a line is given by:

$$R = \rho(l/A) \tag{7}$$

where ρ is the metal resistivity, l is the length, and A is the cross-sectional area of the line. For devices, as feature sizes reduce (i.e., as A decreases), the metal resistivity ρ must also be significantly reduced to maintain the same RC, time constant. The speed of current devices is limited by metal layers (W and Al and Al/Cu alloys and Cu) and the capacitance C is governed by the intrinsic nature of the dielectric insulating material such as SiO_2. Table 3 shows the resistivity and dielectric constant of various materials. It is clear from the table that utilizing pure Cu in devices is advantageous. For transistors with >1 GHz speeds or Giga bit DRAM or >1 billion transistors, switching to Cu and low dielectric constant (κ) materials is absolutely necessary.

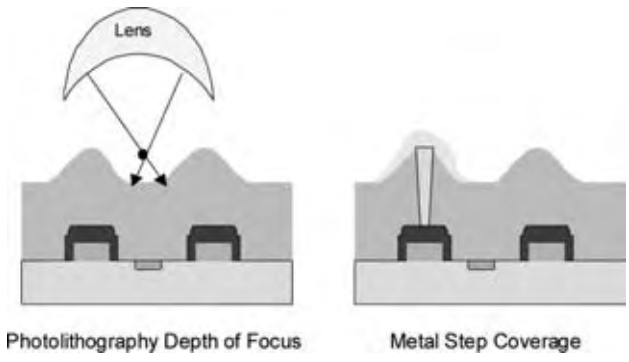

Fig. 8 Topography and its effects prior to CMP. *(View this art in color at www.dekker.com.)*

For Cu CMP, there are two distinct mechanisms for processing that have been proposed in the literature: mechanical abrasion of the Cu surface and subsequent transportation of the abraded material from the vicinity of the wafer surface. In order to fully dissolve all of the abraded material, the solubility of the Cu and the dissolution rates into the slurry must be high. Cu CMP slurries like W CMP slurries employ either a combination of complexing agent and oxidizing agent or an oxidizing acid. Also, like W CMP, surface film formation is also important. Depending on additives in the slurry, nonnative surface films can be formed to protect the film from further dissolution or corrosion during or after polish. Additives like benzonitrile (BTA) can be incorporated in the slurry to form Cu–BTA surface complex to protect the surface from corrosion after CMP. It has been shown elsewhere that the nature of the dishing of the Cu surface will be affected by the presence of the additive.[2]

For Cu CMP, the slurry will typically contain an oxidizer such as H_2O_2 with Al_2O_3 or SiO_2 based abrasives and could be at low or high pH. The most efficient Cu polish is conducted on a multihead and multiplaten tool like the one shown in Fig. 4. Bulk

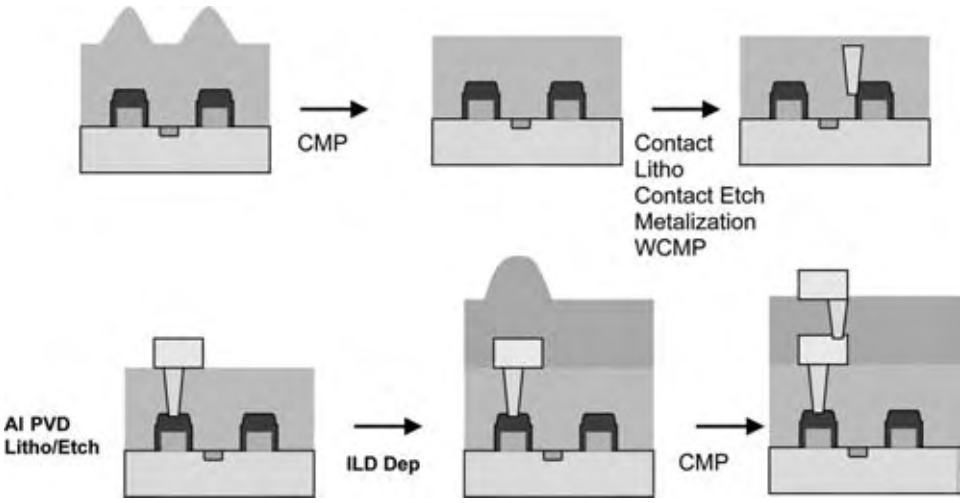

Fig. 9 Back end device construction with CMP. *(View this art in color at www.dekker.com.)*

removal of the polish is first conducted with high polish down-force on a hard pad with an oxidizer and an abrasive on platen 1. The second part of the polish is conducted with the same slurry at low down-force to clear the remaining Cu and the polish is stopped using an end point once the barrier metal is detected. The third part of the polish is used to clear the barrier metal and buff the underlying oxide layer. The slurry on the third platen will be similar to the slurry used for oxide polish.

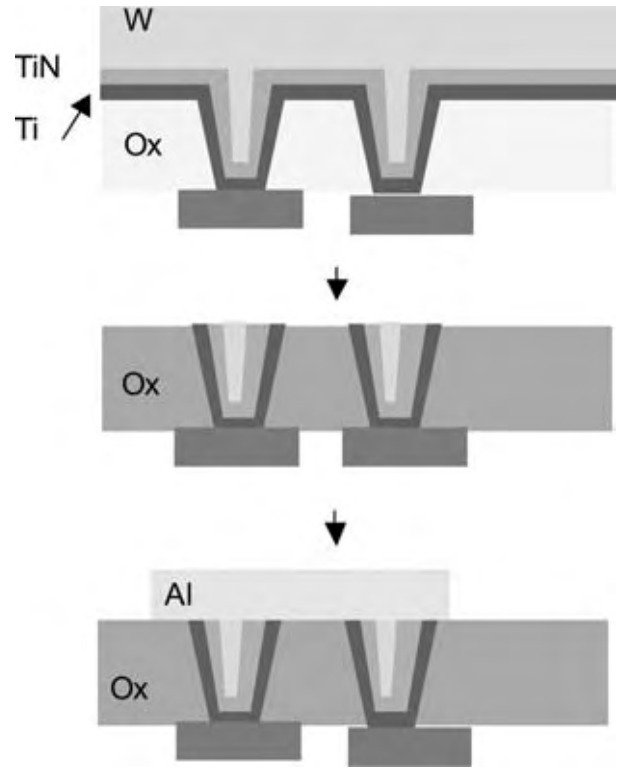

Fig. 10 Formation of Al line on top of W contact plug and Ti/TiN barrier after WCMP and deposition. *(View this art in color at www.dekker.com.)*

A process that is typically used for Cu processing is the damascene process. In the damascene process, the Cu is deposited over the entire wafer surface, including holes (vias or contacts) and grooves (metal lines). All metal that is above the surface is removed through polish.[15] In damascene processing, metal lines are not etched; it is only the dielectric that is etched to form plugs and vias. There are two types of damascene processes, dual damascene and single damascene. The difference between single and dual damascene is that in dual damascene, both the metal plugs and the metal lines are filled and polished at the same time; while in single damascene processes, the plugs and the metal lines are deposited, filled, and polished separately, increasing the number of polishing steps.[16] In single damascene processes with single via polish, maintaining the uniformity of the polish and lowering the defectivity are much more critical due to the higher level of topography associated with having vias as single features sticking out above the surrounding topography.

In addition to reducing the resistance of devices by migrating to higher-conductivity metallic materials such as Cu, a need has also risen to lower the capacitance of the devices to reduce the interconnect delay or time constant. This is done by utilizing low κ materials to replace SiO_2. Examples of low κ materials are shown in Table 3. Utilization of these low κ (dielectric) materials has created more challenges in Cu CMP. One example of a low κ material that has emerged to replace the SiO_2 is black diamond.[17] The dielectric constant of low κ films is on the order of 3.0–2.8. Ultralow κ films with <2.3 dielectric constants are also being considered as device dimensions diminish. Due to the softness of these films, superior planarization

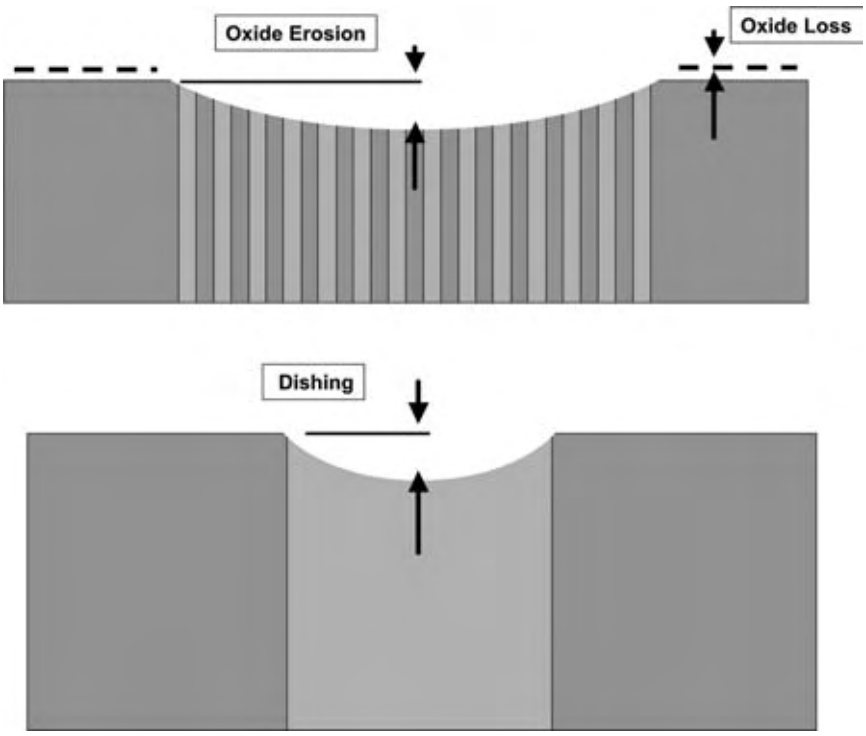

Fig. 11 Schematic definition of dishing and erosion. *(View this art in color at www.dekker.com.)*

and polishing techniques are needed to ensure low dishing and erosion and lower defectivity.

Defectivity in Cu CMP along with Cu-line dishing and oxide erosion is recognized to be an important problem. In-line probe tests immediately after polish are instituted to detect residual metal. Defects due to Cu corrosion are generated using electrochemical and photoinduced mechanisms because of the presence of water and ionized components in the slurry. Galvanic corrosion is also driven by device layout on the wafer formed as a result of galvanic cells generated between adjacent dies. During processing, exposure of the wafer to light must be minimized to limit this corrosion. Also, queue times are instituted immediately after Cu polish and scrub prior to the next processing steps to minimize Cu exposure to ambient conditions, which will cause corrosion. Also, due to the complexity of the slurry, particles and organic defects such as carbon particles generated from slurry residue are generally found and must be removed during the later stages of the polish or at the scrub step.

CONCLUSIONS

In summary, CMP is an enabling process technology that has become critical for manufacturing transistor devices. It has evolved from being an art in the late 20th century to a complex process technology that is an integral part of advanced semiconductor manufacturing for the 21st century. As technologies transitioned to the below 0.1 μm node, complex integration requirements have demanded more robust CMP processes. Due to the increasing sophistication and miniaturization of devices, CMP has become an even more critical technology for device manufacturing. The utilization of more advanced and complex materials such as Cu and low κ materials to meet device requirements will result in demands to understand and optimize process technologies such as CMP, to improve the robustness and flexibility of IC devices. Also, with the advent of more complex and integrated manufacturing fabs with larger-diameter wafers, the challenges of designing CMP processes to optimize the manufacturing

Table 3 Properties of common metals and dielectric materials

	Resistivity	Dielectric material	Dielectric constant, κ
Tungsten/aluminum	4.0	Silicon dioxide (SiO_2)	Thermal = 3.9, PECVD = 4.2
Aluminum	2.4	Fluorinated SiO_2	3.5
Copper	1.7	Inorganic polymers	2.7–3.5

processes in terms of cost will not diminish. With the increasing popularity and convergence of computing, entertainment, home, transportation, and mobile devices in the electronic space, the use of CMP in integrated circuit manufacturing will continue to grow.

Chemical Vapor Deposition

David G. Retzloff
Department of Chemical Engineering, University of Missouri–Columbia, Columbia, Missouri, U.S.A.

INTRODUCTION

Chemical vapor deposition (CVD) is a relatively old process technology. Its early application can be traced back to the production of incandescent lamps in the 1880 time frame, where it was used to enhance the strength of carbon filaments via metal deposition. However, it was the use of CVD in semiconductor fabrication in the 1960s that ushered in the widespread application of this technology to a variety of applications. Chemical vapor deposition is defined as a process in which chemical reactions occur on or near the surface of a solid material called the substrate that result in gaseous molecules called precursors being deposited on the substrate surface as a thin film of solid material. It is the chemistry component that distinguishes this process from physical vapor deposition, which is primarily an evaporation/condensation process that does not involve chemical reactions. The CVD process occurs in a vessel termed the reactor and the residual gaseous material is pumped out of the reactor. The process pressure spans a range from 1 Torr to atmospheric. The temperatures involved range from 300°C to 2000°C. The CVD process is characterized by the method used to activate the reaction(s) that produce the deposited coating or the type of precursor that is used. Thus, thermal CVD, plasma enhanced CVD (plasma assisted CVD, plasma enhanced CVD), thermal laser CVD (LCVD), photochemical vapor CVD (PCVD or photo-CVD), and chemical beam epitaxy are classifications of the CVD process based on the method of activation of the reaction. A subclassification identifies the pressure used in the CVD process. Examples are low-pressure CVD and atmospheric pressure CVD. The only existing classification based precursor is metallo-organic CVD (MOCVD). It is not unusual for CVD occurring under atmospheric conditions to be identified solely by the method for activating the CVD reaction. The CVD reactors can be either vertical or horizontal depending on the application. Epitaxial pancake-type CVD and barrel reactors are vertical. Most other types of reactors are horizontal. These reactors are further classified as either hot-wall or cold-wall reactors. The rationale for choosing a specific CVD process and reactor is to produce a coating (film) on the substrate that strongly adheres to the substrate, is uniform in both composition and thickness, and has specific physical properties. These criteria are the reasons for the large variety of CVD processes and reactors designs.

Chemical vapor deposition is a mature technology and as such has a large literature covering both the theoretical aspects of the process and the applications. This literature is growing due to new applications of CVD as well as new understandings of the fundamental processes that occur in this technology. A review of CVD technology is presented in what follows. The CVD process and general CVD reactors will be discussed first, followed by a discussion of the theoretical aspects of CVD processing. Next, an overview of the equipment used in CVD processing will be considered. Finally, a list of CVD applications is presented to give the reader a feel for the diversity of applications using CVD.

THE CVD PROCESS AND CVD REACTIONS

An essential element of the CVD process is the chemical reaction that occurs to produce the coating/film. The precursors that constitute the chemical reactants must, of course, contain the chemical elements that will ultimately constitute the coating. In addition, these precursors must be stable at room temperature, react cleanly in the reactor without side reactions, not condense in the transfer lines, and be easily produced. The number of CVD reactions that are currently used is quite extensive and a complete listing of every reaction is beyond the scope of this review. However, a classification according to the method to activate the reactions for generic reaction type with specific examples is given in what follows. This will provide the reader with an overview of the diversity of applications of CVD.

Thermal Decomposition Reactions

In this method thermal energy from a heater is used to activate the reaction process. Some typical examples are:

Hydrocarbon deposition: $CH_4 \rightarrow C(s) + 2H_2$

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120008100

This is used to produce graphite and diamond.

Halide decomposition: $WF_6 \rightarrow W + 3F_2$

Hydride decomposition: $GeH_4 \rightarrow Ge(s) + 2H_2$

Hydrogen reduction:
$SiCl_4 + 2H_2 \rightarrow Si(s) + 4HCl$

This is used to produce epitaxial silicon on semiconductor silicon wafers.

Plasma CVD Reactions

In this process either radiofrequency (RF) or microwave sources are used to activate the reactions:

Epitaxial silicon deposition:
$SiHCl_3 + H_2 \rightarrow Si(s) + 3HCL$

Ceramic materials (silicon carbide):
$3SiH_4 + C_3H_8 \rightarrow 3SiC + 10H_2$

Insulators (silicon nitride):
$3SiH_4 + 2N_2 \rightarrow Si_3N_4 + 6H_2$

Microwave CVD to produce diamond:
$CH_4 \rightarrow C(diamond) + 2H_2$

Thermal Laser CVD

In this process a laser at thermal equilibrium is used to initiate the reactions:

Metal deposition: $Cd(CH_3)_2 \rightarrow Cd + C_2H_6$

Photo-CVD

In this process the photons from a light source are used to initiate the reactions:

Silicon oxide: $SiH_4 + 2O_2 \rightarrow SiO_2 + 2H_2O$

Metallo-organic CVD

Gallium arsenide:
$(CH_3)_3Ga + AsH_3 \rightarrow GaAs + 3CH_4$

As can be seen from this short classification the applications of CVD are both numerous and widespread. The particular reactions shown are not unique to the CVD process listed. In fact, most of the reactions can be initiated by all of the methods listed. The rationale for choosing a particular reaction initiating method is discussed next.

The thermal CVD process in which thermal energy in the form of heat is used to activate the reaction process is the most common one used. Thermal activation typically occurs at temperatures above 900°C but can be substantially lower when metallo-organic precursors are used. Thus, the coating/film produced by this technique must be thermally stable at such temperatures and the thermal activation process should not lead to the incorporation of unwanted species.

Plasma activation of the reactions occurs at temperatures in the 300°C to 500°C range. Either an RF generator typically operating at 13.56 MHz to conform to FCC regulations or a microwave generator can be used to produce the plasma. The microwave-generated plasma has the advantage that the electrons that form the plasma have higher energy and can initiate reactions requiring more energy. Radiofrequency plasmas are more common because of their extensive use in plasma processing in the microelectronics industry. However, one cautionary point must be emphasized. Highly energetic plasma electrons can initiate unwanted side reactions when chemically possible. Thus, consideration should be given to this possibility when considering plasma CVD. The lower temperature deposition is the principal advantage of plasma CVD. A secondary benefit of this type of CVD process is the sputtering of the substrate that inevitably occurs. This sputtering changes the chemical character of the substrate surface. This is especially important for substrates that normally have an oxide formed on their surface, which is removed by the sputtering action. In all cases the surface becomes ''chemically active'' and the coating/film that results has better adhesion properties. A less commonly used process for plasma CVD is the plasma arc, which requires a large amount of energy and operates at extremely high temperatures. The plasma arc has been most notably used in the deposition of diamond.

Thermal laser CVD involves the same chemical deposition processes that occur in thermal CVD. It, therefore, is applicable to depositing the same types of materials that the thermal CVD process does. Its major application is the direct writing of thin films in semiconductor processing.

Photo-CVD involves the activation of the reaction by photons. As a result, no thermal energy is required for the deposition. This is the feature that distinguishes it from LCVD. Because the intensity of the photons from current sources is low, the deposition process is slow. Thus, this process currently has limited applicability.

Metallo-organic CVD involves the use of metallo-organic compounds as precursors. Its principal

advantage is the high quality of films produced by this process. Most MOCVD reactions occur at temperatures between 500°C and 1100°C and pressures between 1 Torr and atmospheric. Both the equipment and the chemicals are relatively expensive, resulting in high production costs. Metallo-organic CVD is used in microwave applications, field-effect transistors, solar cells, infrared detectors, and optical cavity lasers. However, the number of applications using this method is growing due to the refinements made in the process.

Chemical vapor deposition is also being used to manufacture complex parts both at the microminiature and the macro scale. The part is represented in a computer as a series of two-dimensional slices. The physical component is built one layer at a time using a laser with computer control to literally write the two-dimensional layer represented in the computer. For macro scale parts the process is slow due to the time it takes to produce a single two-dimensional layer. However, it can be applied to parts that are very difficult to make by any other method. This application is currently in the experimental stage but represents a future direction for the use of CVD.

A variation of CVD termed chemical vapor infiltration is being used to make fiber reinforced ceramic and metal composites as well as ceramic fibers. For reinforced fibers and ceramic composites the gaseous precursors diffuse into the porous structure of the substrate, which can be a fibrous weave or mat or inorganic porous foam. Upon reaction the substrate is densified to form a composite. Because the precursors must diffuse into the porous substrate, the process is operated in the kinetically controlled regime to avoid plugging the pores near the surface and stopping the densification process prematurely. This is inherently a slow process. Ceramic fibers can be produced using LCVD by focusing the laser beam on the end of a growing fiber in a CVD reactor. Either the fiber or the laser beam can be moved as the fiber grows to continue the process. This process is currently in the experimental stage but may be another future direction for the application of CVD.

A variant of CVD, termed plasma polymerization, has been used to produce polymer coatings. So far, it has been used in a limited number of applications most notably to produce biocompatible coatings for electronic sensors that are implanted in humans. This process is also being investigated for polymer coating applications. As the name implies, an RF generator is used to induce a plasma environment into which the monomer components are introduced. The electrons from the plasma induce the polymerization reaction at the surface of the substrate. The power input to the plasma must be kept low to prevent secondary reactions from destroying the polymer structure.

THEORETICAL CONSIDERATIONS IN CVD PROCESSING

A key consideration in CVD is the feasibility of the chemical reactions involved in producing the coating/film. The first step in assessing the viability of the proposed chemical reactions is to establish the thermodynamic feasibility of the reaction process. This is accomplished by determining the change in the Gibbs free energy for the reaction process under the conditions existing in the CVD reactor. The change in Gibbs free energy can be calculated from the free energies of formation of the reactants and products from the formula

$$\Delta G_r = \Sigma \Delta G_f \text{ (products)} - \Sigma \Delta G_f \text{ (reactants)}$$

where ΔG_f is the Gibbs free energy of formation and ΔG_r is the change in Gibbs free energy for the reaction. In most cases the Gibbs free energies of formation of the chemical species involved are readily available in tabulated form. When the Gibbs free energy of formation data are not available for a particular chemical species the well-known group contribution method may be used to estimate both the heat of formation and the entropy of formation. The Gibbs free energy of formation may then be calculated using the thermodynamic relation between the Gibbs free energy, the enthalpy, and the entropy. The thermodynamic feasibility of the CVD reaction(s) then follows from the equilibrium thermodynamic principle that a process will evolve in a direction that will minimize the Gibbs free energy. Thus, a chemical reaction is thermodynamically feasible if ΔG_r is negative. Furthermore, if chemical reaction equilibrium prevails in the CVD reactor, then the Gibbs free energy change for the reaction at constant temperature and pressure is 0. At chemical equilibrium $\Delta G_r = 0$ and it follows from the relationships

$$\Delta G_r = \Delta G_r^0 + RT \ln K, \quad K = \Pi (a_i)_i^v$$

that

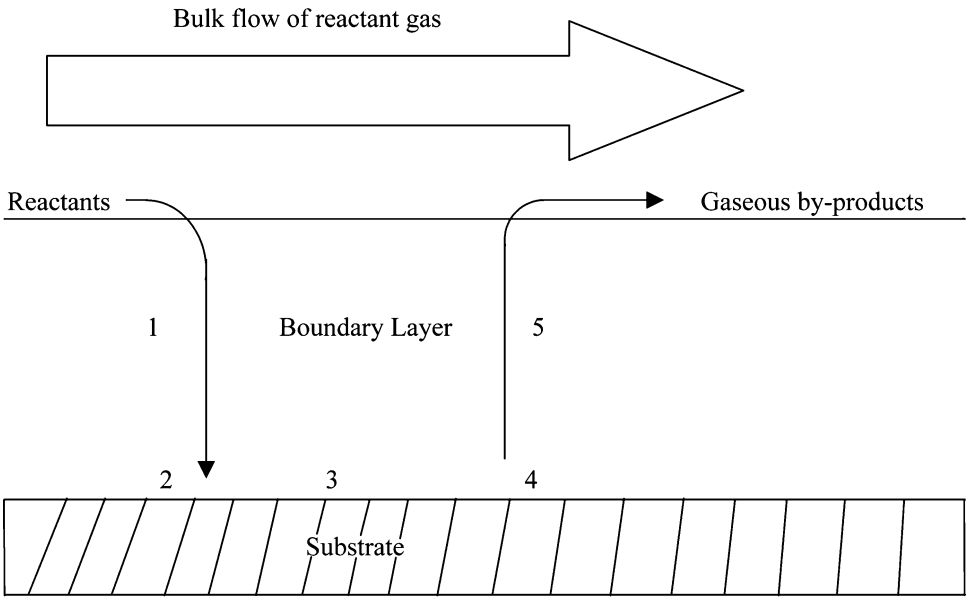
$$RT \ln K = -\Delta G_r^0$$

where a_i is the activity of species i, K is the equilibrium constant, and ΔG_r^0 is the standard Gibbs free energy change for the reaction. In this event the concentration of the chemical species present may be calculated from the equilibrium constant and the relationship between the activity and the concentration of species i. At a given temperature, pressure, and inlet concentration of the reactants, the composition and amount of material deposited can be determined using thermodynamic

principles. In addition, the possibility of multiple reactions, the existence of multiple solid phases and their composition can be determined using equilibrium thermodynamics. However, thermodynamic equilibrium occurs rarely in a CVD reactor and the values of the quantities calculated from thermodynamic considerations should be viewed as theoretical limiting values.

In general, the reactions that occur in the CVD process are kinetically controlled. Accurate theoretical predictions of reaction rates and kinetic parameters are currently not possible from fundamental principles. Thus, to obtain reliable data on the properties of the coating/film that will be obtained as well as the rate at which the coating/film will be formed, laboratory experiments are usually required. Fortunately, such experiments are easy to design and perform at a reasonable cost.

The CVD process is described in much the same manner as a chemical reactor in which a gas–solid reaction is taking place. The reactant gases flow past the substrate, forming a hydrodynamic boundary layer. The reactants diffuse through the boundary layer to the interface, where adsorption of the reactants on the substrate takes place. A chemical reaction occurs on the surface forming the coating/film. The by-products of the reaction are desorbed and diffuse through the boundary layer to the reactor outlet. The process is depicted in Fig. 1. Two important considerations emerge from this description with respect to operation of the CVD reactor. First, the concentration of reactants at the surface of the substrate decreases along the direction of flow. This has implications with respect to the uniformity of the thickness of the coating/film and must be taken into account in the design of the CVD reactor. Second, the rate-limiting step in CVD reactors can be the gas-phase kinetics (this is uncommon), the mass transport across the boundary layer, or the surface reaction kinetics. When the CVD process is limited by mass transport, either the diffusion of the reactants through the boundary layer to the substrate or the diffusion of the reaction by-products from the substrate to the bulk flow is the limiting step. This frequently is the result of a thick boundary and/or a high substrate temperature. For the case when the surface reaction kinetics is the rate-limiting step the reaction proceeds slowly relative to diffusion. This is usually associated with a thin boundary layer due to high gas velocity and low



The processes that occur during CVD are:

1. Diffusion of reactants through the boundary layer
2. Adsorption of the reactants on the substrate surface
3. Chemical reaction on the substrate surface forming the coating
4. Desorption of by-products from substrate surface
5. Diffusion of by-products to bulk flow stream

Fig. 1 Basic phenomena that occur in the CVD process: 1) diffusion of reactants through the boundary layer; 2) adsorption of the reactants on the substrate surface; 3) chemical reaction on the substrate surface forming the coating; 4) desorption of by-products from substrate surface; and 5) diffusion of by-products to bulk flow stream.

substrate temperature. The diffusion coefficients are large and the gas pressure is low. It is possible to change from kinetics as the rate-limiting step to mass transport by changing the temperature. This is because surface kinetics is the rate-limiting step at a lower temperature while mass transport is the rate-limiting step at a higher temperature. Similarly, pressure can be used to control the rate-limiting step since the diffusivity of a gas is inversely proportional to the pressure. Reducing the pressure to the Torr range can change the diffusivity by several orders of magnitude. This type of analysis is used to manipulate the deposition process to obtain the desired coatings/films.

There have been numerous theoretical studies of the CVD process, which include numerical simulations. Generally, the objective of these simulations is to predict the time required to achieve a specified coating thickness and the uniformity of the coverage of the substrate. The investigations are tailored to the specific geometry of the CVD reactor being studied. It is not the objective of this review to enumerate all or even a representative number of the studies that have been done and the reactor geometries that have been investigated. However, two investigations will be mentioned because they represent some of the early studies of the CVD reactor performance and established the basic models that form the basis of current theoretical research on this process. One of the early theoretical studies on the horizontal CVD reactor configuration commonly used in the semiconductor industry to deposit epitaxial silicon on a silicon wafer was undertaken by Jensen and Graves.[1] They applied conservation laws and a kinetic model to predict the growth rate of the epitaxial layer and study the effects of recycling on uniformity and deposition rate. Subsequently, Takoukis and coworkers[2] undertook a similar investigation of a pancake-type CVD reactor, which is a vertical reactor configuration with a rotating susceptor that holds the silicon wafers. This reactor configuration is also used in the semiconductor industry for the formation of epitaxial silicon on a semiconductor wafer. They used conservation laws and a kinetic model for the di-chlorosilane reaction to obtain the equations modeling the process. In their study both the vector velocity field and the growth rate of the epitaxial layer were studied. These numerical investigations illustrate the principles used to understand what is occurring in a CVD reactor as well as the depth of understanding of the physics and chemistry of the process. What is notably missing is a detailed fundamental understanding of what variables control the structure and morphology of the coating/film. The films may be crystalline or amorphous. The crystalline films can be columnar with or without facets or composed of fine grains. What is known from the experiment is that the microstructure of the CVD deposit can be manipulated by changing the temperature, pressure, and/or degree of supersaturation of the vapor. In this regard, at low pressure the boundary layer thickness is small and surface kinetics is the controlling step. Under these conditions the coating/film has a tendency to be fine grained. This is also the case for low temperature and high supersaturation. However, as coating thickness increases a columnar-like grain structure develops and becomes more pronounced as the thickness increases further.

The mechanisms by which a film is formed on a substrate by CVD are still not clearly understood. Several theories have been developed using thermodynamics and/or nucleation theory. However, which view is correct is still a matter of ongoing controversy. It is unlikely that this will be resolved in the near future.

CHEMICAL VAPOR DEPOSITION EQUIPMENT

There are a large variety of designs for CVD equipment. Commercial manufacturers generally offer a limited number of designs that are targeted to specific application needs. However, the total number of applications is large. Chemical vapor deposition equipment is frequently custom built by the user for a specific application. Thus, the discussion of CVD equipment presented here will focus on those features of CVD equipment that are generic to all CVD equipment of a particular class. Because most precursors used in CVD are in the gaseous state, CVD equipment frequently has an inlet train consisting of gas purifiers and flowmeters to regulate the flow of reactants to the CVD reactor. In some cases when the precursor is in the liquid state a vaporizer will also be present in the inlet train.

At the basic level CVD reactors fall into two classifications—open and closed reactor systems. In the closed CVD system the precursors are loaded into the CVD chamber together with the specimens to be treated. The system is then closed and the temperature increased to initiate the chemical process. The process continues for a time sufficient to produce the required effect. The temperature is then reduced to ambient so that the reactor may be opened and the specimens removed. This reactor design is frequently used for the purification of metals and chromizing parts. The dominant type of CVD reactor is the open type. Flowing precursors continuously enter this reactor and the gaseous by-products of the chemical process are continuously removed from the reactor (usually with a vacuum pump) and appropriately treated for discharge into the environment.

The thermal CVD reactors mentioned in the introduction are divided into two classes—hot wall reactors and cold wall reactors. Hot wall reactors consist of

constant temperature furnaces heated by resistance heating elements. The substrates being coated are placed in the reactor, the reactor temperature is raised to the desired level, and the precursors are fed to the reactor. For this type of reactor the temperature control is very tight. However, deposition occurs everywhere inside the reactor including the reactor walls. This requires periodic cleaning of the reactor walls to prevent deposit buildup and cross-contamination. In cold wall reactors the substrate is heated either by induction or by radiant heating. This causes the coating to deposit predominately on the substrate with only minimal coating of the reactor walls. Thermal CVD reactors can be either open or closed reactors.

Chemical vapor deposition reactors that employ a plasma environment to initiate the chemical reactions have the advantage of being able to form coatings at significantly lower temperatures than those required in thermal CVD reactors. In fact, if these temperatures were used for the thermal CVD reactors, no chemical reactions would occur and no coatings would result. These reactors use an RF or microwave generator to produce an electromagnetic field that interacts with the reaction process. The reason why the plasma CVD reactors can operate successfully at these low temperatures is that the electromagnetic field produced by the generator can efficiently couple to the electrons present to produce very energetic electrons (with a characteristic temperature of 24,000 K) that participate as reactants in the chemical reaction process. Essentially, the radiation field supplies the energy required by the chemical reactions. This drives the relevant CVD chemical reaction process at significantly lower thermal temperatures than would be required in a thermal CVD reactor. For thermally sensitive substrates or substrates that are adversely affected by high temperatures, plasma CVD is the method of choice. Plasma CVD reactors are normally open reactors that operate at pressures in the Torr range.

Thermal laser CVD reactors use a laser to provide thermal energy at the adsorbing substrate to initiate the chemical reactions leading to deposition. Due to the laser wavelength used there is essentially no energy adsorption by the gas molecules. This reactor design allows ''direct writing'' of the film on the substrate because the thermal energy required for the CVD reactions to occur is localized at the focal point on the surface of the substrate. This feature is very desirable for applications in the semiconductor industry.

Photo-CVD reactors employ an optical source to supply radiation at a wavelength sufficient to initiate the reaction process. This wavelength is typically in the ultraviolet (UV) part of the electromagnetic spectrum because it is at these wavelengths that the photons have sufficient energy to break chemical bonds. Ultraviolet lasers are frequently used because they are capable of providing the required intensity to achieve a reasonable deposition rate. The energy for the reaction process is supplied by the photon field. As a result no heat is required for this type of reactor. Also, in contrast to LCVD reactors there is no constraint on the type of substrate that can be coated, as there is no requirement for adsorption of the photons by the substrate. A drawback of this type of CVD reactor is the slow rate of deposition that is normally achieved with current UV-lasers. Both laser and photo CVD reactors are more expensive to use when compared to thermal CVD reactors because of the expense of the source used to initiate the reaction process. As a result they are used in more specialized applications where alternatives are limited. Photo-CVD reactors can be either open or closed reactors and operate at subatmospheric pressures.

The MOCVD process does not involve a new type of CVD reactor. The reactor used is basically a thermal CVD rector. Metallo-organic compounds are used as precursors usually in conjunction with other reactants to reduce the operating temperature required in a thermal CVD reactor. The precursors and equipment costs are high for MOCDV reactors. As a result MOCVD is used when high-quality coating is required. These reactors are typically open-type reactors that operate in the Torr to atmospheric pressure range.

Chemical vapor deposition reactors are either horizontal- or vertical-type reactors. The orientation assigned to the reactor (horizontal or vertical) refers to the orientation of the flow and the substrates within the reactor. The effects of buoyancy and inertial forces on the flow within the reactor are the principal distinction for these two types of reactors. A generic depiction of these two types of reactors is given in Fig. 2. A complete list of examples of CVD reactors and the design criteria used for each specific reactor is beyond both the scope and page limitations of this review as the variations in reactor configuration within each classification are truly endless, being limited only by the inventiveness and objectives of the designer.

CVD APPLICATIONS

The number of uses of CVD in providing coatings/films is enormous and growing. In this section a reasonably complete list of applications of CVD is presented to provide the reader an appreciation of the extent to which CVD is used in commercial applications. To make this task manageable and the presentation useful for the reader, the presentation is organized by the coating material produced. The applications of the specific coating are included for each material. The first materials considered are metal coatings followed by nonmetallic materials, semiconductor materials, and ceramic materials.

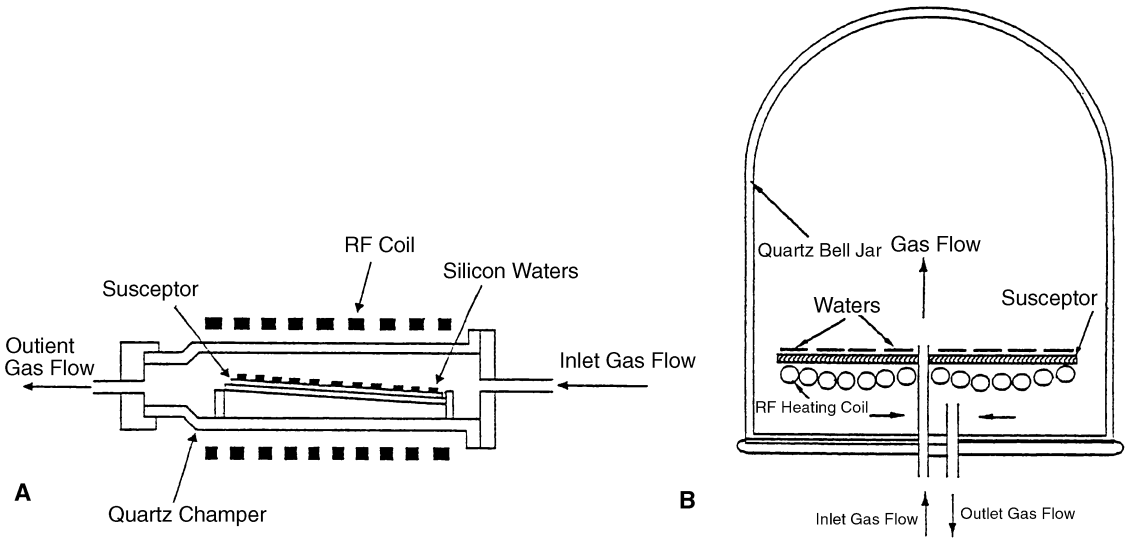


Fig. 2 (A) Schematic of a horizontal CVD reactor. (B) Schematic of a vertical CVD reactor.

Metals

- Beryllium: Wall coatings for nuclear fusion reactors.
- Chromium: Corrosion and oxidation protection of metal parts.
- Copper: Conductive films semiconductor devices.
- Gold: Metallization of contacts in semiconductor applications.
- Iridium: Corrosion resistant coatings for rocket engines.
- Molybdenum: Semiconductor gate metallization, high-power laser mirrors, and coatings for solar converters.
- Nickel: Forming tools for metal and plastic processing, electrical contacts.
- Niobium: Nuclear fuel particle coating.
- Platinum: Catalysts in automobile emissions, ohmic contacts, coatings for high-temperature crucibles.
- Rhenium: Crucibles, high-temperature furnace heaters.
- Tantalum: Corrosion resistant coatings, thin film capacitors.
- Titanium: Corrosion resistant coatings.
- Tungsten: Coatings for targets in x-ray cathode tubes, absorber coatings for solar collectors.
- Zinc oxide: Photoconductor device coatings, piezoelectric devices.

Nonmetallic Material

- Boron: Wall coating for nuclear reactors.
- Graphite: Coating for nuclear reactors, heating electrodes.
- Diamond: Coating for cutting tools, coatings for wear resistance, optical coatings, semiconductor devices.

Semiconductor Applications

- Aluminum nitride: Packaging material for electronic devices, dielectric layers.
- Bismuth titanate: Dielectric material.
- Boron nitride: X-ray lithography masks, high-temperature crucibles.
- Germanium: Photovoltaic devices, photodetectors, tailor bandgap on silicon.
- Lead titanate: Ferroelectric material.
- Silicon dioxide: Electrical insulator.
- Silicon nitride: Diffusion barrier and electrical passivation.
- Epitaxial silicon: To improve the performance of semiconductor devices by reducing defects and impurities.
- Silicides ($AlSi_2$, $CrSi_2$, Cr_3Si, $CoSi_2$, $MoSi_2$, $TiSi_2$, WSi_2, $TaSi_2$, $CoSi_2$): Gate metallization and interconnects.
- III–V and II–VI compounds (GaAs, GaN, GaP, InAs, InP, AlAs, BP, InGaAs, AlInAs, AlGa, As, GaPAs, InGaN, ZnSe, ZnS, ZnTe, CdS, HgTe, CdMnTe): Microwave devices, photovoltaic devices, light emitting diodes, field effect transistors.
- Strontium titanate: Dielectric material.
- Tantalum oxide: Gate insulators in metal–oxide–semiconductor devices, dielectrics for capacitors, optical coatings.
- Titanium oxide: Dielectric layer in thin film capacitors.

Ceramic Materials

- Aluminum oxide: Thin film applications in field effect transistors, coatings for carbide tools.
- Borides (HfB_2, Mo_2B_5, NbB_2, TaB_2, TiB_2, W_2B_5, ZrB_2): Wear and corrosion resistance applications.
- Boron carbide (B_4C): Coating for jet engine nozzles, coatings for shielding in nuclear reactors.
- Chromium carbide: Coating for wear and corrosion resistance.
- Hafnium carbide: Coatings for superalloys.
- Iron oxide: Beam splitters in optical devices.
- Silicon carbide: Coatings for ceramic heat exchangers, radiation resistant semiconductor applications, susceptor coatings, heteroepitaxial film on silicon, coatings for nuclear waste containers.
- Tin oxide: Coatings for solar cells, antistatic coatings, coatings for plate glass and light bulbs.
- Titanium carbide: Coatings for cutting and milling tools, coatings for ball bearings, coatings for extrusion nozzles.
- Tungsten carbide: Porous carbon coating for catalytic applications.
- Zinc selenide: Optical and infrared windows.
- Zinc sulfide: Optical and infrared windows.
- Zirconium oxide: Piezoelectric devices, oxygen sensors.

This list of materials deposited by CVD techniques and their applications is by no means exhaustive. Their number continues to increase as people explore new materials and applications for CVD coatings. What is apparent is the broad range of materials and applications for CVD coatings/films. The CVD process is extremely versatile and simplistic. All that is required are gas phase precursors, an energy source to initiate the chemical reactions involved, and a chamber in which to conduct the CVD process. Experimentation with physical parameters will yield high-quality coatings/films with excellent adhesion properties. What is missing is a detailed understanding at the fundamental level of the cause and effect relationships between the velocity field, reactor variables (temperature, pressure, flow rate) and the structural properties of the coating, adhesion to the substrate, and uniformity of the coverage. The numerical simulations of the flow fields that exist in the CVD reactor show that such flows are quite complex. The details of coating/film growth from the molecular point of view is evolving. It is premature to attempt a prediction of the resulting coating/film and its properties from the operating conditions in the CVD reactor. In the foreseeable future one must be content to have general guidelines coupled with experience to choose a CVD reactor design suitable for the application being considered, and it is equally true that experience and testing will remain the main tools for adjusting reactor variables to achieve the required coating/film properties.

CONCLUSIONS

Chemical vapor deposition has developed into a mature process technology. It has numerous applications in the areas of coatings, semiconductor devices, metal purification, and fiber reinforced ceramic material. It has also been used in conjunction with a closed reactor system to purify metals. It is currently being investigated for applications in producing microminiaturized parts and parts that are too complex to be readily made by standard manufacturing techniques. Plasma CVD techniques have been used with monomer precursors to produce polymer coatings. It is expected that new CVD applications will continue to be developed in the foreseeable future. This is also true for the design of CVD reactors, which is frequently dictated by the application. However, advances in the fundamental understanding of the physics and chemistry that occur in the CVD process are likely to proceed at a much slower pace. The process by which a coating assembles itself on the surface of the substrate is extremely complex. It will take major new insights to identify and describe in mathematical terms the details of this process. The interactions between the transport process, the chemistry, and the mechanism(s) by which the film grows on the substrate surface are not well understood and this is not likely to change in the near future. Fortunately, advances in the applications of CVD can and do proceed without this detailed fundamental knowledge.

INTRODUCTION

Consideration of chirality is now an integral part of drug research and development and the regulatory process. There is no choice! Enantiomeric forms of a drug can differ in potency, toxicity, and behavior in biological systems. Enantiomers of all chiral bioactive molecules have to be separated and tested. The Food and Drug Administration (FDA, U.S.A.), and regulatory authorities in Europe, China, and Japan have provided guidelines indicating that preferably only the active enantiomer of a chiral drug should be brought to market.

This entry discusses the main chiral drug separation methods, viz. gas chromatography (GC), high-performance liquid chromatography (HPLC), capillary electrophoresis (CE), and some new techniques. The first part presents the concept of molecular chirality and some examples of chiral drugs. The importance of chiral drug separation is briefly discussed. The second part describes the main chiral drug separation techniques and related chiral recognition mechanisms, as well as available chiral selectors. Some typical examples are given, and the pros and cons of chromatographic and capillary electrophoretic techniques are compared. Readers are also referred to specialized review articles for details. The last part summarizes and briefly discusses future development trends in chiral drug separation techniques.

BACKGROUND

What are Chiral Molecules?

A molecule with an asymmetric carbon center has a unique three-dimensional shape and is called chiral, from Greek *cheir* meaning ''hand.'' A chiral molecule and its mirror image are not completely identical: they differ in their ''handedness'' and are not superimposable. Such chiral molecules are called ''enantiomers,'' from Greek *enantios*, meaning ''opposite.'' A human right hand and left hand are enantiomers: they are mirror images, but a ''left'' glove cannot be worn on a right hand. The arrangement of thumb and fingers in three dimensions makes a right hand and a left hand distinctly different from each other. The two different forms of a chiral pair comprise the same number and types of atoms, and they are commonly described as D- and L-isomers with reference to their ability to rotate polarized light. An equimolar mixture of enantiomers is called a ''racemate.''

Fig. 1 depicts 2-butanol. The top two structures are mirror images. Below, ''right-handed'' 2-butanol has been rotated so that the OH group points to the left for comparison with ''left-handed'' 2-butanol. Although the carbon frameworks of the two molecules align, the position of the hydroxyl group is different. In the rotated version of right-handed 2-butanol, in the lower left panel, the hydroxyl group points into the page; in left-handed 2-butanol, in the lower right panel, the hydroxyl group points out from the page. It is impossible to align the two molecules completely without breaking bonds. Left-handed and right-handed forms of a molecule can have profoundly different properties in a biological context. In the food industry, for instance, left-handed limonene smells like lemons, while the right-handed molecule smells like oranges. Different enantiomers can differ widely in their biological properties because chirality is related to the three-dimensional structure, and one form may be more suitable for specific interaction with a biological molecule, such as a receptor, enzyme, etc.

Chiral Drugs

Most synthetic drugs developed in the past were not chiral, though some were. Drugs developed from natural products are largely chiral. Currently, about 40% of the drugs in use are known to be chiral. A report from Technology Catalysts International, Falls Church, VA, states that worldwide sales of chiral drugs in single-enantiomer dosage forms grew at an annual rate of more than 13% to $133 billion in 2000, and that sales could hit $200 billion by 2008.[1] About one-third of all dosage-form drug sales in 2000 were single enantiomers. By geography, the United States is the largest consumer of enantiomeric fine chemicals, contributing 60% of the worldwide total. Drug companies continue

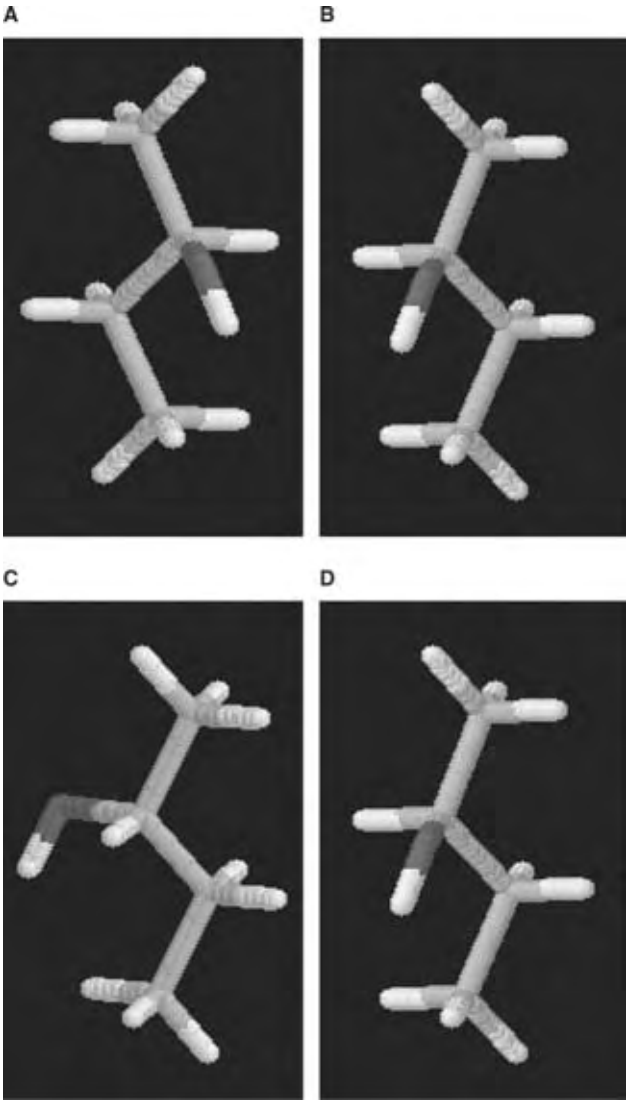

Fig. 1 2-Butanol chiral molecules: (A) right-handed (*R*) 2-butanol, (B) left-handed (*S*) 2-butanol, (C) rotated (*R*) 2-butanol, and (D) (*S*) 2-butanol. *(View this art in color at www.dekker.com.)*

to develop chiral drugs as single enantiomers and use chirality to manage drug life cycles.

Most commercially available drugs are both synthetic and chiral. A large number, however, are still marketed as racemic mixtures. Only about one-third of drugs are administered as pure enantiomers. The respiratory drug montelukast (Merck), the antirheumatoidal infliximab (Centocor), the ophthalmic drug for the treatment of glaucoma latanaprost (Pharmacia), and the prostate hyperplasia agent tamsulosin (Boehringer Ingelheim Pharmacy) are among the best-selling single-enantiomer drugs. The chiral drug (*S*)-(+)-ibuprofen is marketed as fast-acting, and it reaches therapeutic concentrations in blood in 12 vs. 30 min for racemic mixtures. Allegra, an isomer from a metabolite of seldane, is used as an allergy medication. Table 1 lists further examples of chiral drugs and their bioactivities. The enantiomeric forms of a drug can differ markedly in potency, toxicity, and behavior in biological systems.

Importance of Chiral Drug Separation

In the early 1980s analytical chiral separation was a rather difficult task, and preparative synthetic and separation methods were not as advanced as today. Nevertheless, it was clear that chiral drugs should be enantioseparated and that each enantiomer should be used separately. Nowadays, enantiomers are considered distinctly different compounds, as enantiomers of drug substances may have distinct biological interactions and, consequently, profoundly different pharmacological, pharmacokinetic, or toxicological activities.[2] The body is highly chiral selective; it will interact with each racemic drug differently and metabolize each enantiomer by a separate pathway to produce different pharmacological activity. One isomer may thus produce the desired therapeutic activities, while the other may be inactive or produce unwanted side effects (see Table 1). Even when side effects are not serious, the inactive enantiomer must be metabolized and thus represents an unnecessary burden for the organism.

One chiral form of the drug naproxen has 28 times the anti-inflammatory activity of the chiral relative. One isomer of dopamine, used to treat Parkinson's disease, acts on nerve cells to control tremor, while the other is toxic to nerve cells. Racemic mixtures of the drug thalidomide were marketed to pregnant women in the 1960s to counter morning sickness. Therapeutic activity, however, comes exclusively from the (*R*)-(+)-enantiomer. It was discovered only after several hundred birth defects had resulted from administration of thalidomide that the (*S*)-(+)-enantiomer is teratogenic. By then, consideration of chirality has become an integral part of drug research and development and of the regulatory process.

In general, use of the more active isomer of a drug has the following advantages:

- Fewer or diminished side effects, which may result from the unwanted isomeric form.
- Automatically halved dosage for a patient.
- Decreased waste due to decrease in manufacturing of unwanted isomer.
- New commercial opportunities for "racemic switching:" a drug previously marketed as a racemate can be redeveloped and introduced as an enantiomerically pure form, possibly useful for extending patent protection of a key product.

Table 1 Examples of chiral drugs and functions

Chiral drugs	Bioactivity
Albuterol	D-isomer may provoke airway constriction; L-isomer avoids side effects
Ethambutol	The (*S*,*S*)-form of ethambutol is a tuberculostatic agent; the (*R*,*R*)-form causes optical neuritis that can lead to blindness
Levodopa	The levodopa (L-dopa) is a Parkinson's disease agent; the D-form causes serious side effects, such as granulocytopenia
Penicillamine	The (*S*)-enantiomer has antiarthritic activity; the (*R*)-form is extremely toxic
Propanolol	Racemic compound is used as drug; however, only the (*S*)-(−)-isomer has the desired β-adrenergic blocking activity
Propoxyphene	α-L-isomer is antitussive (cough); α-D-isomer is analgesic (pain)
Thalidomide	The (*S*)-isomer has the desired antinausea effects; the (*R*)-form is teratogenic and causes fetal abnormalities, such as severely underdeveloped limbs

There are obvious benefits to studying the properties of the enantiomers of a chiral drug molecule with respect to therapeutic efficacy and safety. In view of this, since 1992 the FDA and the European Committee for Proprietary Medicinal Products have required that the properties of each enantiomer be studied separately before decisions are taken to market the drug as one of the enantiomers or as a racemate.[3] This requires powerful means of chiral drug detection and separation. In addition, there is increasing awareness of the need to reevaluate the properties of individual enantiomers of currently marketed racemic drug molecules. The effect has been a significant increase in demand for sensitive chiral analytical and separation methods. At the same time, the number of new chemicals entering development within the pharmaceutical industry has increased significantly. By now most drug companies have clear guidelines recommending that the enantiomers of all chiral bioactive molecules be separated and tested.

The ideal way to obtain pure drug enantiomers would be enantioselective synthesis. This, however, is rarely practical, usually complicated, and almost always expensive. There is little control over which chiral form of a chemical compound will be formed during a typical production process. This lack of control generally results in production of equal amounts of the various possible chiral forms of a compound. Often, therefore, separation of intermediates or final products from a racemic mixture is required. Increasing interest is being paid to development of methods of efficient, high throughput, and sensitive chiral separations, control of chemical synthesis, assessment of enantiomeric purity, and determination of pharmacodynamics.

The various examples of different therapeutic, toxicological, and pharmacokinetic properties of the enantiomers of chiral drugs provide a strong impulse for the development of techniques for chiral drug separation. Enantiomers can differ in absorption, distribution, protein binding, and affinity to the receptor. Such properties have been exploited for the development of powerful techniques for achieving analytical-scale chiral separations, quantifying minor enantiomeric impurities in chiral drugs, and preparing gram to multi-ton amounts of enantiomerically pure chiral drugs. Chromatographic techniques, such as HPLC, GC, thin layer chromatography, and supercritical fluid chromatography have been developed for chiral separations. Capillary zone electrophoresis, capillary gel electrophoresis, electrokinetic chromatography, and capillary electrochromatography have proved powerful alternatives to chromatographic techniques.

CHIRAL DRUG SEPARATION PRINCIPLES AND TECHNIQUES

Principles of Chiral Separation and Chiral Selectors

Principles of chiral separation

Separation of enantiomers has been achieved using GC, HPLC, and CE. Chiral recognition generally

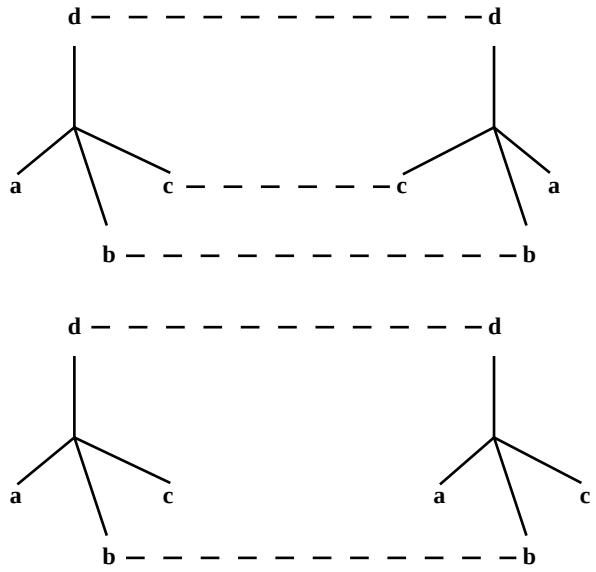

Fig. 2 Three-point interaction model.

depends on a minimum of three simultaneous interactions between the selector and selected—the so-called three-point-interaction rule of Dalgliesh (Fig. 2).[4,5] At least one of these interactions must be stereoselective to form diastereomeric complexes, and thereby enable chiral separation.

The principle task of chiral separation is to create the selectivity essential for separation of stereoselectively different forms of compounds, which may be recognized as such only during the interaction with a chiral selector. This is the separation principle for chromatographic techniques and also for chiral CE. In chromatographic chiral separation, there is a distribution of analyte between two immiscible phases, and these should exhibit different mobilities. Commonly one phase is mobile and the other is stationary. In chiral CE there are not two immiscible phases present but pseudophases at best, or even only one monophasic, homogenous system. Chiral recognition, however, occurs at the molecular level, not on the macroscopic level of the phases. A separation technique therefore must allow the transfer of the molecular level event (in this case chiral recognition) to macroscopic phenomena: different retention times of enantiomers in chromatography and different effective mobilities of enantiomers in electrophoretic techniques.

Immiscibility of phases is a prerequisite in chromatographic separation because pressure as a driving force cannot select a given component from several species in the same phase. Under certain circumstances, however, electrically driven mobility can be selective for one or several species residing in the same phase. So, the immiscibility requirement of the two phases does not apply to chiral CE. In other words, the principal difference between chromatographic techniques and CE is that pressure cannot distinguish between different molecular components in a monophasic system, whereas electrically driven mobility can do this under certain circumstances. The phenomenon responsible for chiral separation is the same in chromatographic and electrophoretic techniques: enantioselective interaction between the analyte enantiomers and a chiral selector.

Chiral selectors

Enantiomers are distinguished on the basis of their interaction with a chiral selector. Development of chiral selectors or chiral stationary phases (CSPs) for GC, HPLC, and CE has rapidly opened a new dimension in the area of chiral drug separation techniques. There are different chiral selectors available for enantiomeric separation of drugs and pharmaceuticals. Finding a suitable chiral selector, whether immobilized on a solid support (GC, HPLC) or added to a running buffer (HPLC, CE), is still often based on trial and error. A few predictions can be made, however, if common structural elements are present. After a selector has been chosen, variables, such as the nature, ionic strength, and pH of buffer, can be varied, as can presence of organic modifiers, temperature, and so on.

Among available selectors, native and derivatized cyclodextrins (CDs) are the most widely used ones at this time. A majority of drug and pharmaceutical applications have been achieved with CDs. Use of CDs as chiral selectors is the subject of a number of reviews (e.g., Refs.[6,7].). Native CDs are cyclic oligosaccharides consisting of six α-CD-, seven β-CD- or eight γ-CD-glucopyranose units. A truncated cone provides a hydrophobic cavity; the exterior surface, surrounded by hydroxyl group, is hydrophilic. Low UV absorbance, low cost, and water solubility are attractive properties of CDs for use as chiral selectors. In addition to CDs, other chiral selectors, such as natural and synthetic chiral surfactants, crown ethers, proteins, oligo- and polysaccharides, macrocyclic antibiotics, and chiral ligands have been applied to chiral separations. Important selectors and some chiral recognition mechanisms are given in Table 2. Some chiral selectors developed thus far can efficiently resolve enantiomers of various important drugs.

Chiral Drug Separation Techniques

The main methods used for chiral drug separation are GC, HPLC, and CE.[2,4,6–25] Other techniques, such as chiral crystallization and enzyme-based kinetic separation, have also attracted attention.[26]

Table 2 A variety of chiral selectors employed for chiral separation and related chiral recognition mechanisms

Chiral selector	Chiral recognition mechanism	Examples	Separated enantiomers
CDs	Chiral recognition is based on inclusion of the bulky hydrophobic group of the analyte into the hydrophobic cavity of the CD and on lateral interactions of the hydroxyl groups, such as hydrogen bonds and dipole–dipole interactions, with the analyte.	Carboxymethylated β-CD, heptakis-*O*-methyl-β-CD, hydroxyethyl-β-CD, mono(6-β-aminoethylamino-6-deoxy)-β-CD, and mono(6-amino-6-deoxy)-β-CD.	Acebutolol, acenocoumarol, carnitine, cathinone, ephedrine, epinephrine, glutethimide, ketotifen, thioridazine, etc.
Macrocyclic antibiotics	The multiple chiral atoms and several functional groups allow multiple interactions with the analytes to enable chiral recognition. The primary interaction is ionic; secondary interactions include hydrogen bonding, dipole–dipole, π–π, hydrophobic interactions, and steric repulsion.	Rifamycin B, rifamycin SV, ristocetin A, teicoplanin, fradiomycin, kanamycin, ansamycins, avoparcin, and vancomycin.	Amephoterin, α-aminoadipic acid, flurbiprofen, fenoprofen, methionine, methotrexate, ketoprofen, and suprofen, etc.
Proteins/ polypeptides	Proteins and peptides are naturally chiral and they often have different qualitative interactions (e.g., different binding sites) and/or quantitative interactions (i.e., different affinity or binding capacity) with the stereoisomers of chiral molecules. Very specific high-affinity binding often occurs, and any sort of intermolecular interactions (e.g., hydrophobic interactions, electrostatic interactions, etc.) may play a role in the binding, which is often reversible.	Bovine serum albumin, human serum albumin, pepsin, lysozyme, avidin, ovomucoid, casein, conalbumin, streptavidin, trypsin, ovoglycoprotein, and β-lactoglobulin.	Benzoin, bunitrolol, epinastine, flurbiprofen, ibuprofen, ketoprofen, leucovorin, pindolol, promethazine, propranolol, trimeputine, warfarin, etc.
Polysaccharides	Hydrogen bonds and dipole–dipole interactions with hydroxyl groups of the sugar molecules are assumed to be the main interactions. In some cases, the helical structure of dextrins might be responsible for chiral recognition.	Heparin, dextran sulfate, dermatan sulfate, streptomycin sulfate, amylose, chondroitin sulfate C, laminaran, dextrin sulfopropyl, and kanamycin sulfate.	Doxylamine, laudanosine, naproxen, oxamniquine, pheniramine, primaquine, timepidium, trimetoquinol, etc.
Chiral surfactants	The chiral separation of analytes is based on their partition coefficients between the chiral micelle phase and the electrolyte bulk phase.	Alkylglucosides, alkylmaltoside, sodium cholate, saponines, sodium dodecyl sulfate, sodium taurocholate.	Ephedrine, fenoldopam, hexobarbital, ketamine, pindolol, timolol, etc.
Chiral crown ethers	Two different diastereomeric inclusion complexes are formed. The primary interactions for complexation are hydrogen bonds between the three amine hydrogens and the oxygens of the macrocyclic ether in a tripod arrangement. Ionic, dipole–dipole interactions, or hydrogen bonds between the carboxylic groups and polar groups of the analytes may act as additional supporting interactions.	18-Crown-6-tetracarboxylic acid, dicyclohexyl-18-crown-6, 18-crown-6-2,3,11,12-tetracarboxylic acid, benzo-monoaza-15-crown-5, and (*R*,*R*)-2,12-bis(hydroxymethyl)-2, 12-dimethyl-18-crown-6.	Aminoglutethimide, aminophenol, baclofen, dopa, ephedrine, mexiletine, noradrenaline, norephedrine, octopamine, primaquine, etc.

(From Refs.[6–8].)

Applications of GC to chiral separation

The first separation of enantiomers was achieved by Gil-Av, Feibush, and Charles-Sigler[9] using capillary GC. Separation of enantiomers using CSPs involves hydrogen bonding, coordination, and inclusion. Typical chiral selectors include modified CDs, derivatized amino acids, and terpene-derived metal coordination compounds. The scope and limitations, applications, and mechanistic considerations of chiral separation by GC have been reviewed by Schurig and Francotte.[10,11]

The main applications of enantiomeric separation by GC concern precise determination of enantiomeric composition of chiral research chemicals, drugs, intermediates, metabolites, pesticides, flavors and fragrances, etc. CHIRBASE, a database of chiral compounds, provides comprehensive structural, experimental, and bibliographic information on successful and unsuccessful chiral separations, and rule sets for each CSP and information about the processes of chiral separations.[27] According to CHIRBASE, an appropriate CSP is available for almost every racemic mixture of compounds ranging form apolar to polar. Some 22,000 separations of enantiomers, involving 5,500 basic chiral compounds and documented in 2,200 publications, have been achieved by GC. This method is particularly suitable for volatile compounds such as inhalation anesthetic agents, e.g., enflurane, isoflurane, desflurane, and racemic α-ionone.

A particularly attractive feature of GC, one that distinguishes it from liquid chromatography methods, is the lack of a sensitive dependence on solvents, modifiers, and gradient elution systems. Prerequisites for the use of GC, however, are volatility, thermostability, and resolvability of the chiral analyte. Obviously, this restricts the utility of the method.

Applications of HPLC to chiral separation

Chromatographic methods have dominated separation of enantiomers during the past several decades, especially HPLC.[4,15–17] Numerous book chapters and review articles deal with the separation of chiral drugs by this method (e.g., Refs.[2,6,12–14].). Chiral HPLC is more versatile than chiral GC for enantiomeric separation because it can separate a wide variety of nonvolatile compounds. It can be used to develop fast and accurate methods of chiral drug separation, and it allows on-line detection and quantitation of both mass and optical rotation of enantiomers when appropriate detection devices are used.

Current chiral separation methods using liquid chromatographic techniques can be divided into two categories: a direct method based on diastereomer formation on CSPs or in mobile phases, and an indirect method based on diastereomer formation by reaction with a homochiral reagent. Direct chiral separation using CSPs is more widely used and predictable in mechanistic terms than methods involving chiral additives in the mobile phase. To date, more than a hundred HPLC CSPs are commercially available. No single CSP can be considered universal; none has the ability to separate all classes of racemic compounds.

Three components should be considered in developing a chiral separation method: analyte, CSP, and mobile phase. The key to successful chiral separation of a particular class of racemates on a given CSP is awareness of possible chiral recognition mechanisms. The enormous increase in recent years in number of groups working on chiral chromatography has led to a rapid and impressive accumulation of data in CHIRBASE.[27]

Some examples of chiral HPLC separations of racemic drugs are the following. Typical chromatograms of the simultaneous determination of isopyramide and its active metabolite, mono-*N*-dealkyldisopyramide, in drug-free human plasma, human plasma spiked with disopyramide and mono-*N*-dealkyldisopyramide, and treated subject plasma are presented in Fig. 3.[4] Chiral HPLC has been used to separate chlorpheniramine and its main monodesmethyl metabolite, verapamil and its metabolite, and tramadol and its metabolite.[15–17]

Applications of CE to chiral separation

CE has become widely popular for enantiomer separation over the past decade as a very powerful complementary or alternative technique to HPLC in pharmaceutical science and industry. Several chiral separation principles successfully applied in HPLC have been transferred to CE. The first chiral separation by CE was by Gassmann, Kuo, and Zare in 1985.[18] This approach offers key advantages such as high efficiency, feasibility of incorporating a large number of chiral selectors that greatly facilitates method development, small amounts of chiral selector and solvents, speed of analysis, low overall cost, and minimal environmental impact. The use of low-UV wavelength (e.g., 200 nm) in CE allows detection of impurities with poor chromophores, which may be difficult or impossible to detect by other methods. CE is suitable for charged and polar compounds for which chromatographic methods are not very strong.

Several comprehensive review articles have appeared in recent years dealing with general aspects and applications of chiral CE separation.[8,19–21] A comprehensive list of more than 280 drugs separate by chiral CE, including the respective chiral selectors and background electrolytes, appears in a review article by Gübitz and Schmid.[21] Chiral CE has also

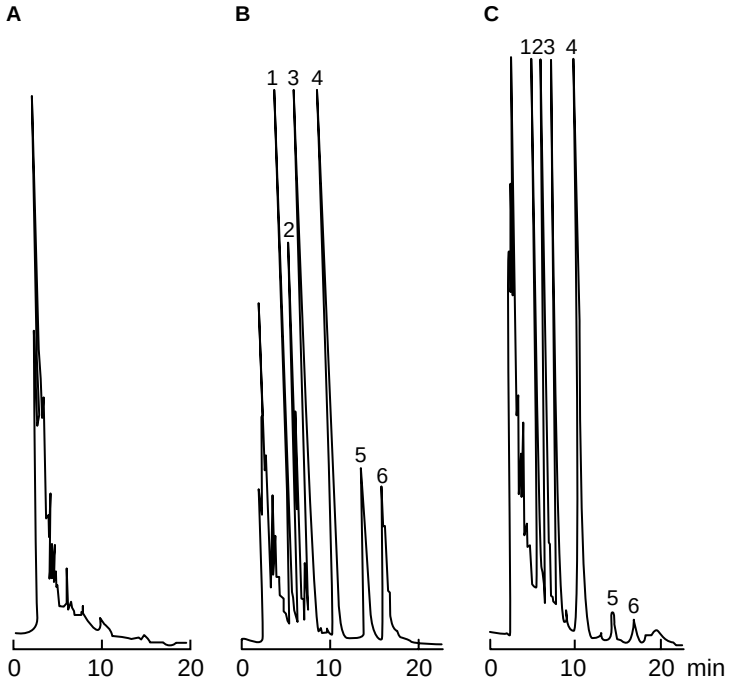

Fig. 3 Chromatograms showing analysis of disopyramide and mono-*N*-dealkyldisopyramide enantiomers in plasma: (A) blank plasma, (B) plasma spiked with 625 ng/ml of disopyramide and mono-*N*-dealkyldisopyramide enantiomers, (C) plasma sample from a healthy volunteer collected 6 hr after administration of 100 mg of Dicorantil. Peak assignments: 1, (*S*)-(+)-disopyramide; 2, (*R*)-(−)-disopyramide; 3, 4, metoprolol; 5, (*S*)-(+)-mono-*N*-dealkyldisopyramide; and 6, (*R*)-(−)-mono-*N*-dealkyldisopyramide. Chromatographic conditions: Chiralpak AD column (250 × 4.6 mm I.D., 10 μm particle size); hexane–ethanol (91 : 9, v/v) mobile phase plus 0.1% diethylamine; 1.2 ml/min flow rate; and detection at 270 nm. (From Ref.[4].)

been the theme of several special issues of *Electrophoresis* and *Journal of Chromatography A*.

Chiral separation in all CE techniques, including capillary zone electrophoresis (CZE), capillary gel electrophoresis (CGE), and capillary isoelectric focusing (CIEF), relies on enatioselective noncovalent/intermolecular interactions between the analyte and a chiral selector, which may be expressed as effective mobility difference (CZE and CGE), stereoselective shift of the acid–base equilibrium (CIEF), etc. Although the fundamental enantioselection mechanisms in CE are the same as in chromatography, migration is driven by electrophoresis. Enantiomers of a chiral drug compound will have the same charge density, so chiral separation in CE is not commonly based on electrophoretic separation, in which different migration velocities are an effect of different charge densities of analyte components. For enantiomers, both the electroosmotic flow and the electrophoretic mobility of the analyte are equally nonstereoselective. What distinguishes enantiomers in chiral CE is their interaction with a chiral selector.

Chiral separation by CE can be achieved by a direct or an indirect method. Direct separation is the more common approach. The chiral selector is dissolved in the running buffer, where it interacts selectively with the enantiomers to form reversible and transient diastereoisomeric or inclusion complexes of differing effective mobility. In indirect chiral CE separation, the enantiomers form covalent diastereomeric derivatives with a chiral reagent. A chiral selector is unnecessary in this approach because of the different electrophoretic mobilities of the diastereomeric derivatives.

Examples of chiral CE separations of racemic drugs are the following. (*R*)-(−)-ketoprofen has successfully been separated from ketoprofen and detected (Fig. 4).[25] (*S*)-(+)-ketoprofen is the active component. Also, simultaneous chiral separation of a basic drug compound, 2(*R*)-*N*-[1-(6-amino-pyridin-2-ylmethyl) piperidin-4-yl]-2-[(1*R*)-3,3-difluorocyclopentyl]-2-hydroxy-2-phenyl-acetamide, and its chiral acidic intermediate, (*R*,*R*)1-(2,2-difluorocyclopentyl)-phenylacetic acid, has been achieved by CE using a single-isomer CD, octakis (2,3-diacetyl-6-sulfo)-γ-CD (ODAS-γ-CD).[22] Carnitine has been separated using 50 mM DM-β-CD in 20 mM phosphate buffer (pH 4.3) as chiral selector.[23] The separations are done at 30°C in a fused-silica capillary, dynamically coated with triethanolamine present in the background electrolytes.

Similarities and differences in chiral separation by chromatographic and capillary electrophoretic techniques

HPLC remains the dominant technique for chiral separation in industry. CE has become well accepted in academic laboratories. Current GC, HPLC, and CE instruments are automated. Chiral separation in CE relies on a chromatographic separation principle. Nevertheless, there are significant differences, as shown in Table 3, between these techniques. The property of

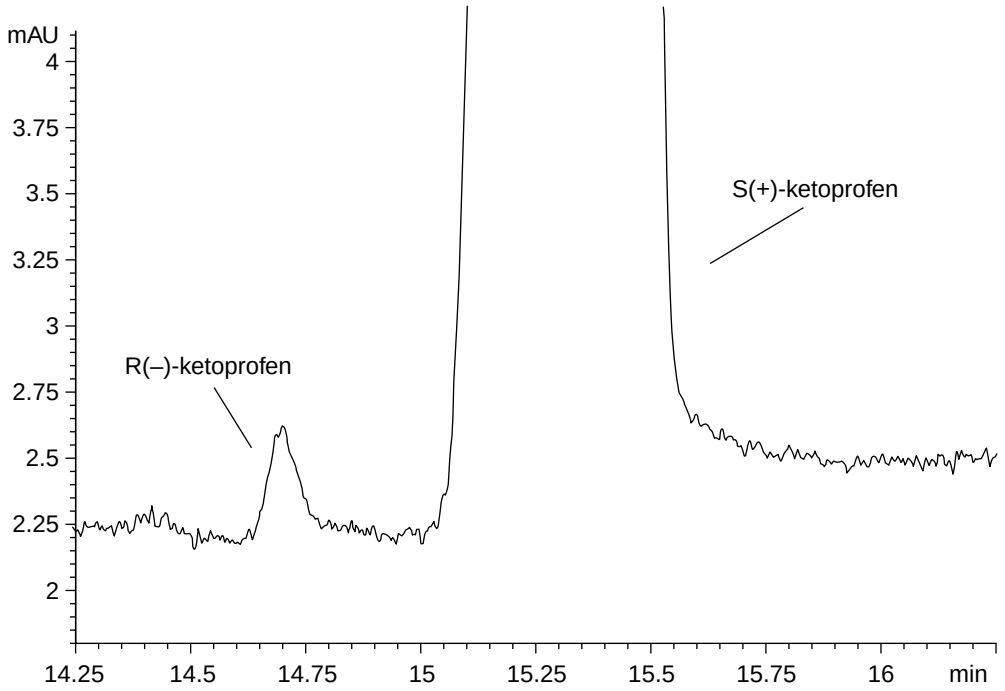

Fig. 4 Detection of the (*R*)-(−)-ketoprofen impurity contained in Enantyum tablets using chiral CE. Conditions: a 20 mM phosphate–20 mM triethanolamine background electrolyte at pH 5.0, with 50 mM of tri-*O*-methyl-β-CD; temperature, 35°C; applied voltage, 20 kV, 8.1 mA. (From Ref.[25].)

electrophoretic mobility in chiral CE in particular, and its ability to be selective for the analytes residing in the same phase, is responsible for all the differences. Another important point is that in chromatographic techniques, except with a chiral mobile phase additive, the analyte is virtually immobile when associated with a chiral selector. By contrast, in CE the analyte selector complex is commonly mobile.

In studies of a chiral drug candidate and its possible metabolites in preclinical and clinical Phase I to Phase III, most of the biological sample matrices, such as urine, plasma, serum, saliva, cerebrospinal fluid, and tissue homogenates, are more compatible with CE than chromatographic techniques. Moreover, it is not possible in GC and difficult in chiral HPLC to achieve the chiral separation of a drug and its phase I and phase II metabolites in a single run. By contrast, this is possible with chiral CE, as in the simultaneous chiral separation of Phase I and Phase II metabolites of chiral antihistaminic drug dimethindene.[24]

In summary, there are significant differences between chiral separations in pressure-driven HPLC and electrically driven CE systems. These differences are advantageous in that they make the techniques complementary. The rules and dependencies observed in one technique, however, are not necessarily applicable to the other.

Recently developed techniques for chiral separation: chiral membranes

HPLC is useful because of its preparative-scale capability. The method is generally slow and labor-intensive, however, requiring specialized engineering approaches for acceptable throughout. In comparison, chiral membrane separation offers significant advantages in simplicity, cost, and throughput.[28]

Polypeptides or modified polypeptides have been tested for use in chiral membrane separation. The partition behavior of optical isomers will largely be influenced by the structure and number of ''recognition sites'' in the polypeptide membrane. Polypeptides could be designed on demand and used to build polypeptide films/membranes.[29] Polypeptide membranes have shown very high enantiomer permeation rates with encouraging selectivity for chiral drug separation.[30] Peptide hydrophobicity, molecular weight, and secondary-structure formation propensity of specially designed peptides will be considered in future work on chiral separation membranes, as polypeptides could be designed to behave like certain proteins in human body and thus to achieve high biomimetic enantioselectivity. This approach would appear to promise very high enantioselectivity and high permeation rates.

Table 3 Differences between HPLC and CE as chiral separation techniques

	HPLC	CE
Instrument, cost, and safety	Expensive columns, consumption of a relatively high amount of buffer solutions, and hazardous organic modifiers.	Simple instrument: no pump, injector valves, and detector cells are required; a minute amount of solvent and an extremely low amount of chiral selector and buffer are required; environmentally friendly and inexpensive.
Chiral selector	Immobilized; great number of commercially available CSPs; a combination of chiral selectors is difficult or at least time-consuming.	Commonly mobile, commercially available chiral selectors are inexpensive, chiral selectors can be mixed in any desired ratio (only limited by the solubility).
Selectivity and efficiency	Chiral separation selectivity may in the best case approach the thermodynamic selectivity of the chiral recognition but will never exceed it; the separation efficiency sometimes is poor.	Separation selectivity may easily exceed the thermodynamic selectivity of the recognition; a chiral separation even in the absence of chiral recognition is, in principle, feasible; high peak efficiency.
Manipulation of mobility terms	Impossible to adjust the selectivity of chiral separation without changing the affinity pattern of the enantiomers toward chiral selector.	Possible to adjust the enantiomer migration order without reverting the affinity pattern between enantiomers of the analyte and a chiral selector.
Separation scale	Semipreparative and preparative scale.	Analytical scale, very small sample volumes.
Reproducibility	Good; high success rate.	Relatively poor and low success rate.
Method development	Relatively slow; changing and conditioning a column is time-consuming.	Rapid; changing a capillary and/or chiral selector takes only few minutes.

CONCLUSIONS

It is necessary to consider the chiral nature of a compound in drug research and development and the drug regulatory process. Enantiomers of all chiral bioactive molecules must be separated and tested. The FDA and regulatory authorities in Europe, China, and Japan have provided guidelines indicating that only the active enantiomer of a chiral drug should be brought to market. Chiral techniques have been developed for the separation and analysis of chiral drugs. Among these, HPLC based on CSPs is widely employed for the assays of drug enantiomers in pharmaceutical preparations and biological fluids. More recently, CE plus chiral selector additives to the running buffer have been used for the same purpose. In both chromatographic and electrophoretic methods, different types of chiral selectors, including CDs, crown ethers, quinine, chiral surfactants, polysaccharides, proteins, and macrocyclic antibiotics, have successfully been used for chiral separation of drugs and drug candidates. In many cases, HPLC and CE are complementary with respect to enantioselectivity. The development of novel separation techniques is an active area of research. Ones showing high throughput and high enantioselectivity are likely to be important to commerce, in view of the increasing trend in marketing single-enantiomer drugs.

Chlorofluorocarbons

Byung Gwon Lee
Youn-Woo Lee
Environment and Process Technology Division, Korea Institute of Science and Technology, Cheongryang, Seoul, South Korea

INTRODUCTION

The chlorofluorocarbons (CFCs) have been the most important organic fluorine chemicals during the past 70 years or so. They have unique properties: chemically stable, low in toxicity, nonflammable, noncorrosive, and compatible with other materials. In addition, the CFCs have thermodynamic and physical properties that make them ideal for a variety of uses. They have been used as refrigerants; as blowing agents in the manufacture of insulations, packaging, and cushioning foams; as cleaning agents for metal and electronic components; and in many other applications.[1–3]

Selected for development by Midgley and his coworkers in the late 1920s, CFC-12 (CF_2Cl_2) was considered to be the ideal refrigerant to replace sulfur dioxide and ammonia.[4] The outstanding properties of CFC-12 quickly led to the search for other CFCs. Kinetic Chemicals, a joint venture between Du Pont and General Motors, was formed to manufacture the new materials, and later it became part of the Freon Division of Du Pont.[3]

The introduction of CFCs marked the inception of the fluorocarbon industry. In terms of both tonnage produced and product value, CFCs have dominated the fluorocarbon industry and provided feedstocks for the development of other products, such as fluoropolymers. By the early 1970s, when they were first linked to the destruction of the ozone layer, CFCs were being produced in many countries around the world. Some major producers and their trade names are shown in Table 1.

The possible implication of CFCs in the depletion of stratospheric ozone, postulated in 1974 and reinforced in the late 1980s by the discovery of a possible link to the thinning of the ozone layer over Antarctica during springtime, had profound effects on the fluorocarbon industry.[5,6] The discovery of the ozone-depleting properties of CFCs led to the Montreal Protocol and the London and Copenhagen amendments (1990, 1992), which scheduled the end of production of CFCs by the end of 1995.

PROPERTIES

The CFCs usually have high densities and low boiling points, viscosities, and surface tensions. The irregularity in the boiling points of the fluorinated methanes and ethanes, however, does not appear in the chlorofluorocarbons. Their boiling points consistently increase with the number of chlorines present. The physical and environmental data of some CFCs are summarized in Table 2.

Although the CFCs are not as stable as the fluorocarbons (FCs), they are unusually stable compounds. Dichlorodifluoromethane, CCl_2F_2 (CFC-12), is stable at 500°C in quartz. Trichloromonofluoromethane, CCl_3F (CFC-11), begins to decompose at 450°C. The CFCs react with molten alkali metals and CCl_2F_2 reacts vigorously with molten aluminum, but with most metals they do not react below 200°C. An exception is the dechlorination of chlorofluorocarbons with two or more carbon atoms in the presence of Zn, Mg, or Al in polar solvents.[1,2]

Most CFCs are hydrolytically stable, CCl_2F_2 being considerably more stable than either CCl_3F or $CHCl_2F$. Chlorofluoromethanes and chlorofluoroethanes disproportionate in the presence of aluminum chloride. For example, CCl_3F and CCl_2F_2 give $CClF_3$ and CCl_4; $CHClF_2$ disproportionates to CHF_3 and $CHCl_3$.

The carbon–chlorine bond in most chlorofluorocarbons can be homolytically cleaved under photolytic conditions (185–225 nm) to give chlorine radicals. This photochemical decomposition is the basis of the prediction that chlorofluorocarbons that reach the upper atmosphere deplete the earth's ozone shield.

PRODUCTION

Industrial production of CFCs is achieved by successive replacement of chlorine in chlorocarbons by fluorine, using anhydrous hydrogen fluoride and a catalyst.[3,7] This use consumes about 50% of the hydrogen fluoride manufactured in the world. The extent of chlorine exchange can be controlled by

varying the hydrogen fluoride concentration, the contact time, or the reaction temperature. Carbon tetrachloride and hexachloroethane (or tetrachloroethylene plus chlorine) are commonly used starting materials for one- and two-carbon CFCs. These feedstocks are prepared by direct chlorination of hydrocarbons.

Historically, most of the CFCs have been made by a liquid-phase process, employing antimony pentachloride as a catalyst. The antimony may be added either as the trichloride and converted to the pentachloride in situ with chlorine or, more conveniently, as the liquid pentachloride itself. Antimony pentachloride reacts with hydrogen fluoride to give mixed chlorofluorides, which are the actual catalysts, and hydrogen chloride [reaction (1)]. The exchange reaction then takes place between the chlorocarbon feedstock and the mixed chlorofluoride, producing the desired CFC and regenerating antimony pentachloride [reaction (2)]. Carbon tetrachloride serves as the feedstock for CFC-11, -12, and -13 [reaction (3)]. The chlorines are exchanged stepwise, the reaction temperature determining the number of fluorines introduced. In commercial reactors, temperatures usually range from 100°C to 150°C and pressures from 10 to 30 atmospheres (atm). The hydrogen chloride is conveniently removed as a liquefied gas for other use or absorbed in water for sale as hydrochloric acid. The crude CFC is washed with base to remove traces of hydrogen chloride and any hydrogen fluoride, dried, and purified by distillation.

$$SbCl_5 + nHF \longrightarrow SbF_nCl_{5-n} + nHCl \quad (1)$$

$$nRCl + SbF_nCl_{5-n} \longrightarrow nRF + SbCl_5 \quad (2)$$

$$CCl_4 \xrightarrow{HF} CCl_3F + CCl_2F_2 + CClF_3 \quad (3)$$

A logical feedstock for the two-carbon CFCs is hexachloroethane. Since it is a high-melting solid, it is generated in situ from tetrachloroethylene and chlorine in the fluorination process. The antimony pentahalides catalyze the addition of chlorine in the fluorination process and may be reduced to the trihalide before subsequent reoxidation with more chlorine. If the feed ratios are not in balance, the excess of hydrogen fluoride may add across the double bond leading to hydrogen-containing compounds. The reaction for the synthesis of CFC-111, -112, -113, and -114 is shown in reaction (4). Again, the temperature of the reaction usually determines the number of chlorines exchanged. While isomers are possible, the carbon atom that is fluorinated is usually the one bearing the most chlorine atoms.

Antimony-based catalysts may become deactivated with use. Simple reduction to the trihalide is easily remedied by oxidation with chlorine. Over time, however, tar formation limits the activity of the catalyst and it needs either purification or removal as waste. Owing to environmental concerns over the disposal of toxic compounds, there is considerable current interest in the detoxification and recovery of antimony waste.[8,9]

This process is being replaced later by a continuous vapor-phase process that employs gaseous hydrogen fluoride in the presence of catalysts. Vapor-phase exchange processes have been developed that avoid the antimony disposal problem. In these processes, vaporized mixtures of the chlorocarbon feedstock and an excess of anhydrous hydrogen fluoride vapors are passed over catalysts at temperatures ranging from 250°C to 400°C. Once again the exchange reaction occurs stepwise, increasing catalyst bed temperatures yielding increased fluorination. The most common catalyst is trivalent chromium, either as the fluoride or as the oxide.[10] The catalyst may be used on a support such as alumina. Other catalysts include iron and fluorinated alumina. Research activity related to the search for CFC substitutes has produced claims of improvements in chromia catalysts, as well as those based on other metals such as cobalt, nickel, manganese, and lanthanum.[11–14]

Chromia (Cr_2O_3) catalysts and, to various extents, the other vapor-phase catalysts, tend to produce some rearrangement of the halogens. This scrambling may be troublesome in the two-carbon series when, for example, some CF_3CCl_3 is produced along with $CF_2ClCFCl_2$ One particular process achieves the halorination of the in situ generated chlorocarbon simultaneously. The catalyst is fluorinated alumina impregnated with thorium fluoride.

Just as with the liquid-phase process, the catalyst requires regeneration from time to time. The usual problem is ''coking,'' which requires treatment of the catalyst bed with oxygen or air at high temperatures. There have been some successful attempts to prolong

catalyst life by adding oxygen along with the feedstocks to remove the coke continually. Reactivation of alumina-based catalysts with high-temperature steam has also been reported.

Vapor-phase fluorinations are very attractive industrially. Reactions can be conducted continuously at modest pressures (10 atm), with appropriate recycle streams as necessary. However, since an excess of hydrogen fluoride is usually employed, downstream purification involving CFC–HF azeotropes may cause difficulties.

While high-molecular-weight CFCs can be synthesized via a variety of methods, from a practical standpoint such materials are best prepared by free-radical telomerization of chlorotrifluoroethylene (CTFE). Either the conversion is carried out in the presence of a chain-transfer agent or higher-molecular-weight polymers are cracked to lighter species. Carbon tetrachloride [reaction (5)] and CFC-113 [reaction (6)] have both been used as telogens. The telomer chains are formed predominantly, but not exclusively, via radical attack on the CF_2 carbon. Trichloromethyl (CCl_3) end groups must be fluorinated, at least partially, to make useful oils or grease since these groups are too reactive for an inert oil. Whichever way the oils are made, they must be free from unsaturation, since oxygen tends to react with C=C sites leading to the formation of acid fluorides and hence unusable material. Saturation and end-group fluorination are generally accomplished using a combination of chlorine and chlorine trifluoride or cobalt trifluoride. Once stabilized, the telomers are fractionated into various standard viscosities for sale as oils. Higher-molecular-weight material forms the basis of the waxes, while grease is made by the addition of suitable thickening agents.

$$CCl_4 + nCF_2{=}CFCl \longrightarrow CCl_3(CF_2CFCl)_nCl \qquad (5)$$

$$CF_2ClCFCl_2 + nCF_2{=}CFCl \longrightarrow CF_2ClCFCl(CF_2CFCl)_nCl \qquad (6)$$

Usually there is an overabundance of lower-molecular-weight telomers, which are not as useful as the heavier products; thus, coupling processes have been developed in which two units are dimerized through the removal of end-group chlorine. One such coupling reaction is achieved by heating telomers with a mixture of copper and zinc powders at 220°C [reaction (7)]. While coupling of CCl_3 end groups is the easiest, it produces CCl_2–CCl_2 units in the middle of the chains, which are difficult to fluorinate. If any remains in the product, stability is adversely affected.

$$2CF_2ClCFClCF_2CFCl_2 \longrightarrow (CF_2ClCFClCF_2CFCl)_2 \qquad (7)$$

APPLICATIONS

It is impossible to overstate the importance of the role that CFCs have played in making refrigeration, air-conditioning, and, to some extent, aerosols such essential facets of modern existence. Life, as we know it, would be impossible in some parts of the world without the means for cooling food and houses. Of course, the very property that made the CFCs so useful, their stability, allows them to reach the stratosphere and there release chlorine atoms, which interact with the ozone layer. There will be a drastic decline in the use of CFCs in most of their high-volume applications of the heavier CFCs and the volumes will be inconsequential compared to the 2.5 billion pounds of volatile CFCs produced worldwide in 1986.

Refrigeration

This has been the area where CFCs have excelled in their application. The air-conditioning industry owes much of its tremendous growth to the chlorofluorocarbons. The CFCs were judged to be safe alternatives to materials such as sulfur dioxide and ammonia over 70 yr ago and allowed refrigeration to become available safely in houses and automobiles.

CFC-12 was commonly used in domestic and mobile air-conditioning. It normally achieved temperatures down to −20°C, and was suitable for use with centrifugal, rotary, and reciprocating compressors. CFC-11 was used in industrial chillers and other units when a temperature of 5–10°C was adequate. For applications where colder temperatures are required, azeotropic blends involving CFC-115 (CF_3CF_2Cl) and HCFC-22 ($CHClF_2$) are employed.

Aerosols and Propellants

Another important commercial application of CFCs has been in the aerosol field as a propellant for a wide variety of products. Personal products such as antiperspirants and hair sprays account for ca. 85% of this use.[1] The characteristic stability, nonflammability, low toxicity, and lack of odor provide a unique combination of properties desirable for propellants.

The most common CFC propellants are CFC-12 (CCl_2F_2), CFC-11 (CCl_3F), and CFC-114 ($CClF_2CClF_2$), used either by themselves or in combination. The principal propellant for nonfood aerosols is $CC1_2F_2$. A combination of $CC1_3F$ and $CC1_2F_2$ is used to reduce the propellant pressure and to increase the compatibility of other compounds in the aerosol formulation. Approximately 60% of the total manufactured CCl_2F_2 and CCl_3F is used in aerosols.

1,2-Dichlorotetrafluoroethane is used primarily in the cosmetic field, often in combination with CCl_2F_2. As CFCs have begun to be replaced, there has been an increase in the use of hydrocarbons, sometimes mixed with HCFC-22 (CHF_2Cl) to lower the flammability.

Foams

Polymers in a foamed or cellular state have many useful properties. Energy-efficient buildings have sheets (or sprayed foams) of polystyrene foam insulation in their construction, sheets made by compounding CFC-12 under pressure with liquid polymer followed by release to atmospheric pressure via extrusion. Polyurethane foams were produced using CFC-11, which was vaporized by the heat of reaction of the isocyanate with the polyol. The foaming mass was usually heat-treated to complete the process.

When employed as a foam to fill cavities, however, CFC-12 was used to expand the polymer mass. Although some CFC, especially CFC-11, remained behind in the foam, almost all of the material was lost to the atmosphere during foaming operations. This was one application, therefore, where recycling was not feasible. Approximately 30% of the CFC-11 was produced as a blowing agent for rigid and flexible polyurethane foams. The CFC trapped in the rigid foam significantly increased its insulation properties.

Minor quantities of rigid polyurethane foam are manufactured by a frothing process using CCl_2FCClF_2 and $CClF_2CClF_2$. Extruded polystyrene foams have used CCl_2F_2 as the principal blowing agent. Both $CClF_2CClF_2$ and $CClF_2CClF_2$ are used in low-density polyethylene and polystyrene foams.

Chlorofluorocarbons were completely removed from plastic foam products for food packaging, such as egg cartons and meat trays in the early 1990s; currently, HCFC-22 mixed with carbon dioxide, HFCs, supercritical fluids, pentane, or isopentane is being used as an alternative. Dow Chemical has reported that it uses HCFC-142b in its polystyrene and polyethylene fabricated foams.[1]

Solvents

CFC-113 ($CF_2ClCFCl_2$) was an ideal solvent and cleaning agent for the electronics and aerospace industries.[15] It had excellent wetting properties, was noncorrosive, and was easily removed, leaving no residue. Oil and greases were dissolved without affecting most plastic, elastomeric, or metal components. For applications where greater solvent power was needed, it might be mixed with alcohols and ketones, usually at an azeotropic composition. Solvents based on CFC-113 were used to remove flux from printed wiring boards, and as degreasers for precision and polished surfaces where no residue could be tolerated. CFC-113 was also used in the dry-cleaning of expensive, heat-sensitive fabrics. CFC-11 has also been used in dry-cleaning because of its better solvency. Other minor applications of chlorofluorocarbons included their use as dielectric fluids and in wind tunnels and bubble chambers.

Lubricants

The chlorotrifluoroethylene (CTFE) telomer oils were originally developed as lubricants for the mechanical equipment needed in the separation of uranium isotopes using the extremely reactive uranium hexafluoride. These inert oils, greases, and waxes now find many applications in aggressive environments where a hydrocarbon oil will not survive. Like hydrocarbon oils, they are sold as blend according to certain viscosities. Greases are made by mixing an appropriate oil with a thickener such as silica or higher-molecular-weight CTFE polymer.

Chlorotrifluoroethylene telomer lubricants are used primarily where chemical inertness and nonflammability are required. The chemical industry and the cryogenic gas industry (primarily oxygen) are the major users of these materials. They are used to lubricate all types of process equipment, such as dryers, conveyers, pumps, valves, and compressor seals. Extreme pressure tests using the four-ball method show that they are good lubricants, without any seizure even at an applied load of 800 kg.

In the aerospace industry, as well as finding use in the oxygen-delivery system to the space shuttle oxidizer tanks, a light CTFE oil is under development as a nonflammable hydraulic fluid for future aircraft. Since the CTFE oil is much heavier than presently used hydraulic oils, retrofitting of existing aircraft is not feasible. The CTFE oil operates in smaller lines at much higher (8000 psi) pressure. New elastomeric seals, which are compatible with the oil, have been developed. In modern aircraft, serious fires can occur during landing if a hydraulic hose ruptures and sprays fluid onto the hot braking system. Tests done with CTFE hydraulic fluid show the material is completely nonflammable during such an event.

Chlorotrifluoroethylene telomers find use as vacuum pump oils in the electronics industry, where reactive gases and aluminum chloride would be harmful to hydrocarbon oils. They are also used as instrument fill fluids where they substitute for glycerice or silicone fluids in pressure gauge sensors and diaphragm seals in aggressive chemical service. Other uses include application as a cutting or drawing oil in tantalum, molybdenum, and niobium processing, as

a lubricant for life-support systems in oxygen-rich atmospheres, and as a cold-temperature batch fluid in laboratory apparatus.

Chlorotrifluoroethylene oils are used as flotation fluids in gyroscopes. Specific density and viscosity values are achieved by blending together oils of different weights. Navigational devices containing these oils are found in many commercial and military aircraft, as well as missiles. Newer technologies such as fiber optics are now increasingly used, but the floated gyroscopes have a well-deserved reputation for accuracy and a long field life.

Chemical Intermediates

Chlorofluorocarbons function as chemical intermediates, provided they are consumed rather than released into the atmosphere. CFC-113 serves as the starting material for the production of CTFE monomer. Despite the many years of research into a catalytic vapor-phase process for this conversion, the preferred current method still involves zinc dechlorination in methanol [reaction (8)].[16,17]

$$CF_2ClCFCl_2 + Zn \longrightarrow CF_2{=}CFCl + ZnCl_2 \quad (8)$$

Chlorotrifluoroethylene monomer serves as a building block for the CTFE telomer oils as well as the solid higher polymer and various copolymers. CFC-113 also may be used in the production of trifluoroethylene monomer by vapor-phase reduction using hydrogen and a precious metal catalyst, usually palladium [reaction (9)]. Copolymers of trifluoroethylene and vinylidene fluoride show interesting piezoelectric properties.

$$CF_2ClCFCl_2 + H_2 \longrightarrow CF_2{=}CHF + 3HCl \quad (9)$$

CFC-113 may also serve as the starting material for some of the CFC alternatives. Conversion to CFC-113a [reaction (10)] may be accomplished using aluminum chloride as a catalyst, followed by reduction with sodium sulfite under basic conditions to give HCFC-123 [reaction (11)]. Alternatively, CFC-113a may be reduced with isopropanol in the presence of UV light [reaction (12)]. Both these processes produce HCFC-123 cleanly, with no over-reduction, and essentially free from HCFC-123a ($CF_2ClCHFCl$), which is usually found in several percent yield when HCFC-123 is made by the direct fluorination of tetrachloroethylene. The presence of the less stable HCFC-123a isomer may be problematic in some projected uses of HCFC-123.

$$CF_2ClCFCl_2 \longrightarrow CF_3CCl_3 \quad (10)$$

$$CF_3CCl_3 + Na_2SO_3 + NaOH \longrightarrow CF_3CHCl_2 + NaCl + Na_2SO_4 \quad (11)$$

$$CF_3CCl_3 + (CH_3)_2CHOH \longrightarrow CF_3CHCl_2 + HCl + (CH_3)_2C{=}O \quad (12)$$

CFC-113a can be fluorinated to CFC-114a and CFC-115 using vapor-phase techniques [reaction (13)]. Vapor-phase reduction of CFC-114a [reaction (14)] gives HCFC-124 and HFC-134a, both of which are under development as CFC alternatives. A similar reduction of CFC-115 gives its possible replacement HFC-125 [reaction (15)].

$$CF_3CCl_3 + HF \longrightarrow CF_3CFCl_2 + CF_3CF_2Cl \quad (13)$$

$$CF_3CFCl_2 + H_2 \longrightarrow CF_3CHClF + CF_3CH_2F \quad (14)$$

$$CF_3CF_2Cl + H_2 \longrightarrow CF_3CHF_2 + HCl \quad (15)$$

REGULATION OF CFCs PRODUCTION

Depletion of Ozone Layer

In the 1970s Lovelock and coworkers, using his newly developed electron capture detector, demonstrated that CFCs 11 and 12 were trace constituents in the atmosphere.[18] In 1972, at a meeting initiated by Du Pont, representatives of the leading CFC manufacturers discussed the environmental fate of their products. Ray McCarthy succinctly summarized their opinion in the following way: ''Fluorocarbons are intentionally or accidentally vented to the atmosphere world-wide at a rate approaching one billion pounds per year. These compounds may be either accumulating in the atmosphere or returning to the surface, land or sea, in pure form or as decomposition products. Under any of these alternatives it is prudent that we investigate any effects which the compounds may produce on plants or animals now or in the future.''

As a result, they initiated the industry research program to investigate the environmental impact of CFCs through an organization called the ''Fluorocarbon Program Panel'' (FPP) in 1972, 2 yr before publication of the Rowland–Molina hypothesis implicating chlorofluorocarbons in stratospheric ozone depletion.[5] This organization and its variously named successors sponsored much of the fundamental research into

atmospheric chemistry through the 1970s. Although the chemical industry is often depicted as not caring about environmental concerns, in the case of the CFCs the fluorocarbon producers adopted a demonstrably responsible attitude. Through FPP they jointly funded an extensive and high-quality atmospheric research program to test the validity of the Rowland and Molina hypothesis using independent experts who were free to publish their results as peer reviewed papers in reputable journals. Simultaneously, each company initiated its own research program to identify CFC replacements that retained the advantages of CFCs, notably low toxicity and nonflammability, while avoiding their implied threat to the ozone layer.

The atmospheric research program confirmed that CFCs were likely to deplete stratospheric ozone, as predicted by Rowland and Molina. The high stability of the chlorofluorocarbons, which made them so attractive as refrigerants, etc., was thought to enable themselves to pass unchanged through the troposphere to the stratosphere; once there, it was pointed out that the intense UV radiation from the sun could cause the carbon–chlorine bonds to break homolytically, giving chlorine atoms (e.g., $CF_2C1_2 + UV \rightarrow Cl^{\bullet} + {}^{\bullet}CF_2Cl$), which were known from laboratory experiments to catalyze the destruction of ozone: [$Cl^{\bullet} + O_3 \rightarrow ClO^{\bullet} + O_2$; $ClO^{\bullet} + O \rightarrow Cl^{\bullet} + O_2$ (net: $O_3 + O \rightarrow 2O_2$)]. The trace gas ozone, which is present throughout Earth's atmosphere, reaches its peak concentration within the stratosphere. The ozone layer plays an important role for life on Earth by absorbing biologically harmful UV radiation in the shorter-wavelength regions below 320 nm, i.e., in the UV-C (<290 nm) and UV-B (290–320 nm) regions. The stratospheric chlorine catalyzes the reversal of the photochemical generation of ozone (trioxygen, O_3) from the more familiar respirable form of oxygen (dioxygen, O_2): $O_2 + UV$ (<240 nm) $\rightarrow O_2$, $2O$; $O + O_2 \rightarrow O_3$; $O_3 + UV$ (210–320 nm) $\rightarrow O + O_2$. One million ozone molecules may be decomposed by just 10 chlorine atoms before the latter are eliminated, mainly through encounters with natural methane ($Cl^{\bullet} + CH_4 \rightarrow HCI + {}^{\bullet}CH_3$). The hydrogen chloride produced ultimately precipitates as hydrochloric acid in rain (''rains out'') in quantities negligible compared with natural background concentrations.

The observational techniques in the late 1970s were thought to be incapable of detecting any depletion that had already occurred. It was concluded that CFCs should be phased out, but that this could occur over a sufficiently long period to minimize the economic impact of the change to CFC users. Nevertheless, several developed countries including the United States pursued this changeover more proactively by banning the use of CFCs in most aerosols and by 1980 this had significantly reduced world CFC production.

Replacements for CFCs

Initial evidence of the effect of chlorofluorocarbons on the ozone layer was very limited and based mainly on computer models of the atmosphere. In the 1970s there was no observational support for ozone depletion, but the refrigeration manufacturers responded positively to the challenge. By 1976 most companies had initiated substantial research programs to identify environmentally acceptable replacements for CFCs. Alternatives to the CFCs need to retain the attractive properties of CFCs, but avoid any adverse environmental impact. Low toxicity, nonflammability, good thermodynamic properties, and accessibility via economically viable manufacturing routes were key factors in the selection. The inclusion of one or more hydrogen atoms in their molecules results in products being largely destructible in the lower atmosphere by naturally occurring hydroxyl radicals, ensuring that relatively little of the material survives to enter the stratosphere.

In the first stage of the research, producers were primarily seeking alternatives for the major CFC refrigerants and foam blowing agents CFC-12 and CFC-11, which were also the main aerosol propellants. This search was crucially influenced by the major customer: the refrigeration and air-conditioning industry. Between 1931 and 1974 the Industry owed its rapid development to the availability of the CFCs, designing its equipment around their specific thermodynamic properties. By careful, evolutionary development the industry had acquired an enviable reputation for reliability. Not surprisingly, the refrigerant manufacturers were expected to develop substitutes whose physical properties were similar to those of the CFCs fluids that were being replaced. In particular, similar vapor pressures were needed, since pressure was a key factor in refrigerator and air-conditioning design. Essentially, this meant searching for fluids with similar boiling points to those of CFC-l2 and CFC-11, which also met the other criteria outlined above.

By 1976, HFC-l34a had emerged from the research program as the fluid closest in physical properties to CFC-l2 and therefore the most acceptable to the refrigeration and air-conditioning industry. Its isomer HFC-134 was not favored, however, because of its significantly lower vapor pressure. HFC-l52a was rejected, primarily because of its flammability. The search for a CFC-11 replacement proved more difficult; but by the end of the 1970s, HCFC-123 and HCFC-141b had been identified as potential substitutes. Other candidates, such as HCFC-l33a, HCFC-31, and HCFC-21, had failed on toxicity grounds. To hasten the development program, manufacturers shared data about the toxicity of candidate compounds to avoid needless expense and time-consuming duplication.

In parallel with their own research programs, the manufacturers, through the FPP also jointly funded research to study the atmospheric chemistry of CFCs in order to assess the extent of any risk they might pose. Independent research workers of universities and research institutes worldwide were contracted to measure the rates of reactions, which were essential input data for the complex computer models needed to predict the rate of ozone depletion. This value could not be measured directly in the 1970s because the large daily and seasonal fluctuations in stratospheric ozone concentrations swamped the modest depletion expected from CFCs.

By 1980, the consensus of informed scientific opinion based on the best available evidence was that, although CFCs could cause depletion of stratospheric ozone, the overall effect at the production levels would be less then 3%. This suggested that action to replace CFCs would be required, but this could be taken over a sufficiently long period to minimize the cost to the refrigeration industry and ultimately to the customers. As a follow-up to the 1978 ban in the United States on the use of CFCs as aerosol propellants, the U.S. Environmental Protection Agency undertook in 1980 to promote legislation restricting the manufacture and other uses of CFCs. However, the perceived low rate of ozone depletion coupled with changing U.S. political priorities removed the urgency to enact the appropriate legislation.

Discovery of Antarctic Ozone Depletion

In 1984, a remarkable and totally unpredicted phenomenon was discovered by the British Antarctic Survey, the so-called ''ozone hole.''[2] The discovery of ozone depletion over Antarctica during the spring period provided the first observational support for the possible effect of CFCs on the stratospheric ozone. However, the observation of ozone loss did not indicate its cause. From 1984 to 1988, several theories were postulated from CFC chemistry to atmospheric dynamics or even to cosmic electron fluxes. It was not until 1988, with the results of the 1987 Airborne Antarctic Ozone Expedition, that a probable link with CFCs was established. This prompted the Natural Resources Defense Council, an American pressure group, to sue the EPA to fulfill its 1980 promise to seek legislation to further control the manufacture and use of CFCs in the United States of America.

Industrial research programs to develop CFC substitutes were renewed with vigor, and the refrigerant manufacturers set up in 1988 the jointly funded ''Program for Alternative Fluorocarbon Toxicity Testing'' (PAFT) to initiate and manage the toxicity testing of the preferred candidates. The refrigerant manufacturing industry also renewed its research into the atmospheric aspects of fluorocarbon fluids by forming in 1989 and funding an organization called ''Alternative Fluorocarbons Environmental Acceptability Study'' (AFEAS). Continuing the work started in the 1970s, this organization contracted independent research scientists to develop the understanding of the complex interactions of chemical species in the atmosphere.

An important outcome of this work has been the formulation of the ozone depletion potentials (ODPs) for chlorine-containing fluids. Arbitrarily. CFC-11 is assigned an ODP of unity; the ODPs of other fluids are normalized to that of CFC-11 on a mass-for-mass basis. Important factors in determining the ODP of a fluid include its atmospheric lifetime and the quantity of chlorine it contains. Hydrochlorofluorocarbons (HCFCs) have much lower ODPs than CFCs—a consequence mainly of the former's lower atmospheric lifetimes. Hydrofluorocarbons (HFCs), which by definition contain no chlorine, have zero ODPs.

The Montreal Protocol

Worldwide concern over the depletion of the ozone layer was discussed at the Vienna Convention in 1985 under the auspices of the United Nations Environment Program (UNEP). This culminated in the Montreal Protocol, the first international agreement made to protect the global environment. Signed in September 1987 and revised in June 1990, the Protocol now controls, throughout much of the world, the use and production of CFCs, halons (firefighting agents), carbon tetrachloride, and 1,1,1-trichloroethane (base solvent for degreasing formulations used in the electronic industry).

This agreement originally mandated a 50% reduction in CFC production and consumption by July 1, 1999, but, importantly, allowed for future revision in light of new scientific evidence. Subsequent atmospheric studies suggested that ozone was likely to be depleted at a faster rate than had been previously thought. Following revisions of the Protocol the complete phase-out of CFCs and HCFCs were also mandated. Although the European Union did not convince other signatories to the Protocol to accept proposals for earlier CFC and HCFC phase-out, it decided to include them in its own regulations. The European Union unilaterally banned the use of all recycled CFCs from January 2000. Chlorofluorocarbon recycling is still allowed in the United States and it has even become attractive to recover CFC-12 from its azeotrope with CHF_2CH_3 (HFC-152a) known as R500.

CONCLUSIONS

Since the early 1930s, the CFCs have been widely used as refrigerants, foam blowing agents, propellants, and

so on due to their outstanding physical and thermodynamic properties. However, the CFCs were unfortunately revealed to be responsible for depleting the ozone layer of the stratosphere on Earth. Production and use of CFCs began to be regulated by the international agreement, Montreal Protocol. The HCFCs and HFCs were recommended as the promising alternatives of the CFCs.[19,20] Outstanding physical properties of CFCs, in particular CFC-12, are very difficult to match or substitute by alternative materials in a variety of industrial applications. This fact has rendered a challenge to the research on CFC alternatives.

INTRODUCTION

The traditional model of electric power generation and delivery is based on the construction of large, centrally located power plants. ''Central'' means that a power plant is located on a hub surrounded by major electrical load centers. For instance, a power plant may be located close to a city to serve the electrical loads in the city and its suburbs, or a plant may be located in the midpoint of a triangle formed by three cities. Power must be transferred from a centrally located plant to the users. This transfer is accomplished through an electricity grid that consists of high-voltage transmission systems and low-voltage distribution systems. The traditional structures of the electrical utility market, green engineering issues, and environmental acceptability have resulted in a relatively small number of public electric utilities. However, today's technology permits development of smaller, less expensive power plants, bringing in new, independent producers. Competition from these independent producers, along with the re-thinking of existing regulations, is affecting the conventional structure of electric utilities. Concerns about the environment and the availability of ''green'' power have also become more important factors in the willingness to consider alternatives to the traditional centrally located electrical power plants. The restructuring of the electric utility industry and the development of new ''onsite and near-site'' power generation technologies have opened up new possibilities for buildings, building complexes, and communities to generate and sell power. Competitive forces have created new challenges as well as opportunities for companies that can anticipate technological needs and emerging market trends.

Historically, research, development, and commercialization efforts have been focused on individual system components (cooling, thermal storage, heating, ventilation air, and power). A new category consisting of power generation equipment coupled with thermally activated components has evolved as cooling, heating, and power (CHP). A successful CHP system requires a need for both generated electric/shaft power and thermal energy. An operation that does not have a need for both electric/shaft power and thermal energy will not likely benefit from CHP. Cooling, heating, and power is especially beneficial to the buildings that typically require electric power and can utilize thermally activated HVAC system components. The application of CHP system focuses on onsite fuel conversion, combining power generation and HVAC system optimization, and integration with other innovative technologies. Cooling, heating, and power holds some of the answers to the efficiency, pollution, environmental, and deregulation issues that the utility industry currently faces. Economic considerations are an important factor in the specification or retrofit of CHP systems. Not only are first costs and operating and maintenance (O and M) costs important, but also O and M costs uncertainties, especially for new and emerging technologies, can present barriers to CHP acceptance.

A review of CHP technology and systems is presented in this entry. Specific types of distributed power generation (DPG) and thermally activated technologies will be introduced and briefly previewed. Then, an overview of the equipment used in CHP systems is discussed. Finally, a bibliography of CHP systems and related equipment is included at the end of the entry.

THE CHP SYSTEM

Inefficiencies are associated with the traditional method of electric power generation and delivery. Figs. 1 and 2 illustrate the losses inherent in the generation and delivery of electric power in traditional power plants and in combined-cycle power plants. Traditional power plants convert about 30% of the fuel's available energy into electric power, and highly efficient, combined-cycle power plants convert over 50% of the available energy into electric power. The majority of the energy content of the fuel is lost at the power plant through the discharge of waste heat. Further, energy losses occur in the transmission and distribution of electric power to the individual user. Inefficiencies, environmental, and pollution issues associated with conventional power plants provide the impetus for new developments in ''onsite and near-site'' power generation.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120041074

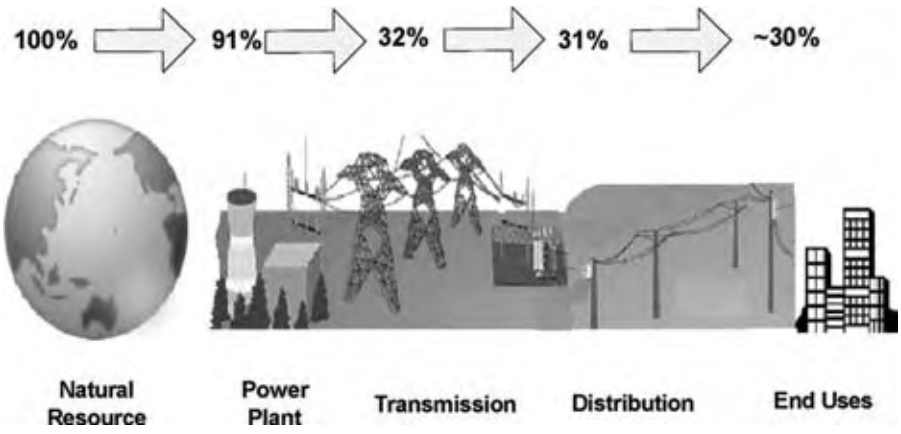

Fig. 1 Efficiency of central power generation. *(View this art in color at www.dekker.com.)*

Cooling, heating, and power combines DPG with thermally activated components to meet the CHP needs of buildings. Cooling, heating, and power systems consist of integrated power generation equipment (gas turbines, microturbines, internal combustion (IC) engines, and fuel cells), thermal systems (water chillers, absorption chillers, air conditioners and refrigeration—electric or engine driven, boilers, and thermal storage), ventilation/IAQ systems (desiccant, enthalpy, and other energy recovery devices), and building control and system integration technologies. Technological advances in both power generation and thermally activated systems have contributed to the development of diverse CHP applications.

Cooling, heating, and power has the potential to reduce carbon dioxide and air pollutant emissions and to increase resource energy efficiency dramatically. It produces both electric or shaft power and useable thermal energy onsite or near-site, converting as much as 80% of the fuel into useable energy. A higher efficiency in energy conversion means less fuel is necessary to meet energy demands. Also, onsite power generation reduces the load on the existing electricity grid and infers better power quality and reliability. Fig. 3 illustrates the increase in efficiency of CHP systems over the power plant efficiencies seen in Figs. 1 and 2. The economic viability of CHP systems is dependent on a number of factors: 1) the cost of CHP-generated electricity and recovered thermal energy vis-à-vis the cost of electrical and thermal (gas) power purchased from the grid; 2) the cost of grid connect charges (and penalties) for back-up and outage power requirements; 3) additional costs incurred by CHP component maintenance (e.g., overhauls and oil changes); and 4) costs associated with additional personnel time for CHP operations.

DISTRIBUTED POWER GENERATION

A number of technologies are commercially available for generating electric power or mechanical shaft power onsite or near-site where the power is used. The three major categories for distributed generation are combustion turbines, IC engines, and fuel cells.

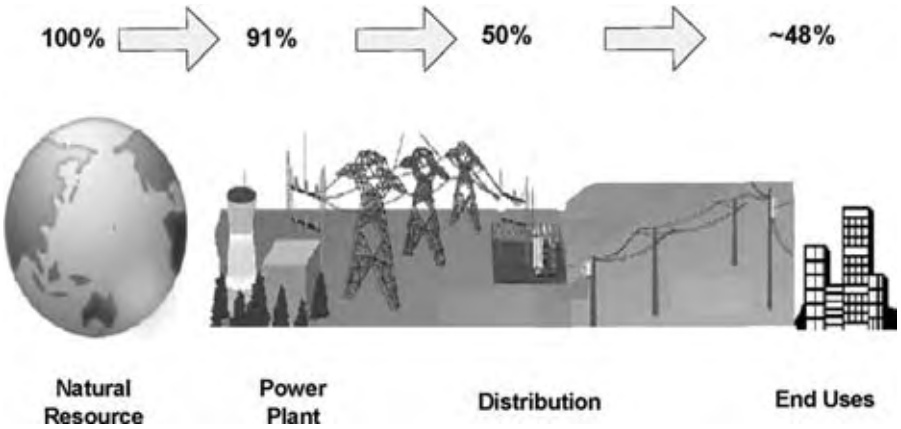

Fig. 2 Efficiency of combined-cycle power generation. *(View this art in color at www.dekker.com.)*

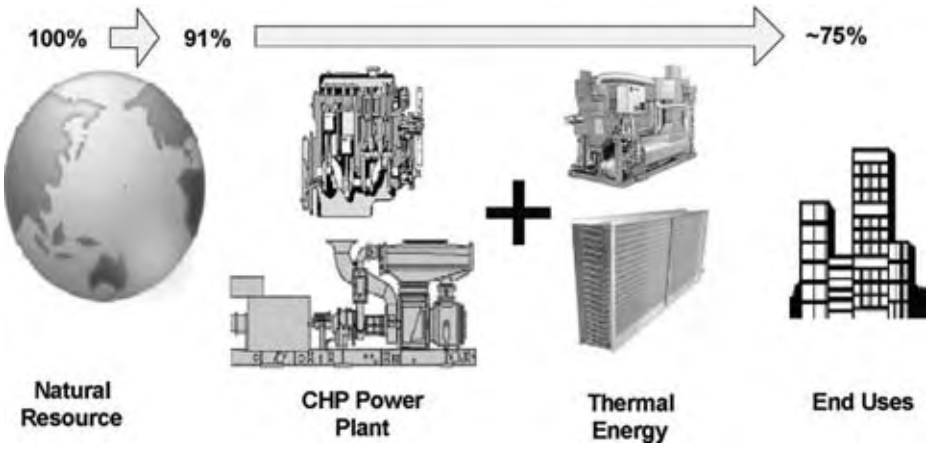

Fig. 3 Efficiency of CHP systems. *(View this art in color at www.dekker.com.)*

Combustion Turbines

Combustion turbines are based on gas turbines and use a variety of fuels, including natural gas, fuel oil, or bio-derived fuels. They can also use recuperators to recover thermal energy in the turbine exhaust streams for pre-heating the air/fuel mixtures for the combustor sections.

The efficiency of electric power generation for combustion turbine systems, operating in a simple-cycle mode (i.e., without external use of heat recovery in the turbine exhaust), ranges from 21% to 40%. Combustion turbines produce high-quality heat that can be used to generate steam or hot water for thermally activated applications, including heating and cooling.

Utilization of thermal energy in a combustion turbine exhaust stream significantly enhances fuel efficiency. Maintenance costs per unit of power output for combustion turbines are among the lowest of all power-generating technologies. As the output capacity of combustion turbines decreases with the increases in ambient air temperature, in hot weather climates or on hot days, cooling of inlet air has been found to be cost effective for many power plants.

Industrial turbines and microturbines are the two types of combustion turbines that are commercially available. Industrial turbines represent a well-established technology for power generation and also represent the ''high'' end of power generating capacity equipment. These can provide from 1 MW to more than 100 MW of electric power. Most CHP systems need capacities below 20 MW, sufficient for large office buildings, hospitals, or small campuses of offices and commercial buildings. The thermal efficiency of industrial gas turbines for power generation ranges from 25% to 40%. A picture of the rotating spool of an industrial turbine is shown in Fig. 4.

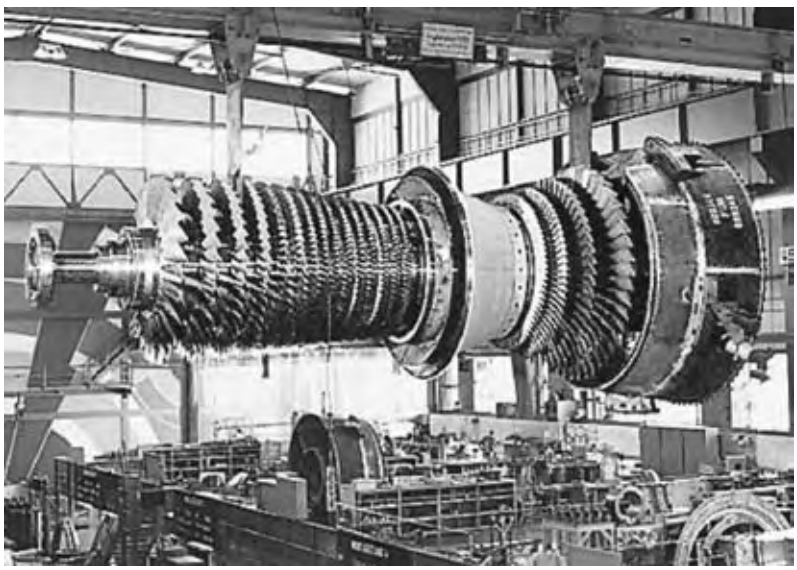

Fig. 4 Industrial turbine spool by Siemens Westinghouse. *(View this art in color at www.dekker.com.)*

Fig. 5 Thirty-kilowatt microturbine by Capstone. *(View this art in color at www.dekker.com.)*

Microturbines are a new generation of smaller turbines. The capacities of microturbines range from 25 to 500 kW. Fig. 5 pictures a 30-kW microturbine by Capstone Turbine, Inc.

Microturbines can use natural gas, propane, and bio-derived gases produced from landfills, sewage treatment facilities, and animal waste processing plants as a primary fuel. The fuel source versatility of microturbines allows their application in rural as well as urban areas. Microturbines evolved from automotive and truck turbochargers, auxiliary power units for airplanes, and small jet engines used on remotely piloted military aircraft. Because microturbines have fewer moving parts than conventional generating equipment of similar capacity, they have the potential to significantly reduce maintenance and operating costs as compared to traditional distributed-energy prime movers. By using recuperators, microturbine systems are capable of energy efficiencies for power generation in the 25–30% range. These turbines have a significant potential for onsite power generation for CHP systems.

Internal Combustion Engines

A reciprocating engine, either four-cycle IC or diesel, is used for producing mechanical shaft power. Shaft power can be used to drive a generator to produce electric power or to operate other equipment including air compressors for process or vapor compression systems for space conditioning. These applications of reciprocating engines are very well established and widespread. Engines can use natural gas, propane, diesel fuel, or bio-derived fuels and are available in capacities ranging from 5 kW to 10 MW. A diesel fuel engine generator is pictured in Fig. 6.

Fig. 6 Engine-generator set by Caterpillar. *(View this art in color at www.dekker.com.)*

Reciprocating engines used for power generation have low capital cost, easy startup, proven reliability, good load-following characteristics, and significant heat recovery potential. They are the most widespread distributed-generation technology in the world today. Existing engines achieve electric generation efficiencies in the range from 25% to over 40%. The incorporation of exhaust catalysts and better combustion design and control has significantly reduced pollutant emissions during the past few years.

Thermal energy in the engine exhaust gases and from the engine cooling system can be employed to provide space heating, hot water, or to power thermally activated equipment. Emissions of engines tend to be higher than those of microturbines and fuel cells. In some locations, depending on local air quality standards, engine emissions may limit reciprocating engine applications for CHP systems.

In a gas engine-driven chiller, the engine produces mechanical shaft power that is used for operating a chiller compressor. Such chillers are very similar to conventional electric-driven chillers. The only difference is that the electric motor that drives the compressor in an electric chiller is replaced with a reciprocating engine.

Fuel Cells

Fuel cells produce electric power by electrochemical reactions, generally between hydrogen and oxygen without the combustion processes. Unlike turbine- and engine-generator sets, fuel cells have no moving parts and, thus, no mechanical inefficiencies.

Phosphoric acid fuel cells (PAFCs) are commercially available. Several hundred PAFC units, most of the order of 200 kW, are operating worldwide. PAFCs are realizing efficiencies of up to 40%. The only byproducts of PAFC operation are water and heat. However, enriched hydrogen fuel must be produced by subjecting hydrocarbon resources (natural gas or

Fig. 7 PureCell™ fuel cell by United Technologies. *(View this art in color at www.dekker.com.)*

methanol) to a reforming or gasification process. This process results in chemical reactions that produce carbon dioxide and other environmental emissions.

Like a battery, a fuel cell produces direct current (DC). However, fuel cells come in a complete package in which the fuel cell stack is integrated with an inverter to convert DC to alternating current and a reformer to provide the hydrogen-rich fuel. Thus, a complete fuel cell system includes a fuel reformer, a fuel cell stack, and a power conditioner. A 200-kW PAFC unit by United Technologies Company is illustrated in Fig. 7.

There are other types of fuel cells of which proton exchange membranes (PEMFC), molten carbonate (MCFC), and solid oxide (SOFC) are the most promising. These fuel cells are at various stages of technology demonstration and are not commercially available. Each type of fuel cell has its own ''preferred'' range of capacities and waste heat temperatures that determine where they can be used to best advantage in CHP systems. Table 1 gives an overview of fuel cell characteristics for the PAFC, SOFC, MCFC, and PEMFC.

Fuel cells are expected to deliver electrical conversion efficiencies in the range of 40–60%. These are used in cogeneration applications that could realize thermal efficiencies of 80–90% for the overall system. Cooling, heating, and power applications can benefit from the high electrical conversion efficiencies of fuel cells and the even higher overall energy conversion efficiencies of fuel cells used in combined cycles and fuel cells coupled with thermally activated components. Fuel cells produce electricity without combustion and with very low NO_x emissions, therefore limiting adverse environmental effects in populated CHP installation

Table 1 Overview of fuel cell characteristics

Electrolyte	PAFC	SOFC	MCFC	PEMFC
Size range	100–200 kW	1 kW–10 MW	250 kW–10 MW	3–250 kW
Operating temperature	200°C (400°F)	1000°C (1800°F)	650°C (1200°F)	90°C (200°F)
Fuel	Natural gas, landfill gas, digester gas, propane	Natural gas, hydrogen, landfill gas, fuel oil	Natural gas, hydrogen	Natural gas, hydrogen, propane, diesel
Efficiency (%)	40–45	50–60	50–60	40–50

locations. Residential and commercial buildings will also benefit from the quiet and reliable operation of fuel cells. Strengths and weaknesses of each type of fuel cell are listed in Table 2.

Distributed power generation is a required component of a CHP system. Internal combustion engines, combustion turbines, and fuel cells are the current prime movers that have the most potential for DPG. Characteristics of these DPG technologies such as electric efficiency, power output, and cost are presented in Table 3.

HEAT RECOVERY

In most CHP applications, the exhaust gas from a prime mover is ducted to a heat exchanger to recover the thermal energy in the gas stream. Generally, these heat exchangers are air-to-water heat exchangers, where the exhaust gas flows over some form of tube-and-fin heat exchanger surface and the heat from the exhaust gas is used to make hot water or steam. The hot water or steam is then used to provide process energy and/or to operate thermally activated equipment, such as absorption chillers or desiccant dehumidifiers. Many of the thermal-recovery technologies used in building CHP systems require hot water, some at moderate pressures of 15–150 psig. In the cases where additional steam or pressurized hot water is needed, supplemental heat can be added to the exhaust gas with a duct burner.

In some applications, air-to-air heat exchangers can be used. If the emissions from the generation equipment are low enough, the hot exhaust gases can be mixed with make-up air and vented directly into the heating system for building space heating.

In the majority of installations, a flapper damper or ''diverter'' valve is employed to vary the flow across the heat exchanger to maintain a specific design temperature of the hot water or a specific steam generation rate. In some CHP designs, the exhaust gases are used to activate a thermal enthalpy wheel or a desiccant dehumidifier. A thermal wheel uses the exhaust gas to heat a rotating wheel with a medium that absorbs the heat and then transfers the heat into the incoming airflow into which the wheel is rotated.

THERMALLY ACTIVATED DEVICES

Thermally activated devices are based on technologies that use thermal energy, preferably heat from the exhaust gases of power generation equipment, instead of electric energy for providing heating, cooling, or humidity control for buildings. The two primary components for thermally activated devices for application in CHP systems are absorption chillers and desiccant dehumidifiers.

Absorption Chillers

Absorption chillers use heat as the primary source of energy for driving an absorption refrigeration cycle. These chillers require very little electric power (0.02 kW/ton) compared to electric chillers that need 0.47–0.88 kW/ton, depending on the type of electric chiller. Absorption chillers have fewer and smaller moving parts and are quieter during operation than electric chillers. These chillers are also environment-friendly in that they use non-CFC refrigerants.

Commercially available absorption chillers can utilize the following sources of heat:

- Steam
- Hot water
- Exhaust gases
- Direct combustion

Absorption chillers, except those that use direct combustion, are excellent candidates for providing some or the entire cooling load in a CHP system for a building. Modern absorption chillers can also provide heat during winter and feature electronic controls that provide quick startup, automatic purge, and greater turndown capability than many electric chillers. Maintenance contracts and extended warranties are also available for absorption chillers at costs similar to those for electric chillers. Many facilities across the United States are already benefiting from the use of absorption chillers, such as the one pictured in Fig. 8.

Table 3 Comparison of DPG technologies

	Diesel engine	Natural gas engine	Gas turbine	Microturbine	Fuel cell
Electric efficiency	30–50%	25–45%	25–40%	20–30%	40–70%
Power output (MW)	0.05–5	0.05–5	3–200	0.025–0.25	0.2–2
CHP installed cost ($/kW)	800–1500	800–1500	700–900	500–1300	>3000
Footprint (ft^2/kW)	0.22	0.22–0.31	0.02–0.61	0.15–1.5	0.6–4
O and M costs ($/kW hr)	0.005–0.010	0.007–0.015	0.002–0.008	0.002–0.01	0.003–0.015

Fig. 8 Absorption chiller by broad air conditioning. *(View this art in color at www.dekker.com.)*

Two types of absorption chillers are commercially available: single effect and multiple effect. Compared to single-effect chillers, multiple-effect absorption chillers cost more (higher capital cost) but are more energy efficient and are, thus, less expensive to operate (lower energy cost). The overall economic attractiveness of each chiller depends on many factors, including the cost of capital and the cost of energy.

Desiccant Dehumidifiers

There are two separate aspects of space conditioning for comfort cooling:

- Lowering the temperature of the air (sensible cooling), and
- Reducing humidity in the air (latent cooling)

Fig. 9 Desiccant dehumidifier. *(View this art in color at www.dekker.com.)*

The humidity level should remain below 60% relative humidity to prevent growth of mold, bacteria, and other harmful microorganisms in buildings and to prevent adverse health effects.

Traditionally, temperature and humidity control have been accomplished using a single piece of equipment that reduces the air temperature below the dew point temperature. Moisture in the incoming air condenses on the outside of a cooling coil over which the air passes, and cooler air, containing less moisture, is sent to the space being conditioned. Reducing humidity in the air by cooling often requires lowering the air temperature below a comfortable level and may necessitate reheating of the dehumidified air to achieve comfort.

Desiccant dehumidifiers reduce humidity in the air by using solid desiccant materials or liquid desiccant materials to attract and hold moisture. They can operate independent of chillers and can also be operated in series or parallel with chillers. Recoverable heat from the exhaust gases of turbines and engines for power generation or engine-driven chillers is used for regenerating desiccant material in these dehumidifiers.

In some CHP systems, the moisture content of the air is reduced using a desiccant dehumidifier and the dehumidified air is then cooled using conventional cooling equipment. By reducing the moisture content of the air, desiccant dehumidifiers satisfy the latent cooling load and, thus, reduce the load of the chillers to the sensible cooling (reducing the temperature). Alternatively, a desiccant dehumidifier can be used to further dehumidify and partially reheat cool, saturated air leaving a conventional cooling coil. By positioning the desiccant dehumidifier after the cooling coil, the dehumidification performance of the desiccant is enhanced. This allows the use of moderate or lower temperatures, typical of CHP systems, for regenerating the desiccant. A typical, commercially available desiccant system is shown in Fig. 9.

CASE STUDY: MISSISSIPPI BAPTIST MEDICAL CENTER

The Mississippi Baptist Medical Center (MBMC) in Jackson, Mississippi, represents an excellent example of a CHP system with a long and economically successful record. The MBMC CHP system was brought online in 1991, so it has a long operational history. This case study examines the details of the system as well as the operating experiences.

Fig. 10 is a site photograph of the MBMC. The full-service hospital has 694 beds, a 24-hr emergency room, a medical staff of 500, and more than 3000 total employees.

The history of CHP at MBMC started in 1990 when hospital officials were interested in exploring options to reduce energy costs. In 1990, the hospital had a large electricity requirement, a large steam requirement, a significant price differential per Btu between electricity and gas, a centralized physical plant, and small daily variations in energy requirements. Taken together, the 1990 energy profile indicated CHP, or cogeneration as it was then called, to be a viable economic option, and a CHP system was proposed. The system was expected to provide 70% of the electricity requirement, 95% of the steam required, and 75% of the cooling load. The system contains the following components:

1. Gas turbine generator set: Solar Centaur H Model
2. Diverter valve

Fig. 10 Site view of the MBMC. *(View this art in color at www.dekker.com.)*

3. ABCO waste heat recovery boiler
4. Economizer
5. Steam absorption chiller
6. Primary switch gear

The performance specifications as well as the details of each of the system components are presented in the following paragraphs. System operation can be best understood by examining Fig. 11, which presents a schematic of the system.

The Solar Centaur Turbine is fired by natural gas; shaft power is extracted from the turbine, via a gearbox, and used to drive the generator. The Solar Centaur H Turbine is rated at 5600 hp with an electrical output of 4.0 MW on an ISO standard day. The turbine is controlled by an Allen Bradley PLC 5/20 microprocessor with starting and synchronizing controls, a fire detection/protection system, and vibration analyzer capability. The nominal generator output is 13, 800 V. Fig. 12 shows the turbine installation arrangement.

The diverter valve operation is controlled by the waste heat recovery boiler (WHRB) and directs the exhaust gas to the WHRB boiler or out of the bypass stack to maintain the required steam pressure. The ABCO WHRB is rated at 30,000 lb/hr and has two firing modes. In the turbine-firing mode, a 5.8 MMBtu duct burner is available to supplement the turbine exhaust stream. In the direct-fire mode, used when the turbine is offline, the direct fresh-air fire at 41.5 MMBtu is available.

The economizer utilizes the remaining waste heat to preheat boiler feed water; water treatment chemicals

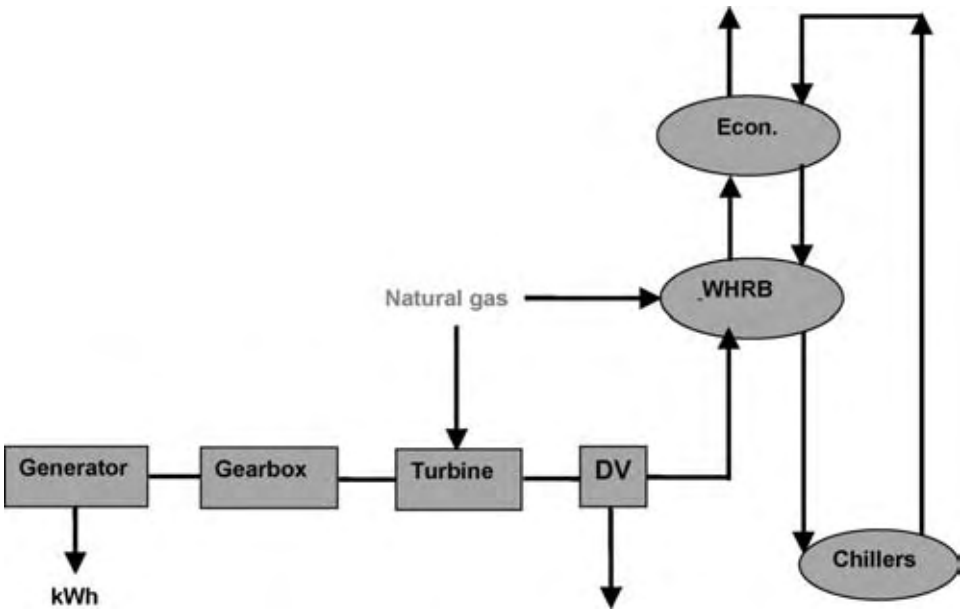

Fig. 11 MBMC CHP system schematic. *(View this art in color at www.dekker.com.)*

Fig. 12 Centaur H turbine installation. *(View this art in color at www.dekker.com.)*

are added to the feed water prior to the economizer. Two absorption chillers are used by the system: a 1250-ton York Paraflow double effect chiller utilizes 115 psi steam at 11.8 lb/hr-ton to produce chilled water at 42°F and a 750-ton Trane double effect chiller utilizes 115 psi steam at 9.6 lb/hr-ton to produce chilled water at 42°F. The chillers supply approximately 60% of the MBMC's 2002 total chilled water requirements. Additions to the facility since 1991 have added cooling load and resulted in 60% rather than 70% of the chilled water load being supplied by the absorption chillers. Fig. 13 shows the two chillers and their installation arrangements.

The primary switchgear is Powell metal-clad 4-bay switchgear that uses vacuum breakers for generator output and primary utility feed and contains generator and utility protective relays as well as synchronizing controls for generator/utility grid interconnect. The turbine-generator does not supply 100% of the electrical load, so the MBMC remains connected to the grid in normal operation. If a CHP problem is sensed by the switchgear, the full hospital load is instantaneously shifted to the grid. If the primary utility grid connection fails, the switchgear will shift the electrical load to a secondary utility feed in 2 sec. The combination of turbine-generator, primary grid, and secondary grid provides the MBMC with triple redundancy for emergency situations.

Schmidt and Hodge[3] examined in detail the economics of the MBMC CHP system and concluded that the actual yearly cost avoidance was close to the original estimate of $800,000/yr. Their economic study results are presented in Table 4.

The actual average yearly cost avoidance for 1994–1996 was $701,000, which compares favorably with the original estimate. The actual payback period

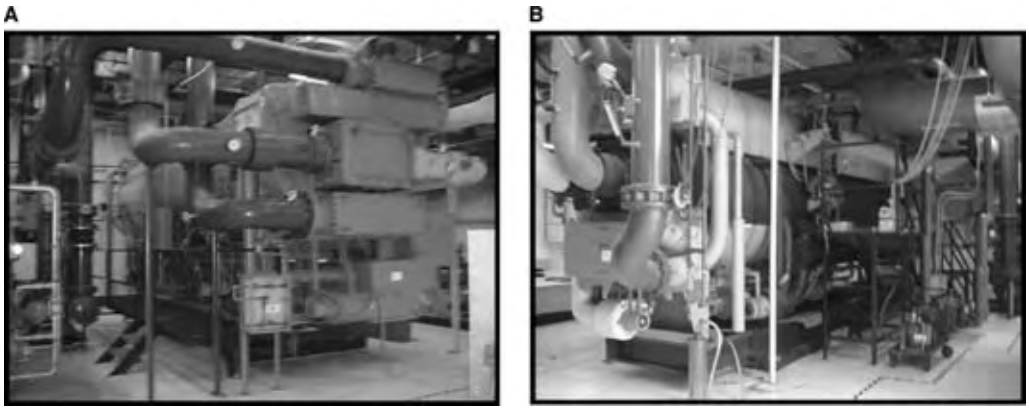

Fig. 13 The York and Trane absorption chillers: (A) York chiller; (B) Trane chiller. *(View this art in color at www.dekker.com.)*

Table 4 Actual cost avoidance

Year	Electricity savings ($)	Natural gas ($)	Maintenance ($)	Savings ($)
1994	1,250,000	402,000	159,000	686,000
1995	1,240,000	432,000	159,000	648,000
1996	1,400,000	468,000	163,000	770,000
Average				701,000

was about 6 yr, which again compares favorably with the estimated payback period of the original economic study of 1990.

One indication of the overall system performance is the percentage of time the CHP system was online. Table 5 presents the online percentage for the years for which the data were available as well as the total electrical generation as a percentage of the electrical requirement for the entire hospital.

As illustrated in Table 5, except for 1998 and 2001, the system provided in excess of 70% of the electricity for the hospital and online percentages mirrored the percentage generation. In 1998, generator problems caused a multi-day outage, and in 2001 the high spike in natural gas costs caused the MBMC to rely solely on grid electricity during the peak-cost period. Taken over the 11 yr of operation, the system was online and producing electricity for all but 2 out of 132 months!

Performance data for a recent calendar year of operation are provided in Table 6. These data illustrate the effectiveness of the system in the MBMC.

The average steam requirements for the absorption chillers and the ancillary hospital usage were virtually satisfied by the turbine exhaust as the duct burner used only 5% of the total gas usage for the system (turbine plus duct burner). Moreover, 2001 was the year in which gas costs caused a curtailment in the turbine usage; nonetheless, the turbine generator accounted for more than 60% of the required electricity.

Many factors have contributed to the successful long-term operation of the MBMC CHP system. The most important of these factors are delineated as follows:

1. A high reliability for all system components.
2. A comprehensive maintenance program.
3. An enthusiastic and competent power-house staff.
4. An accurate and consistent monitoring procedure. A no-penalty switchover-to-grid electrical rate structure. A continuous assessment and improvement process.

Based on the initial desire to avoid electricity costs and the initial estimate of cost avoidance of about $800,000/yr, the CHP systems at MBMC must be rated a success. In the United States, situations where CHP make sense exist by the thousands. This case study illustrates how effective CHP can be as a solution to energy costs.

CONCLUSIONS

For myriad reasons including increasing concerns about energy security, escalating energy costs, power quality requirements, environmental issues, and overall thermal efficiency, CHP is emerging as a viable alternative to conventional grid-based electricity. The driving potential behind CHP systems is the thermal efficiency that can be achieved. Projected system efficiencies of 75% are well above the overall thermal efficiencies experienced by conventional energy systems. Reliability, enhanced power quality, and lower emissions are additional benefits that make CHP systems attractive. In most instances (except where power quality and

Small scale capacity	Microturbine ⇒ Fuel cell ⇒ IC engine ⇒ Gas turbine

dependability are primary concerns), the deciding factor in specifying or retrofitting CHP systems will be driven by economic considerations. The case study demonstrated long-term favorable economics for a CHP system in a large hospital. Many such situations exist; indeed, examples abound where long-term favorable economics have been demonstrated. However, the energy mix in the United States is very complicated and especially in times of escalating and uncertain energy costs, a detailed economic analysis is needed if an informed decision is to be made concerning a CHP installation. As more electricity is being generated by natural gas and as natural gas is a likely first choice for many CHP installations, in the long-term, electricity generated by centrally located power plant and that by CHP installations are likely to share common economics. That being the case, the increased thermal efficiency of CHP systems will continue to favorably impact the economics of CHP even in the face of increasing natural gas prices.

A variety of DPG technologies may be selected for a CHP system. Table 7 illustrates how these technologies compare in efficiency, cost/technology status, emissions, noise, and small-scale capacity. The technologies are ranked from those having the most positive characteristics to those having the most negative characteristics. For example, fuel cells have the lowest emissions and, therefore, the best characteristics in this category, and IC engines have the most emissions and, therefore, the most negative characteristics in this category. The rankings in Table 7 are based on the technologies as a whole and may vary in some cases for specific components.

Chromatographic Separations

C

Scott M. Husson
Department of Chemical and Biomolecular Engineering, Clemson University, Clemson, South Carolina, U.S.A.

INTRODUCTION

This contribution provides an introduction to various types of chromatographic separations, operating configurations, and methods to characterize chromatographic separation data. After a brief introduction and background, the three chromatography process techniques are described. Gas and liquid chromatography (LC) concepts are presented along with brief introductions to the common stationary phase materials and geometries, the various mechanisms of retaining solutes on the stationary phase, and the common methods of detection. Next, modes of operation from batch to continuous, simulated moving-bed (SMB) chromatography are described with references given to commercialized systems. Finally, chromatographic separation theory is introduced, leading to the definitions of chromatographic figures of merit, including the number of theoretical plates and peak resolution.

The basis of chromatographic separation is the partitioning of chemical solutes between a moving fluid phase, called the mobile phase, and a stationary phase over which the mobile phase flows. The mobile phase can be either a gas or a liquid, while the stationary phase is either a solid or a liquid applied to a solid substrate. Separation of the chemical solutes in the mobile phase occurs based on differences in their partitioning between the two phases. Those that partition to the stationary phase to a greater extent will take longer to flow past it.

Categorization of chromatographic separations begins with process techniques: elution development, displacement development, and frontal analysis chromatography. Next, the types of chromatographic separations can be categorized based on mobile phase: gas or liquid. Further categorization is based on the mechanism of retaining solutes on the stationary phase, e.g., adsorption, ion exchange, etc. Still further categorization is based on the stationary phase geometry: thin layer, packed bed, capillary column, membrane module, etc. Finally, the mode of operation also has categories: batch, continuous, moving-bed operation; continuous, SMB; continuous annular chromatography, etc. For detailed information on these topics, see the Bibliography section.

BACKGROUND

The Russian botanist Mikhail Tswett is generally recognized as the inventor of chromatography for his work 100 yr ago. His work involved separating plant pigments by eluting a mixture of the pigments on a column of calcium carbonate. The pigments separated into colored bands on the column, hence the name chromatography.[1] However, the observations of Tswett attracted little attention until about the 1950s, when Martin and Synge demonstrated its usefulness for biological separations. In 1952, Martin and Synge received the Nobel Prize for their work, which revolutionized analytical chemistry. In addition to its wide use in analytical chemistry and laboratory-scale separations, chromatography is used on a preparative scale ($<$1 ton/day) in the production of pharmaceuticals and fine chemicals, and on a larger, bulk scale ($>$50 tons/day) in separations of close-boiling isomers and mixed sugars.[2,3] To understand these and other aspects of chromatography, limited definitions and nomenclature are presented as needed. For a more comprehensive listing of chromatography nomenclature, see Ref.[4].

PROCESS TECHNIQUES IN CHROMATOGRAPHIC SEPARATIONS

The term development is used to describe the process by which chemical solutes are transported through the stationary phase. For batch modes of operation, solute development is done by elution or displacement processes. For continuous modes of operation, solute development is accomplished by the process of frontal analysis.

Elution Development

Elution development is the most common process technique for chromatographic separations. A pulse of sample mixture is introduced into the mobile phase at a point near the inlet of the stationary phase, and all of the chemical solutes migrate through the

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007704

stationary phase at rates that depend on their degrees of interaction with the stationary phase material. If the migration rates of the solutes differ, the solutes will gradually form distinct zones separated by pure mobile phase solvent. Fractional collection of the fluid zones as they exit the column results in pure solute products diluted in the mobile phase solvent.

Displacement Development

In displacement development chromatography, a pulse of the sample is introduced into the system at the inlet of the stationary phase. The difference from elution development is the use of one or more mobile phase solvents, or displacing agents that interact strongly with the stationary phase material. If the chromatographic conditions and the mobile phase are kept constant throughout the entire experiment, then the mode of operation is termed isocratic elution. In the case where multiple mobile phase solvents are used, a first solvent is chosen, which interacts with the stationary phase more strongly than does the least-interacting solute. Once this solute has been displaced far enough along the stationary phase, a second mobile phase solvent is introduced, which is able to displace the next most weakly interacting solute, and so forth. Gradient elution is a type of displacement development in which the mobile phase continuously changes composition, gradually becoming stronger in its ability to displace bound solutes.

Frontal Analysis

Frontal analysis chromatography allows greater flexibility for continuous scale-up than elution or displacement chromatography. The primary difference is that the sample to be separated is introduced as a step change in frontal analysis. As the sample mixture is fed continuously into one end of the stationary phase bed, the least retained solute begins to emerge at the outlet of the bed as a pure product. This product can be recovered until, eventually, the stationary phase material becomes saturated with the next most strongly retained solute, which then begins to ''break through'' into the product stream. Operating as such, frontal analysis allows recovery of only one pure product. Advances in stationary phase–mobile phase contactor design overcome this apparent limitation; these advances are described under the section ''Modes of Operation.''

GAS CHROMATOGRAPHY

In gas chromatography (GC), a sample is vaporized into a flowing gas stream called the carrier gas, and the components of the sample are separated based on differences in the extent to which they are retained by a stationary phase. Fig. 1 illustrates the components of a typical GC instrument. A standard setup comprises a sample introduction system, the column and oven heater, and the detector. Microliter samples are injected through a rubber septum into a heated sample port at the inlet of the column that holds the stationary phase. For applications that use a capillary column, a stream-splitter is employed that directs only a fraction of the sample through the column. A carrier gas (mobile phase) moves the sample through the system. An oven is used to control the temperature of the column, detector, and injection port. The sample port is maintained at a temperature above the normal boiling point of the least volatile component. A limitation for GC separations, then, is that the sample components must be stable thermally at the temperatures used in the sample port and column oven. The oven may operate at a constant temperature, or it may be programmed in time to ramp to higher temperatures. Most GC systems now have computer software packages that control all aspects of operation and data collection, including operation of automated injection systems.

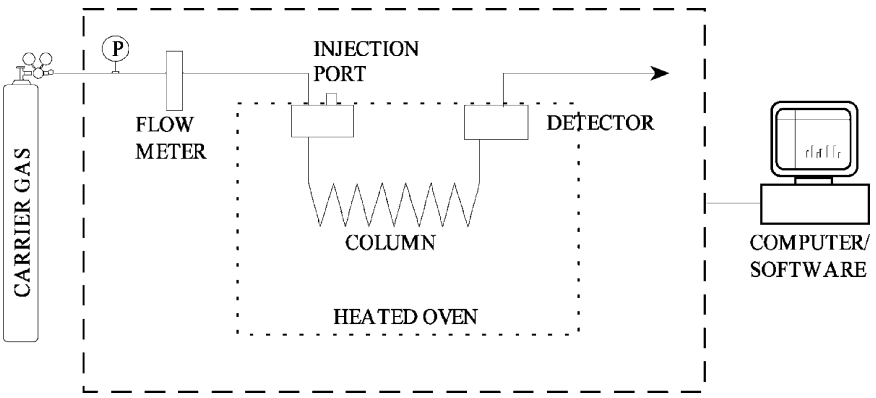

Fig. 1 Schematic illustration of a basic GC system.

Carrier Gases for GC

The most common carrier gases are helium, nitrogen, argon, and hydrogen. Research-grade gases (preferably 99.995%) are used for GC separations to avoid low-level contaminants such as water, hydrocarbons, and carbon dioxide. Even at low concentrations, these impurities can affect detector stability seriously.[5] Carrier gases are supplied from a generator or a cylinder with a regulator that allows pressure regulation between 10 and 250 psig at its outlet. Selection of appropriate carrier gases depends primarily on the type of detector, as described in the following sections.

Detectors for GC

Dozens of detectors have been developed for use in GC. The two most widely used, low-cost detectors are the thermal conductivity detector (TCD) and the flame ionization detector (FID). For descriptions of other detectors see Grob (1995) in Bibliography.

Thermal conductivity detector

A TCD uses heating filaments to measure differences in thermal conductivity between the sample stream exiting from the column and pure carrier gas. As the concentration of sample in the gas phase affects the ability of the gas to conduct heat, differences in the thermal conductivity are proportional to the molar concentration of sample in the gas. Maximum signal response occurs with hydrogen as the carrier gas, because its high thermal conductivity maximizes the difference in thermal conductivity between sample and carrier. Helium is used commonly and offers a safer option than hydrogen. Good control of carrier flow rate is needed for TCD, because it detects changes in sample concentration, not mass. The minimum detectable level (MDL) for TCD is $\sim 5 \times 10^{-10}$ g/ml.[6]

Flame ionization detector

For FID detection, hydrogen is mixed with the carrier gas, and the column effluent stream is burned in air. The FID measures the ionization of the sample stream, which is proportional to the mass of the sample in the gas. Flame ionization detector has high sensitivity (MDL is $\sim 10^{-12}$ g/sec), but it has two main disadvantages: FID cannot detect compounds that do not produce ions in a hydrogen–oxygen flame (e.g., H_2O, CO_2, CO, CS_2, N_2, H_2S, formic acid, and nitrogen oxides). Further, FID destroys the sample material in the detection process.[6] Therefore, if the gas effluent is to be examined further, an effluent splitter is required prior to the FID detector.

Gas Chromatography Columns

Both packed and capillary columns can be used to house the stationary phase for GC. Packed columns offer high capacity and low cost. Packed GC columns are typically used in process laboratories for separating or determining components in a sample, or for gas analysis applications (e.g., for the determination of BTU content in natural gas). Capillary columns offer higher efficiencies, but are generally more expensive. These are used commonly in analytical laboratories when resolution, rather than capacity, is most important (e.g., chiral separations). In capillary chromatography, the stationary phase material is coated on the inner surface of a capillary tube. Hybrids of a sort are the support-coated open tubular and porous layer open tubular (PLOT) columns that use a deposited layer of liquid-coated particles or porous particles on the inner wall of a length of tubing. Column lengths vary from 2 to 3 m for typical packed columns to 25–50 m for typical capillary columns.

Gas Chromatography Stationary Phases

Gas chromatography is often divided into categories based on the type of stationary phase used. Gas–liquid chromatography (GLC) implements a porous, inert solid support that is coated with a viscous, nonvolatile liquid phase. On the other hand, gas–solid chromatography (GSC) uses a solid adsorbent as the stationary phase. Klee offers these general rules-of-thumb for selection of stationary phase materials: use solid adsorbents to separate room-temperature gases, liquid stationary phases to separate room-temperature liquid and solid mixtures, polar phases for polar solutes, and nonpolar phases for nonpolar solutes.[7] Table 1 lists common liquid- and solid-stationary phase materials available for use in capillary columns. Barry cross-refers numerous column materials from nine different manufacturers.[8]

Gas–liquid chromatography

In GLC, separation occurs based on differences in partitioning of the sample components between the carrier gas and the liquid phase. A wide selection of liquid phases makes GLC a versatile separation technique. Further, the liquid phase can be a polymer or a chemically bonded phase. In all cases, the liquid phase is film coated or chemically bonded onto a solid support surface or a column wall. Liquid-bonded phases overcome the problem of leakage of the stationary phase material into the carrier. They are used commonly in LC also, and the process to fabricate

[a]NP, nonpolar; P, polar.

''bonded-phase'' materials is described under the section ''Partition Liquid Chromatography.''

Gas–solid chromatography

In GSC, separation occurs based on differences in the adsorption of the various components in the sample onto the solid adsorbent. While GSC may not offer as much flexibility in stationary phase functionality as GLC, it has its own advantages. For separation applications, advantages include higher available operating temperatures, higher column efficiencies, and no stationary phase leakage.[5] Typical solid phases for GSC include zeolites, silica gel, activated alumina, carbon, carbon molecular sieves, diatomites, and porous polymers.

Separation Applications of GC

Gas chromatography finds routine use as an analytical tool in numerous industries, universities, and government and private laboratories. Gas chromatography is used to separate and identify components of gaseous, liquid, or volatile solid mixtures. For nonvolatile compounds, special techniques can be used to derivatize the sample to a form amenable to GC. Alternatively, nonvolatile samples can be pyrolyzed and their pyrolysis products are separated and analyzed.[5]

Separation applications are far too numerous to list; a few applications that demonstrate the breadth of use are listed. In the petroleum industry, for example, GC is used to separate complex mixtures during exploration, production, and refining of crude oil, and to simulate distillation of petroleum fractions. In clinical medicine and forensic science, GC is used to separate and identify drug compounds in biological fluids and tissues. In environmental laboratories, GC is used to separate and identify chemical compounds in air, soil, and water samples. In food science, GC is used to separate and identify antioxidants and preservatives, among other applications.

LIQUID CHROMATOGRAPHY

In LC, the components of a flowing liquid sample are separated based on differences in the extent to which they are retained by a solid stationary phase. The stationary phase may be packed into a glass, plastic, or metal column or cartridge (column chromatography); alternatively, it can be spread out on a flat glass, plastic, or metal surface (layer chromatography). Fig. 2 illustrates a typical LC instrument used for analytical or laboratory-scale applications; LC systems for continuous, large-scale separations are described under the section ''Modes of Operation.'' A standard setup has a solvent delivery system, a column that performs the separation, a detection system, and a fraction collection system. For low-pressure LC, the solvent delivery system can be a reservoir of mobile phase that drains into the column by gravity flow. For high-pressure (or high-performance) LC (HPLC), the solvent delivery system comprises a solvent reservoir(s), a mechanism for solvent degassing, and a solvent pump. The column is commonly held in a thermostatted chamber to control temperature. Sample components emerge from the end of the column and are

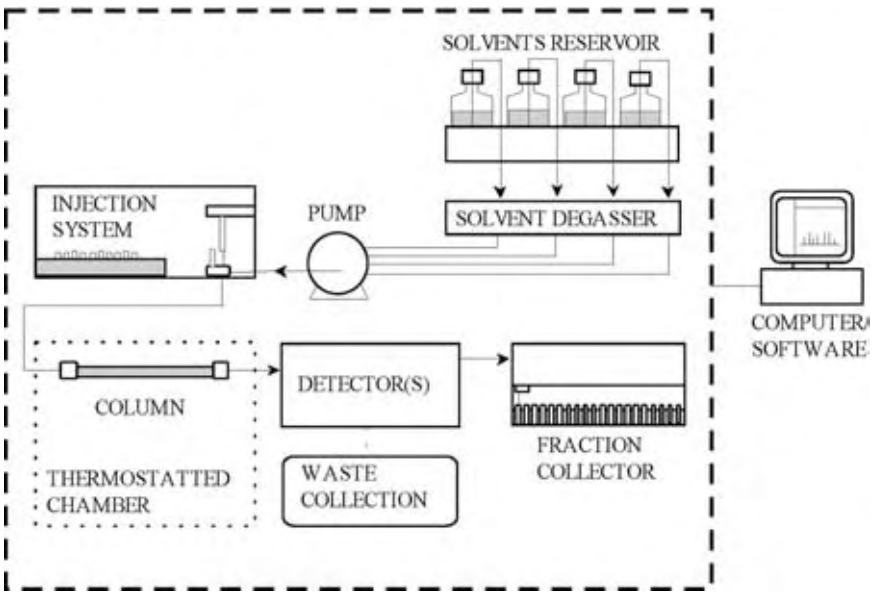

Fig. 2 Schematic illustration of a basic LC system.

monitored by a detector and/or collected in fractions. As with GC, most LC systems now have computer software that controls all aspects of operation and data collection, including operation of automated injection systems and time-dependent programming of temperature and solvent composition.

Detectors for LC

As with GC, numerous detectors have been developed for LC. Each can be categorized as one of two types of detectors: solute property and bulk property. The two most commonly used detectors for LC are the ultraviolet-photometric (UV) detector and the refractive index (RI) detector. Wheals describes these and other common LC detectors.[9]

Ultraviolet-photometric detector

The UV detector is the most widely used detector for LC. It is a solute property detector that is suitable for those solute compounds that absorb radiation in the UV range (~190–400 nm). Ultraviolet-photometric detectors are relatively insensitive to temperature and flow rate fluctuations. The sensitivity to solute detection is high (noise equivalent concentration $\sim 10^{-10}$ g/ml).[9] Ultraviolet-photometric detectors are also well suited to applications that use gradient elution, given that many common LC solvents have low UV absorptivities.

Refractive index detector

Refractive index detectors continuously monitor the difference in bulk RI of the mobile phase and that of a reference mobile phase containing no solute. As such, RI is a bulk property detector. Unlike UV detectors, RI detectors are highly sensitive to temperature fluctuations and somewhat sensitive to flow rate fluctuations.[10] Temperature should be maintained within $\pm 0.001^{\circ}$C for high-sensitivity measurements.[10] Noise equivalent concentration for RI is $\sim 10^{-7}$ g/ml.[9]

Liquid Chromatography Columns

For analytical LC, standard packed columns (4–8 mm I.D.), capillary packed columns (50–100 μm I.D.), and microbore packed columns (0.5–1.5 mm I.D.) are used widely. Column sizes depend on the application, e.g., analytical, preparative, or commercial separations. Special configurations also exist, including membrane chromatography modules (stacks and hollow fibers) that offer lower pressure drops and easier scale-up than packed beds.

Liquid Chromatography Stationary Phases

Gas chromatography achieves separation based on solute partitioning into a thin liquid coating or adsorption onto a solid stationary phase material, whereas LC uses these and other mechanisms to achieve separation. The type of stationary phase and, in some cases, mobile phase determines the mechanism to achieve separation. Descriptions that follow are of the mechanisms and materials used most often.

Absorption (partition) chromatography

Nowadays, liquid stationary phases in LC comprise a liquid material bonded covalently to a solid support material. These bonded-phase materials allow liquid phase partition chromatography without the concern of leakage of the stationary phase into the flowing mobile liquid phase. Partition chromatography offers a wide range of selectivity effects; separations depend on differences among the functional groups in the solutes and also the two liquid phases. The ability to tune the solute selectivity by changing both liquid phases makes partition chromatography particularly well suited for separations that involve mixtures of chemicals from a homologous series.[11]

A common method to prepare bonded-phase materials is to use silica gel as the solid support and to react functionalized organosilanes onto the surface hydroxyl groups of the silica gel. Of course, other solid support materials can be used provided that they present surface functional groups (e.g., OH, COOH, and NH_2) that can participate in modification reactions. The flexibility offered by this approach leads to stationary phase materials with myriad functionalities. Fig. 3 illustrates commonly used organosilane reactants and two example reaction paths that lead to bonded-phase silica. For more discussion on bonded-phase materials, see Ref.[12].

Adsorption chromatography

Adsorption chromatography exploits differences in the relative affinity of solutes for a solid adsorbent used as the stationary phase. Common stationary phase materials for adsorption chromatography are porous silica gel, activated alumina, activated carbon, magnesium oxide, carbonates, and highly cross-linked polymers such as styrene-divinylbenzene and methacrylates.[11] The chemical natures of these adsorbent stationary phase materials make them well suited for separations of solute mixtures that differ in polarity and chemical functionality. For example, silica is an acidic adsorbent that retains basic compounds to a greater extent than nonbasic ones. In contrast, alumina

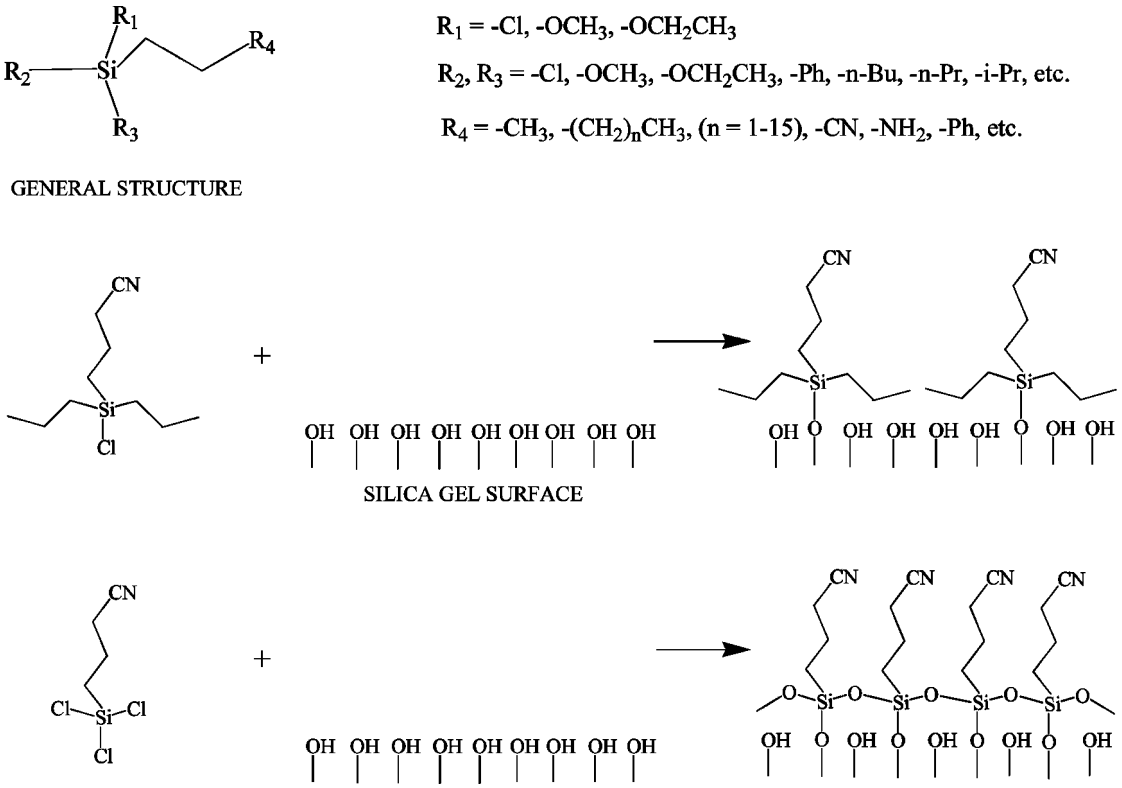

Fig. 3 Chemistries involved in the preparation of bonded phases from organosilane modifiers.

is a basic adsorbent that retains acidic compounds preferentially.

Ion exchange chromatography

Ion exchange chromatography utilizes a reversible chemical reaction as the mechanism to achieve separation. The stationary phase for ion exchange chromatography comprises a charged support, with freely exchangeable counterions. Charged solutes ($M^{\pm}$) in solution become fixed to the stationary phase according to the following ion exchange reaction:

$$M^{\pm} + \left(C^{\pm}R^{\mp}\right)_{solid} \leftrightarrow \left(M^{\pm}R^{\mp}\right)_{solid} + C^{\pm} \qquad (1)$$

In effect, ion exchange chromatography exploits differences in the degree of charge and affinity (measured by the reaction equilibrium constant or molar selectivity coefficient) of ions in solution for sites of opposite charge in the stationary phase to accomplish separation.

Depending on the ionic charge(s) of the solutes to be separated, anion or cation exchange stationary phases must be used. Common ion exchange support materials include silica, poly(styrene-divinylbenzene), and cellulose. Common anion exchange groups anchored to these supports include 1°, 2°, 3°, and 4° amines. The latter results in a strong anion exchange phase. Common cation exchange groups are carboxylic and sulfonic acids. The latter produces a strong cation exchange phase.

Ion exclusion and ion pair chromatography also exploit differences in solute charge to accomplish separation. In ion exclusion, fully dissociated compounds are restricted from accessing the stationary phase pores caused by Donnan exclusion, thereby eluting at the column void volume, whereas nondissociated compounds have full access to pore volume. Ion pair chromatography uses an ion exchange compound in the mobile phase, along with a nonfunctionalized poly(styrene-divinylbenzene) stationary phase to accomplish separation of solute ions of opposite charge. (For details on ion exchange, ion exclusion, and ion pair chromatography, see Weiss in ''Bibliography.'')

Size exclusion chromatography

Size exclusion chromatography (SEC) separates molecules based on differences in their hydrodynamic volume (or size). For this reason, SEC has become a standard technique for determining molecular weight distributions of polymer samples. Common separation applications include polymer, protein, and nucleic

acid separations; plasmid purification; and polysaccharide fractionation. When applied to organosoluble polymers (e.g., polystyrenes, polyurethanes, and polysiloxanes), SEC is often called gel permeation chromatography; when applied to water-soluble polymers and biopolymers (e.g., polyacrylamide, proteins, peptides, and oligonucleotides), it is sometimes called gel filtration chromatography (GFC). Size exclusion chromatography can be performed at high temperatures (>200°C) for the analysis of compounds that are only sparingly soluble at room temperature, including high molecular weight polymers.

The column packing in SEC comprises porous, spherical gel beads with a defined pore size distribution. Most often, these beads are made from poly(styrene-divinylbenzene). (For GFC, cross-linked dextran and agarose gels are often used.[13]) The sample is dissolved in a suitable solvent that is often used as the mobile phase as well. Separation occurs as a result of differences in accessibility of pore volume. Small molecules can freely access the whole pore volume; as a result, the column retards these molecules the greatest. As molecular volume increases, less and less pore volume is accessible for molecules to sample, and elution times decrease. For all molecules with hydrodynamic volumes that are too large to penetrate into the pores of the packing, elution occurs at the (interstitial) void volume of the column. The retention volume for each solute can be described mathematically as:

$$V_R = V_0 + KV_P \quad (2)$$

where V_R is the retention volume, V_0 is the void volume, V_P is the pore volume, and K is a distribution constant. In SEC, the distribution constant is defined as the ratio of the average concentration of the solute in the pores to that in the interstitial volume. For systems where separation is based on hydrodynamic volume only, i.e., no enthalpic interactions between solute and packing, values for K are bound between 0 and 1. Small molecules have $K = 1$, whereas large molecules that cannot penetrate into the pore volume have $K = 0$ (see Fig. 4). (For details on SEC see Mori and Barth in ''Bibliography.'')

Affinity chromatography

Affinity chromatography is a form of adsorption chromatography, wherein the solid support surface has been functionalized with an immobilized compound (ligand) that complements the solute (ligate) to be separated from a complex mixture.[13] It is an important technique for difficult biological separations. Here, it exploits the unique ability of proteins to specifically bind molecules noncovalently.

A common solid support is functionalized agarose beads, which provide high capacity, low nonspecific solute binding, and high stability.[13] The ligand (e.g., a protein, nucleic acid, biopolymer, etc.) is anchored covalently to the support matrix using well-developed coupling chemistries. A solution containing the protein of interest is flowed past this affinity stationary phase, whereby the protein binds to the tethered ligand. After this step, the protein is recovered from the stationary phase by displacement with a wash solution. Displacement can be done by adding free ligand to the wash solution, or by changing its pH,

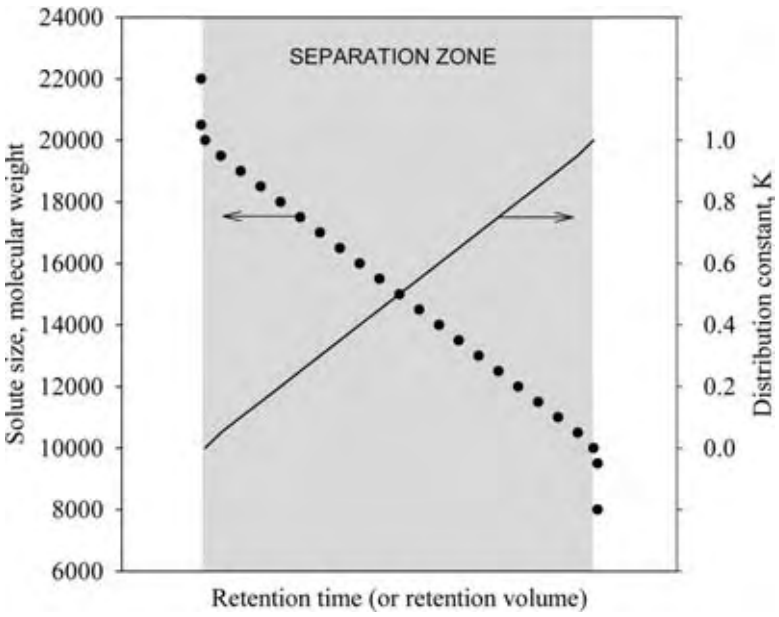

Fig. 4 Illustration of an SEC calibration curve. High-MW molecules that have $K = 0$ and low-MW molecules that have $K = 1$ pass through the column with no separation. For molecules that have $0 < K < 1$, size-based separation occurs.

ionic strength, or temperature relative to the initial protein solution.

Mobile Phase Selection for LC

Selection of a mobile phase for LC is more difficult than for GC. In LC, solute interactions with the mobile phase affect solute retention dramatically. The goal is to optimize the interactions between the solutes and the mobile phase and the solutes and the stationary phase to accomplish separation. If the solutes are to be separated based on differences in polarity, then a common approach is to use a polar stationary phase with a less polar mobile phase; this approach is termed normal-phase chromatography. If the solutes are to be separated based on differences in polarizabilities, then a common approach is to use a nonpolar stationary phase and a polar mobile phase; this approach is termed reverse-phase chromatography.

Practically speaking, the mobile phase should not degrade the stationary phase, should have adequate solvency for the solute mixture, and should not interfere with product recovery in preparatory or commercial separations.[14] For guidelines on solvent selection for partition and adsorption LC, see Refs.[12,14,15]. (For guidelines in ion chromatography see Weiss in ''Bibliography.'')

Gradient Elution

Gradient elution refers to the use of a mobile phase that changes composition during separation. As such, gradient elution is actually a displacement development technique whereby the solvent strength is increased gradually from the start to the end of separation. Solutes that are held weakly to the stationary phase elute from the column in the early stages when the mobile phase solvent strength is low. More strongly held solutes are eluted by mobile phase with high solvent strength. After separation, the stationary phase must be washed before it is reused to flush away the last part of the mobile phase gradient. For ion exchange chromatography, solvent strength can be altered by solvent composition, temperature, ionic strength, and pH.

MODES OF OPERATION

Batch Operation

The commonly used elution and displacement chromatography process techniques use batch operation, wherein a pulse of the mixture to be separated is loaded onto the inlet of the chromatography column. For this reason, batch operation is suitable for small-scale separations. For scale-up to high-volume separations, continuous modes of operation are used typically.

Continuous Operation

Continuous modes of LC are based on the frontal analysis process technique, whereby the mixture to be separated is introduced to the chromatography column as a step change, rather than a pulse. The inherent difficulty for continuous operation is that the stationary phase has a finite capacity that becomes saturated after relatively few bed volumes of liquid have passed.[3] Also, in nearly all cases, the stationary phase must be regenerated for reuse. To achieve continuous operation, the stationary phase must pass through a loading zone, then through a regeneration zone, subsequently back through the loading zone, and so forth. Two options exist for moving the solid stationary phase through these loading and regeneration zones: physically moving the solids (moving bed) and simulating the movement of the solids by changing the locations of the feed and regenerant entry points (simulated moving bed).

Moving-bed operation

Humphrey and Keller note that few successful moving-bed systems have been in operation for liquid systems.[3] Most moving-bed systems fail owing to stationary phase attrition, equipment erosion, and difficulty in achieving plug flow of the solid and liquid phases.[3] Nevertheless, two continuous moving-bed contactors have been used successfully for ion exchange separations: the Higgins contactor and the Himsley fluidized-bed process. The reader is directed to Ref.[11] for more discussion on these contacting devices.

Simulated moving-bed operation

To overcome problems associated with moving solid stationary phase materials, SMB operation fixes the location of the stationary phase and changes the feed and regenerant entry points and the raffinate and product removal points with time. Single- and multicolumn SMB systems are in use. Humphrey and Keller[3] instruct that the single-column system is favored economically when processing feed flows over $\sim$50 million lb/yr, while the multicolumn system is favored for processing lesser feed amounts.

A commercial example of the single-column SMB system is the Sorbex technology of UOP. Table 2 lists

Table 2 Commercial technologies based on UOP Sorbex Technology

Process name[a]	Separation
Parex™	*p*-Xylene from mixed C8 aromatics
Ebex™	Ethylbenzene from mixed C8 aromatics
MX Sorbex™	*m*-Xylene from mixed C8 aromatics
Molex™	Linear paraffins from branched/cyclic hydrocarbons
Olex™	Olefins from paraffins
Cresex™	*p*-Cresol or *m*-cresol from other cresols
Cymex™	*p*-Cymene or *m*-cymene from other cymenes
Sarex™	Fructose from mixed sugars

[a]Trademarks of UOP LLC.

examples of commercial processes licensed by UOP that utilize the Sorbex technology.

In a multicolumn SMB system, the stationary phase is distributed among a number of separate columns that are connected to one another and to lines that introduce feed and regenerant and that recover products. A commercial example of a multicolumn SMB system is the ISEP Continuous Contactor from Advanced Separation Technologies, Inc., in which a series of stationary phase columns rotate on a carousel that delivers them to loading and regeneration zones. For more discussion and illustrations of single- and multicolumn SMB systems, see Ref.[3]. (For further discussion on preparative and production-scale chromatography see Ganetsos and Barker in ''Bibliography.'')

INTRODUCTION TO CHROMATOGRAPHIC SEPARATION THEORY

Consider a closed system comprising two phases and two solutes as illustrated in Fig. 5. When the number of moles of solute in each phase becomes ''statistically'' constant, then the system is in equilibrium. The term ''statistically'' was introduced to emphasize that equilibrium is a dynamic state in which molecules move back and forth between the two phases. At equilibrium, a distribution constant (or partition coefficient) can be defined as

$$K = \frac{c_S}{c_M} = \frac{\text{Molar concentration in stationary phase}}{\text{Molar concentration in mobile phase}} \quad (3)$$

The units of concentration in Eq. (3) are typically moles per volume. However, in some cases (e.g., with capillary columns), it is more convenient to express concentration of solute in the stationary phase in units of moles per mass of stationary phase, rather than per volume.[16]

A second way of defining the distribution constant results from considering a single solute molecule. Under the conditions of dynamic equilibrium, this single molecule spends some of its time in each phase. The time spent in the stationary phase relative to the time spent in the mobile phase is also given by the distribution constant. This definition forms the basis of the chromatography theory.

Fig. 5 illustrates a physical model of the chromatography process. Initially, there is a dynamic equilibrium of molecules between the phases. Then, one phase is moved relative to the other with an average velocity, v. In the stationary phase, molecules do not move; while in the mobile phase, molecules move with a velocity equal to v. Provided that the interphase mass transfer rate is fast relative to the flow rate of the mobile phase, the time-average distribution of a molecule between the phases is statistically equal to the equilibrium distribution as determined by the distribution constant.

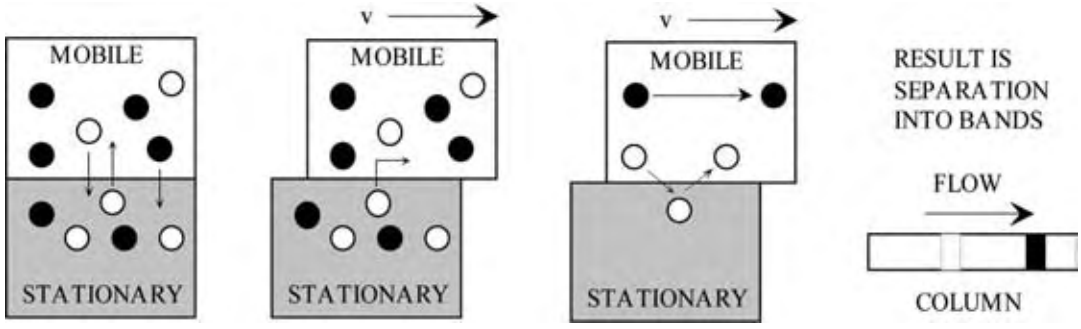

Fig. 5 Model of the physical process used to separate mixtures by chromatography.

With the time-average distribution equal to the equilibrium distribution, the fraction of time spent by a particular molecule in the mobile phase, τ_i, can be evaluated mathematically as

$$\tau_i = \frac{V_M}{V_M + K_i V_S} \quad (4)$$

where V_M is the volume of the mobile phase, K_i is the distribution constant of component i (based on a molar concentration per volume of stationary phase), and V_S is the volume of the stationary phase.

As the molecule is immobile during its time in the stationary phase, it will move down the chromatographic column with an effective velocity given as

$$u_i = \tau_i v \quad (5)$$

where u_i is the effective velocity of component i and v is the average velocity of the mobile phase. Therefore, if two solutes have different distribution constants, they will move down the length of the column with different effective velocities. The solutes will elute from the column in discrete bands. In a real system, many molecules are present, and these will disperse about an average value. For components with linear adsorption isotherms, the result for each component approximates a Gaussian distribution whose width depends on the molecular dispersion of that component.[17]

Calculating the Distribution Constant from the Chromatogram

With a suitable detector placed at the exit of the column, the concentration of solute in the mobile phase can be monitored continuously. A plot of the concentration vs. time is called a chromatogram. Fig. 6 shows a typical chromatogram.

The time at which a peak appears in the detector response is called the retention time of the solute; it is the time it takes a given solute to travel the length of the column. For a Gaussian peak distribution, the retention time corresponds to the peak center. Mathematically, the retention time of component i is simply

$$t_{Ri} = \frac{L}{u_i} \quad (6)$$

where L is the column length. If a compound does not partition into the stationary phase, then it will travel down the length of the column with a velocity equal to the mobile phase. The time that it takes this unretained compound is called the holdup time, and is defined as

$$t_0 = \frac{L}{v} \quad (7)$$

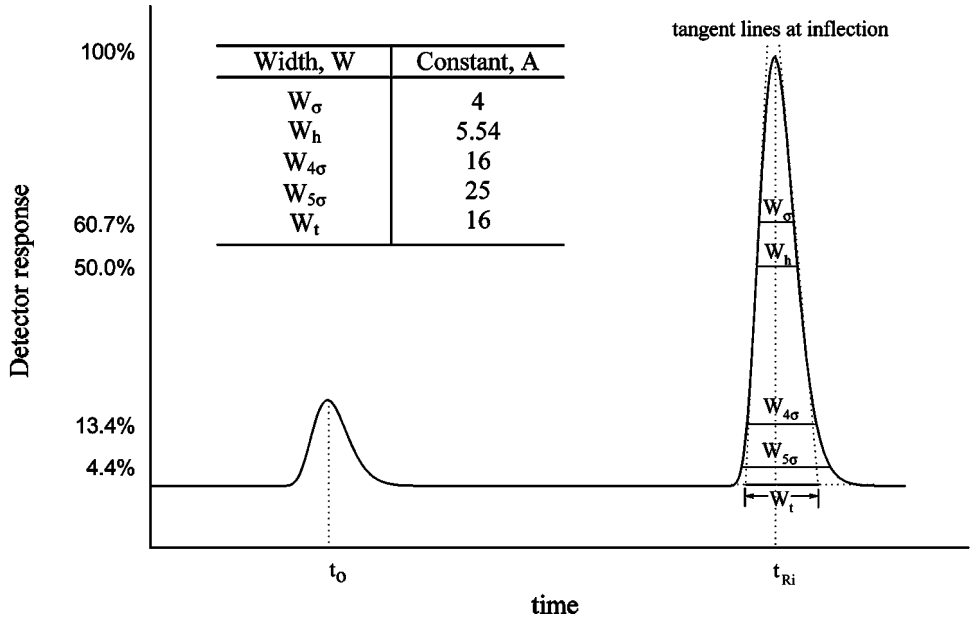

Fig. 6 Chromatogram for a two-component mixture with Gaussian responses. The small peak represents an unretained compound. The large peak is used to illustrate common definitions of peak width.

Combining Eqs. (4)–(7), the distribution constant for a given solute i is given as

$$K_i = \frac{V_M}{V_S}\left(\frac{t_{Ri} - t_0}{t_0}\right) \quad (8)$$

The ratio in brackets is called the capacity factor, k; it is used commonly as a measure of the ability of the stationary phase to retain a solute. Using Eq. (8), the distribution constant of component i can be calculated from readily measurable quantities.

To standardize reported retention times for a given column, manufacturers often report adjusted or relative retention factors rather than distribution constants. The adjusted retention time of a given compound is reported relative to the retention time of an unretained component. The relative distribution coefficient is reported relative to the distribution coefficient of a reference compound:

$$t'_{Ri} = t_{Ri} - t_0 \quad (9)$$

$$K'_i = \frac{K_i}{K_{i,REF}} = \frac{t'_i}{t'_{i,REF}} \quad (10)$$

Column Efficiency

Column efficiency refers to the amount of band broadening that occurs when a compound passes through the column. The typical Gaussian shape of the chromatographic band results from the random motions of the molecules making up the band as it moves down the column. The result of these random individual motions is a symmetric spread of velocities around the mean value. This spreading is referred to as molecular diffusion.

Chromatodiffusion also contributes to this band broadening. At the center of a component band, the chemical potential of that component is high. At the edges of the band, it is low. There is a net diffusion of molecules from the center of the band to the edges because of this chemical potential difference.

Nonuniform column packing also affects band broadening. Different molecules travel along various paths through the column. Depending on the length of their respective path, two molecules of the same component will have varying retention times.

The plate height concept applied to chromatographic separations

A good chromatographic method will usually produce peaks with adequate separation and symmetry to allow the user to treat all peaks as Gaussian distributions. This treatment leads to a simple definition of the number of theoretical plates for a given separation.[5]

$$N_i = A\left(\frac{t_{Ri}}{W_A}\right)^2 \quad (11)$$

where N_i is the number of theoretical plates for the separation of species i, W is the width of the peak in time units, and A is a constant based on the definition of W. Fig. 6 summarizes the common definitions of W, along with the corresponding value of the constant A.

From the usual definition of equilibrium-staged separations, the plate height is calculated as $H = L/N$. The efficiency of chromatographic columns increases as the number of plates increases and as the plate height decreases. Both of these values are used widely in the literature as measures of column performance.

Effect of velocity on plate height

Some of the variables that affect column efficiency can be controlled to improve separations. The extent of band broadening, and thus column efficiency, depends on the amount of contact time between the mobile and stationary phases. Therefore, column efficiency depends on the flow velocity of the mobile phase. Plots of plate height vs. velocity are called van Deemter curves. The plots are fit to the van Deemter equation

$$H = A + \frac{B}{v} + Cv \quad (12)$$

where the constants A, B, and C are dependent on uniformity of packing, molecular diffusion, and chromatodiffusion, respectively. (For capillary columns, $A = 0$.) Fig. 7 shows typical van Deemter curves for GC and LC.

For LC, the second term in Eq. (12) is often negligible because liquid diffusion coefficients are low ($\sim 10^5$ times lower than for gases). Furthermore, for LC, the parameter A depends on v, and A and C are coupled.[18] For these reasons, LC plate heights increase with velocity for all reasonable operating values of v. One might be tempted to use low velocities in LC to achieve low plate heights; however, lower velocities translate into longer retention times.

For GC, the optimum velocity corresponds to the minimum plate height, which occurs at $v = (B/C)^{1/2}$. The first term in Eq. (12) is independent of velocity and depends only on how efficiently the column is packed. To obtain a small H and, thus, efficient separation, uniform packing is essential.

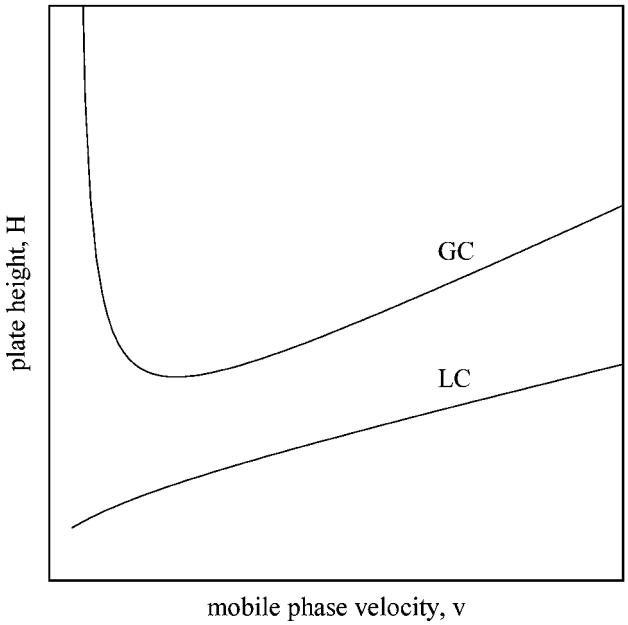

Fig. 7 Typical van Deemter plots for GC and LC.

Column Resolution

The resolution R_s of a column describes the ability to separate two compounds, 1 and 2; assuming that both peaks can be treated as Gaussian distributions, a resolution can be calculated:

$$R_S = \frac{2(t_{R1} - t_{R2})}{W_1 + W_2} \quad (13)$$

In Eq. (13), W_1 and W_2 are measured at the base of each peak. For Gaussian peak distributions, these widths equal 4σ, and a column resolution of 1.0 means that there is 4.6% overlap of peak 1 in peak 2 and vice versa; a resolution of 1.5 means there is 0.3% overlap between the two peaks. Generally, the resolution for a given separation can be increased by lengthening the column and, thus, increasing the number of theoretical plates. Here again, the trade-off for this increased resolution is a longer retention time.

Effect of the distribution constant on resolution

Given information about the distribution constants for two solutes, the column length necessary to provide a given resolution between them can be calculated, with reasonable assumptions, from the definition of resolution.[17]

$$L = 16R_S^2 H\left(\frac{K_2/K_1}{K_2/K_1 - 1}\right)^2\left(\frac{1 + k_2'}{k_2'}\right)^2 \quad (14)$$

The result demonstrates that the distribution constants of 1 and 2 must have different values for separation to occur. If they were exactly the same, then resolution would have to be zero.

Asymmetric Peak Distributions

Real chromatographic peaks generally have some degree of asymmetry. For asymmetric peaks, it is a mistake to use equations based on the Gaussian distribution function to calculate peak parameters. More accurate functions are available for use with asymmetric peaks, including the commonly used exponentially modified Gaussian function (EMG). Di Marco and Bombi present tabulated information on empirical functions for characterizing chromatographic peaks.[19] Foley and Dorsey give relations between the measurable retention time, peak width, asymmetry factor, and chromatographic figures of merit, including the number of theoretical plates, for the EMG model.[20]

CONCLUSIONS

Chromatography is used both as an analytical method and an industrial unit operation to separate and/or identify the chemical components in complex mixtures. Its basis is the partitioning of solutes between a moving fluid phase and a stationary phase. The fluid phase can be either a gas or a liquid, while the stationary phase is either a solid or a liquid applied to a solid substrate.

Coal–Water Slurries

S. Komar Kawatra
Department of Chemical Engineering, Michigan Technological University, Houghton, Michigan, U.S.A.

INTRODUCTION

A slurry is defined as a fluid mixture of a pulverized solid with a liquid, usually water.

The term ''coal slurry,'' therefore, includes all mixtures of coal and water that can flow as a fluid. There are four main types of high-percent-solid coal slurries discussed in the literature, with different characteristics depending on the application:

1. *Coal–water slurry fuels*: High-percent-solid slurries that are stable against settling, so they can be pumped, stored, handled, and burned much like heavy fuel oil. Coal–water fuels have about half the heating value of fuel oil, and because of their water content they burn cooler than pulverized coal, leading to lower production of nitrogen oxides.

2. *Coal slurry pipelines*: Slurry is used for transporting the coal through pipelines, but the coal is dewatered at the end before utilization. The slurry is unstable, and the particles are kept in suspension by the turbulence of the flow as they travel through the pipeline. The particles rapidly settle out of suspension once the slurry stops moving.

3. *Gasifier feedstock*: Integrated gasification/combined cycle (IGCC) plants use coal slurry as their feedstock. This simplifies transport of the coal and provides the water needed along with the coal in the gasification reaction. The slurries used must flow and atomize well in the reactor, but do not need to have long-term stability against settling.

4. *Coal slurry waste*: This is fine coal processing tailings that contain a significant amount of coal and enough water so that they can flow. These slurries can be processed to recover fine coal particulates, or disposed of in tailings impoundments. These slurries can easily flow over large areas and cause considerable damage if the impoundment dam breaks. Coal slurry wastes are very high-percent solids and are described as having ''about the consistency of molasses.''

The properties of coal slurries that are of most interest are: 1) the viscosity/rheology, which controls the ease of pumping and atomization; 2) the stability against settling, which controls the ability of the slurry to be stored in tanks without the solids forming a hard mass that clogs the system; and 3) the solid concentration and coal type/composition, which determines the heating value per unit volume of slurry.[1]

Of the four applications for coal slurries given here, coal slurry fuels have the most stringent requirements. Hence, the following discussion of slurry properties is with reference to coal slurry fuels.

RHEOLOGY OF COAL SLURRIES

There are two competing considerations for the flow properties (rheology) of coal-water slurry fuels. The first is that the slurry must have a low viscosity (preferably less than 2000 centipoise) at high shear rates so that it can be pumped and atomized readily.[1] The second is that it should be sufficiently viscous so that the particles will not settle out during storage, as otherwise the settled solids will clog the pipes leading from the storage tank. There are two factors that contribute to prevention of slurry settling: development of a yield stress and thixotropy.

In a slurry that develops a yield stress, the slurry does not begin to flow until a particular level of shear stress is applied to it. These types of slurries are classified as either pseudoplastic with yield, or Bingham plastic, as shown in Fig. 1. Pseudoplastic and Bingham plastic slurries have a high apparent viscosity (ratio of the shear rate to the shear stress) at low shear rates, but at higher shear rates the apparent viscosity decreases. Coal slurry rheology can generally be modeled using Herschel and Buckley's yield-power law:[2]

$$\tau = \tau_0 + K\gamma^n$$

where τ is the shear stress (in Pa), τ_0 is the yield stress required to initiate slurry flow (in Pa), γ is the shear rate (sec^{-1}), n is the flow behavior index (equals 1 for Newtonian slurries, <1 for pseudoplastic slurries, and >1 for dilatant slurries), and K is the consistency number (equal to the apparent viscosity for Newtonian slurries).

Slurries that exhibit a yield stress will resist settling when stationary, which is a low shear condition, but

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120008028

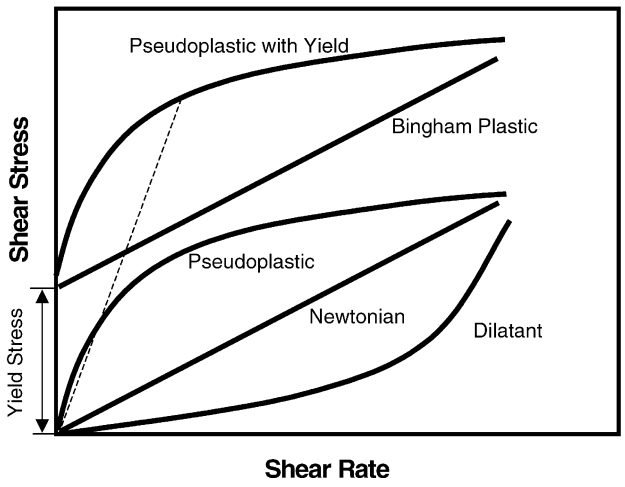

Fig. 1 Classes of rheological behavior that can be shown by coal slurries, as they appear when plotted on a shear rate/shear stress graph. It is desirable for coal slurries to be Bingham plastic or pseudoplastic with yield, as such slurries flow readily at high shear rates (such as during pumping or atomization), while remaining stable against settling at low shear rates because of their yield stress. Dilatant slurries are completely unsuitable for coal slurry applications because they are extremely difficult to pump.

will flow readily when a higher shear force is applied, such as by a pump or an atomizer.

In a thixotropic slurry, the slurry will, when left undisturbed, develop a three-dimensional network structure where particles attach loosely to each other in an extremely weak gel. This holds the solid particles suspended indefinitely. The shear stress required to cause the thixotropic slurry to flow can then be broken into two parts:[3]

$$\tau = \tau_e + \tau_s$$

where τ is the total shear stress (in Pa) required to produce slurry flow, τ_e is the equilibrium shear stress (in Pa) reached after agitating the slurry for an extended time, and τ_s is the structural shear stress (in Pa) resulting from the formation of the structural network.

The structure can then be broken up by stirring, so that the slurry can be refluidized to a free-flowing state. The structural shear stress of the thixotropic slurry decreases with time during agitation according to the following expression:[3]

$$d\tau_s/dt = [\tau_{s\infty} - \tau_s]/\lambda_s - K\eta^{1/2}\gamma\tau_s$$

where $d\tau_s/dt$ is the rate of change of structural shear stress with respect to time, τ_s is the structural shear stress (in Pa), η is the apparent viscosity (in Pa sec), γ is the shear rate (sec^{-1}), $\tau_{s\infty}$ is the final structural shear stress achieved under shear-free conditions, λ_s is the time constant for buildup of structural stress, and K is the proportional constant for the rate of structure breakdown.

Solid Loading

The rheological properties of coal slurries depend on the quantity of solids suspended in the liquid and on the physical and surface chemical properties of the solid particles. The viscosity of the slurry will typically increase gradually with increasing solid loading until a critical point is reached where interparticle friction becomes important. Beyond this point, the viscosity will rapidly increase until the slurry ceases to flow, as shown in Fig. 2. The value of the critical solid loading will vary considerably between coal slurries, depending on the physical and chemical properties of the particles. For most coal slurries, and particularly for coal–water slurry fuels, it is important to be able to make the solid loading of the slurry as high as possible so that the energy content per liter of fuel is maximized, while keeping the viscosity low enough so that the slurry can be pumped economically.

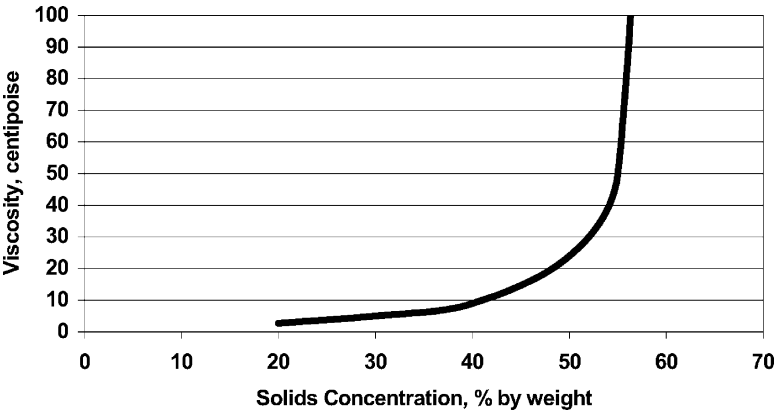

Fig. 2 Effects of solid concentration on the viscosity of a particular coal slurry. Beyond a certain limiting concentration, the viscosity rapidly increases to extremely high values. (From Ref.[4].)

Particle Size Distribution

The size distribution of particles will control the amount of liquid needed to fluidize a given quantity of coal. In general, a fine size distribution will produce a more viscous slurry than a coarse size distribution at the same wt% solids, and the fine particles will produce a more non-Newtonian rheological curve. This can be seen in the laboratory results shown in Fig. 3, which compares a coarse coal slurry to a fine coal slurry. It is clearly seen that the fine slurry is much more viscous, its pseudoplastic character is very pronounced, and its yield value is high, while the coarse coal slurry is clearly a Bingham plastic.[5]

A graded size distribution, where fine particles fill the interstices between coarse particles as shown schematically in Fig. 4, will minimize the amount of void space that must be filled by fluid, and so will reduce the quantity of liquid needed to produce a flowable slurry. The best size distributions for this purpose have proven to be multimodal distributions, made up of several fairly narrow size fractions. An example of such a size distribution is shown in Table 1.[1] To achieve such a multimodal size distribution, coal slurry production facilities are designed to generate several coal streams, which are each ground and sized to the desired particle sizes and then combined to give the proper size distribution.

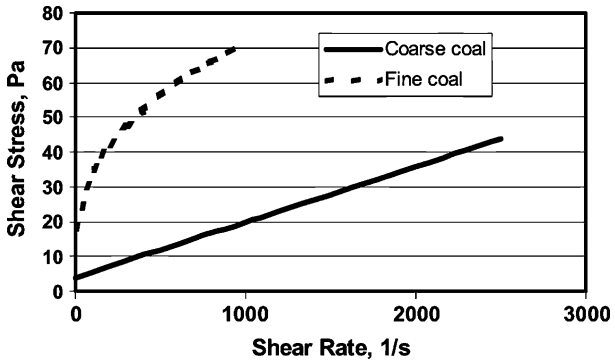

Fig. 3 Comparison of the rheological curves for a fine coal slurry (80% passing 34 μm, top size 100 μm, 52 wt% solids) and for a coarse coal slurry (58 wt% solids). Neither slurry used any additives. Because it is extremely difficult to measure the rheology of unstable slurries with conventional rheometers, these results were obtained using a continuous-pressure-vessel rheometer, which was specially designed for this purpose. The fine coal curve is the average of 10 measurements and the coarse coal curve is the average of 5 measurements, and the standard error of the shear rate measurements was approximately 1.0 Pa for these slurries. The fine coal slurry is clearly pseudoplastic with a yield value of approximately 18 Pa, while the coarse coal slurry is Bingham plastic with an estimated yield value of 4 Pa.

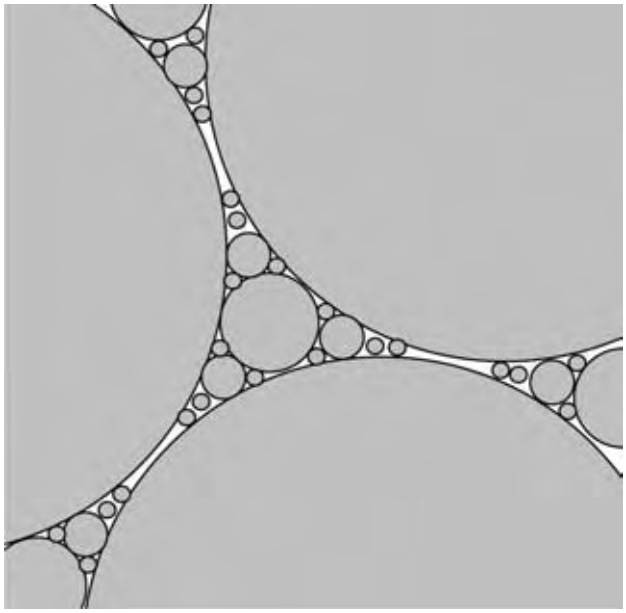

Fig. 4 Graded size distribution to maximize the packing fraction of ideal spherical particles, and thereby minimize the amount of water needed to fluidize the slurry. In this illustration, there are four different sizes of particles present. A similar principle will maximize the packing fraction of real, irregularly shaped particles.

An example of how slurry rheology is affected by combining a ''coarse'' size distribution (208–279 μm) with a ''fine'' size distribution (smaller than 45 μm) can be seen in Figs. 5 and 6. Adding increasing amounts of coarse particles made the suspensions examined less viscous until approximately 40% of the solids were coarse particles. Increasing the proportion of coarse particles beyond that level produced no further viscosity decrease and tended to destabilize the slurry so that the particles would rapidly settle out.[6]

Surfactants and Dispersants

The interparticle friction in the slurry can be reduced through the use of surface-active reagents (surfactants). The surfactants, therefore, alter the viscosity and overall rheology of the slurry. It is important to

Table 1 Example of a multimodal size distribution to produce a very high solid loading in a coal slurry (This results in a powder with only 24% pore volume)

Size fraction (μm)	Total solids by weight (%)
701–833	60
88–104	30
38–43	8
<25	2

(From Ref.[1].)

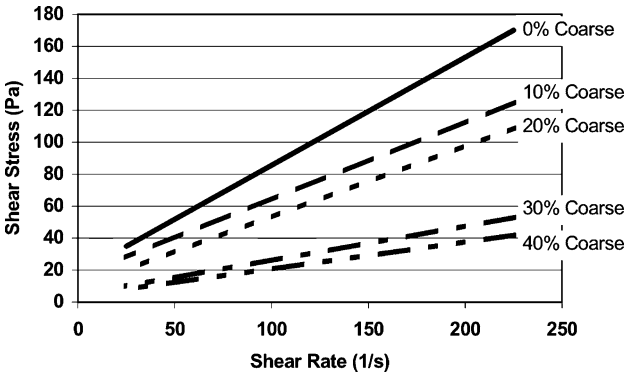

Fig. 5 Changes in the rheology of 40 wt% coal suspensions as the proportion of coarse particles (208–279 μm) to fine particles (<45 μm) is increased. As the fraction of coarse particles increases, the viscosity drops and the yield stress is decreased. (From Ref.[6].)

remember that coal is not a single tightly defined substance. It covers a wide range of fossilized high-carbon solids, which vary a great deal in composition, heating value, and chemistry. High-rank, high-volatile coals tend to be more hydrophobic than low-rank or low-volatile coals, which contain larger quantities of moisture and oxygen in their structure. It is therefore critical that the surfactants used be selected to match the properties of the coal being used for the production of the slurry, as surfactants that are highly successful in one application may be largely ineffective in another.

Because of their structure and chemistry, surfactants are chemicals that tend to concentrate at surfaces in preference to dissolving in the volume of the liquid. They can, therefore, be used to selectively alter the surfaces of particles, changing the way they interact with each other.

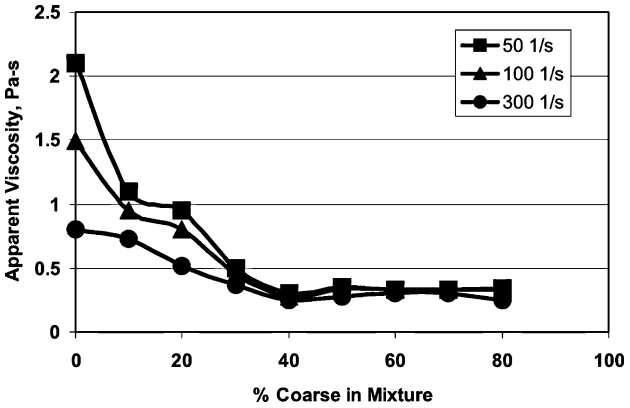

Fig. 6 Apparent viscosity of a 50% solid coal slurry as the proportion of coarse particles (208–279 μm) to fine particles (<45 μm) is increased, at three different shear rates. The viscosity was minimized at 40% coarse particles. (From Ref.[6].)

In the case of coal particles suspended in water, there are two effects that control interparticle interactions: hydrophobic properties and electrical charge effects. Strongly hydrophobic coal particles will tend to flocculate because of the reduced surface energy of a coal–coal interface compared to a coal–water interface. Surfactants that increase hydrophobicity will therefore tend to increase viscosity owing to increased interparticle interaction. The electrical charge on the particle surfaces, which arises by ion exchange with the fluid, will also affect the viscosity. A low magnitude of charge, within approximately ±5 mV of zero net charge, will allow particles to interact and flocculate readily, resulting in a high viscosity and significantly non-Newtonian behavior. A high magnitude of charge, exceeding –20 mV, will cause particles to repel each other, minimizing flocculation and reducing viscosity.

There are hundreds of different surfactants that have been considered for control of coal slurry rheology. The majority of these reagents fall broadly into the three classes described in Table 2: anionic surfactants, nonionic surfactants, and polysaccharides. Anionic surfactants are those that have a negative charge in solution. When they adsorb on the coal surface, they provide it a net negative charge, which increases interparticle repulsion. Nonionic surfactants and polysaccharides have no net charge in solution and are believed to form a more physical barrier that prevents particles from interacting with each other.

Other Factors Affecting Rheology

The rheology of a coal-water slurry is also affected by the composition of the coal. It has been determined that increases in coal ash content lead to increasing viscosity and that slurries are more viscous at pH 6 than at pH 8.[7] Many coals, particularly low-rank or partially oxidized coals, contain humic acids, which act as surfactants and can affect the properties of the slurry.[8] The presence of these humic acids helps to decrease slurry viscosity and increase the maximum particle loading. Additionally, the viscosity is affected by the temperature of the slurry, with increasing temperature tending to decrease the slurry viscosity. It has also been reported that high shear agitation can reduce the viscosity of the coal slurry, apparently by improving the dispersion of surfactants.[9]

APPLICATIONS OF COAL SLURRIES

Slurry Fuels

As petroleum-based fuels are being depleted, it is expected that coal-derived fuels such as coal slurry

Table 2 Types of surfactants that have been used for preparing highly concentrated coal-water slurries: Many of these surfactants are used in combination with formulations that depend on the characteristics of the coal

Anionic surfactants	Nonionic surfactants	Polysaccharides
Ethylene diamine tetra-acetic acid (EDTA)	Polyethylene glycol ethers	Carboxymethyl cellulose salts
Calcium lignosulfonate	Polypropylene glycol	Cellulose
Ammonium lignosulfonate	Ethoxylated/propoxylated alcohols	Wood particles
Sodium lignosulfonate	Alkylphenyl decaethylene glycol ether	Uronic acid
Sodium tripolyphosphate	Polyethyleneimine	Hydroxypropyl cellulose
Polyalkylene oxide	Propylene oxide polymers	Polysaccharose (produced by lipomyces micro-organisms)
Polysodium styrene sulfonate	Ethylene oxide polymers	
Polyacrylic acid	Phenol butyl naphthalene polymers	Cellulose ether
Sodium allyl sulfonate	Methacrylic acid polymers	
Polyacrylamide	Butyric acid lauryl ethylene diamine salt	
Polyoxyethylene nonyl phenol ether		
Polyvinyl sulfonic acid		
Sulfonated benzene sodium salt		
Naphthalene sulfonic acid		
Tallow soap		
Isobutylene		
Maleic anhydride		
Sodium humate (extracted from brown coal)		

(From Ref.[1].)

fuels will become more important. These fuels are attractive mainly because they are made from coal, which is of low cost compared to petroleum products, and can be pumped, stored, and burned much like fuel oil. The demonstrated coal reserve base in the United States is 508 billion tons, with predicted reserves as high as 1.7 trillion tons.[10] At the current rate of consumption (approximately 1 billion tons/year) this would last for 500–1700 yr, which means that coal, and therefore coal slurry fuels, will be available long after petroleum deposits are depleted. Most of the activity in coal slurry fuel development has used highly cleaned high-rank coals, which can be produced using advanced physical, chemical, and biological techniques to remove ash-forming minerals and sulfur.[11] In addition, processes have been developed to upgrade low-rank coals so that they can be used to produce coal slurries with a high heating value.[12]

Coal slurry fuel production plants have been constructed for producing coal-water slurry fuels. These plants consist of facilities for grinding highly cleaned coal to the desired fineness, adding stabilizing reagents, and increasing the solid content of the slurry to approximately 65–70% solids by weight. A schematic of a typical plant is shown in Fig. 7. The key design features of such a plant are:

1. *Particle size control*: The plant pictured produces a multimodal size distribution, consisting of relatively large particles from the first stage of grinding, an intermediate size of particles from the second stage of grinding, and particles from the hydrocyclone oversize product that are reground to a very fine size when they are returned to the second grinding stage.

2. *Water content control*: Grinding and size classification of the coal require a slurry with considerably more water than is desired in the final fuel. Hence, filters must be used to remove this excess water once the particles reach their target size.

3. *Reagent addition*: Before the reagents are added, the material coming from the drum filter will be extremely viscous. Pug mills, which can handle a very high solid content, are, therefore, used to combine the reagents with the coal slurry both to combine the desired particle size fractions and to uniformly disperse the reagents through the coal.

Coal slurry fuels are of interest for the following markets:

Replacement of Heavy Fuel Oil: The original concept for coal-water slurry fuels was as a direct replacement for heavy #5 and #6 fuel oils. The intent was that power plants and industrial heating operations that were using these fuel oils could switch directly to a coal-water slurry with a minimum of modification to their combustors. This requires a very

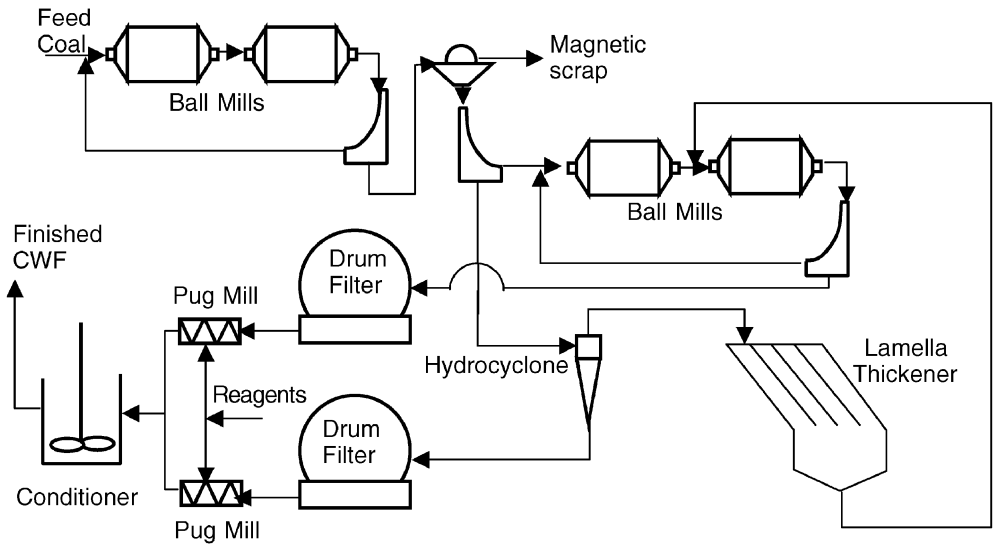

Fig. 7 Simplified schematic of the Beijing Coal Water Fuel Plant, China. Clean coal is first ground in multiple stages to produce a graded size distribution that will fluidize with the minimum amount of water. Drum filters are used to remove excess water from the slurry, and surfactant reagents are combined with the slurry using pug mills. This plant processes 35 metric tons of coal per hour and produces a slurry that is 65% coal by weight. (From Ref.[22].)

low-ash coal to prevent fouling of the burners and is most attractive when fuel oil prices abruptly increase. The disadvantage of coal-water slurry fuels in this application is that they only provide about half the energy per unit volume as the fuel oil does. Currently, there do not appear to be any industries that see these fuels as an attractive alternative, and they are not being sold commercially for this purpose.

Supplement for Pulverized Coal Combustors: The water content of coal-water slurry fuels has made them attractive for control of nitrogen oxide emissions from pulverized coal combustors at power plants. If the slurry fuel is injected as a supplement for the main fuel (dry coal), the water lowers the combustion temperature and prevents nitrogen oxides from forming, while still allowing complete combustion of the coal. As nitrogen oxides are troublesome to remove or destroy once they are formed, it is generally preferable to prevent their formation at the source. This technology is currently in use for low-NO_x coal combustors. It has also been determined that, when coal-water slurry is added in pulverized coal combustors, a greater fraction of the inorganic hazardous air pollutants (including mercury) became trapped in the bottom ash rather than escaping with the flue gases.[13]

Injection into Fluid-Bed Combustors: Similarly, fluid-bed combustors can be operated with part of the fuel supplied as a coal-water slurry. In Italy, coal-water slurries are currently considered to be a standard fuel for this application.[14]

Diesel Engines: Coal slurry fuels have been proposed as diesel engine fuel as a direct replacement for fuel oil, and diesel engines designed for this purpose have been developed and successfully operated.[15] The main issues with using coal slurry in this application are: first, to prevent clogging of the injectors while still adequately atomizing the slurry; second, to minimize wear of the piston rings caused by abrasive particles in the coal; and third, to control the higher level of particulate emissions compared to conventionally-fueled diesel engines. This application requires particularly low-ash coal for production of the slurry to minimize the quantity of ash formed in the engine.

Pipeline Transport

A coal slurry pipeline is a system for transporting solid coal particles in a liquid carrier. Long-distance coal slurry pipelines are an alternative to railroad transport, and their practicality and economics are largely dependent on land ownership, terrain, water availability and water contamination concerns, political considerations, and coal demand.[16] An example of pipeline transport is the 440 km Black Mesa pipeline, which was completed in 1970 and is currently the only long-distance coal slurry pipeline operating in the United States.[17] Slurry pipelines are also used over shorter distances to transport material within a processing facility.

Unlike coal slurry fuels, which are utilized in a fluid form, coal transported by pipeline is used as a solid after dewatering. As a result, it does not need to be stable when stored in tanks, and it is not so critical that its solid loading be maximized. The following variables are important for a pipeline system:

- Solid concentration range
- Flow velocity range
- Pipe diameter
- Friction losses

These are, in turn, controlled by the size distribution and density of the coal particles. To maintain homogenous flow, which is necessary to minimize wear of the pipeline, a coal slurry should have the following properties, assuming a coal specific gravity of 1.4:[4]

- Maximum particle size: 2400 μm
- Percentage finer than 44 μm: 20%
- Slurry concentration: 50 wt%.

To keep the particles in suspension, the flow should be at least 0.15 m/sec faster than either: 1) the critical deposition velocity of the coarsest particles, or 2) the laminar/turbulent flow transition velocity. The flow rate should also be kept below approximately 3 m/sec to minimize pipe wear. The critical deposition velocity is the fluid flow rate that will just keep the coarsest particles suspended, and is dependent on the particle diameter, the effective slurry density, and the slurry viscosity. It is best determined experimentally by slurry loop testing, and for typical slurries it will lie in the range from 1 m/s to 4.5 m/sec. Many empirical models exist for estimating the value of the deposition velocity, such as the following relations, which are valid over the ranges of slurry characteristics typical for coal slurries:[18]

$$F_L = V_c/[2gD(\rho_s - \rho z_f)/\rho_f]^{1/2}$$

where

$$F_L = \exp[0.165 - 0.073C_D - 12.5K_2]$$
$$K_2 = [K_1 - 0.14]^2$$
$$K_1 = [\mu_L/\rho_L]^{2/3}/g^{1/3}d_{50}$$

C_D = particle drag coefficient
d_{50} = mass median diameter of $+74\,\mu m$ particles (m)
μ_L = viscosity of liquid (Pa sec)
V_c = deposition velocity (m/sec)
g = gravitational acceleration (m/sec^2)
D = pipe diameter (m)
ρ_s = density of solid particles coarser than $74\,\mu m$ (kg/m^3)
ρ_L = density of fluid (kg/m^3)
$\rho_f = [\rho_s C_f + (1 - C_t)\rho_L]/[1 - C_t + C_f]$
$C_t = C_f + C_r$
C_f = volume fraction of $-74\,\mu m$ particles in slurry
C_r = volume fraction of $+74\,\mu m$ particles in slurry

Once the coal slurry has been transported to its destination by pipeline, it is dewatered for utilization.[19] Chemical additives are not normally used in slurry pipelines, as they would be an unnecessary added cost and a possible source of water contamination. It is important to monitor the quality of the water removed from the slurry, as it could contaminate waterways if it dissolves harmful materials before being released.

Coal Gasification

For integrated gasification combined cycle (IGCC) plants, coal slurries are pumped under pressure into the reactor, where they react with water to produce combustible gases, particularly methane. There are two reasons for using coal slurries for this application rather than dry coal: 1) a fluid slurry can be easily pumped into a pressurized reactor, whereas it is much more difficult to convey dry solids against a pressure gradient, and 2) the gasification reaction requires water in any case; hence, it is simplest to introduce water along with the coal particles.

The requirements for coal slurry intended to be used in IGCC are similar to those for pipeline transport, with the added requirement that, as for coal-water fuels, the slurry needs to atomize easily in the reactor. Atomization has been found to be easier (producing smaller-diameter droplets at lower jet pressures) as the size of the coal particles in the slurry increases, because of weaker capillary forces holding the slurry together and decreased interparticle friction.[20] As the capillary forces and interparticle friction are also responsible for increasing the viscosity in coal slurries, it is clear that low-viscosity slurries will atomize more readily than high-viscosity slurries.

Coal Slurry Wastes

The bulk of the fine coal that makes up coal slurry wastes is produced in the mine by the miner cutting heads. These fine particles are typically mixed with

large quantities of mineral fine substances, particularly clays, to the extent that the fine coal has a very high ash content. Additional fine particles are produced by rotary breakers and other size reduction equipment that is in use in most coal-washing plants. Processing methods exist that can be used to separate coal from the mineral matter in these fine coal slurries, specifically, froth flotation techniques. However, not all plants have the facilities to recover this fine coal, either because their coal is not suited to froth flotation processing, or because they have difficulty meeting ash and moisture specifications with fine coal produced by this means. As a result, many plants must dispose of their fine coal slurries as waste.

Large volumes of coal waste slurry are disposed of in surface impoundments. As the slurry remains easily liquefied long after being impounded, it represents a serious hazard if the impoundment fails. An example of this occurred in Martin County, KY, in 2000, when a breakthrough in a coal slurry impoundment released 245 million gallons of slurry into 75 mi of streams, and caused in excess of $37 million in damages.[21]

Unlike other coal slurry applications where the slurry must be kept fluid and pumpable, coal slurry in impoundments needs to be stabilized to prevent flow. Treatments of coal waste slurry, therefore, concentrate on promoting complete settling, strong interparticle interactions and high viscosities so that impoundment breaks will not release the material as a damaging flow.

CONCLUSIONS

Coal slurries are of great importance in a wide variety of coal-handling situations, as the slurry form makes the coal easy to handle by pumping with minimal dust. Highly concentrated slurries that can be burned directly as fuel make it possible to eliminate the need for handling dry coal in the combustion process. The primary considerations in producing and handling coal-water slurries are managing the slurry rheology through manipulation of particle size and surface chemistry and minimizing the water content needed to maintain fluidity. Currently, the most common use of coal-water slurries is as a means for transporting coal, either within a plant or through pipelines. While coal-water slurry fuels have not yet become a widespread replacement for liquid fossil fuels, they are a viable alternative to heavy fuel oils provided that they are made from coal with sufficiently low ash content.

Computational Fluid Dynamics

André Bakker
Elizabeth Marden Marshall
Fluent Inc., Lebanon, New Hampshire, U.S.A.

INTRODUCTION

Computational fluid dynamics (CFD) is an engineering field in which flow fields and fields of related scalar variables, such as temperature and chemical species concentrations, are calculated in great detail for the domain of interest. The flow field calculations are performed by solving discretized forms of the equations for the conservation of mass, momentum, energy, and other relevant variables. The final results are detailed maps of the flow field showing fluid velocities, temperatures, and species concentrations throughout the system. These results can be used to gain a better understanding of the system of interest. Results of computational fluid dynamics can illustrate how a piece of equipment operates, how to troubleshoot problems, how to optimize performance, and how to design new equipment. During the 1950s and 1960s, CFD was used mainly in the aerospace and defense industries. This was followed by the power generation industry (especially the nuclear industry) and the automotive industry during the 1970s. The process industries did not start to use CFD seriously until the 1980s and 1990s. One of the important reasons for the relatively late adoption was that chemical reactors are characterized by so many complex phenomena. These include heat transfer, multiphase flow, and homogenous and heterogenous reactions. The development of methods to model these complex physical phenomena has occurred in recent years. Much progress has been made, and CFD is now used to model accurately many pieces of plant equipment, such as fluidized beds, packed-bed reactors, cyclone separators, spray dryers, bubble columns, stirred vessels, static mixers, and more.

One way the CFD results differ from traditional analysis methods is in the amount of detail they provide. Whereas traditional methods, such as design based on correlations of experimental data or overall thermodynamic balances, provide general design guidelines, they do not usually provide insight into the internal working of the equipment. For example, in a chemical reactor where several competing reactions take place, the final product composition may depend on nonuniformities in the concentration, flow, or temperature fields inside the reactor. Traditional methods that make use of average values inside the reactor are not able to take into account the effect of such nonuniformities. Computational fluid dynamics methods, which typically calculate flow field variables at hundreds of thousands of points inside the reactor to come up with overall reaction rates, are far better suited for the analysis of such systems. Another difference between CFD and traditional design methods is the minimal reliance of CFD on experimental data and extrapolation of that data to different scales, a process known as scale-up. Computational fluid dynamics relies on solving the fundamental equations of motion and conservation. These equations are scale independent and can be solved directly for the full-scale equipment.

While CFD provides a number of advantages over other analysis methods, high-fidelity CFD can come at a cost. It typically requires the use of specialized CFD software that offers extensive modeling capabilities, the availability of a skilled CFD analyst to set up the model and interpret the results, and high-end computing resources. In recent years, however, the cost of high-end computing has dropped substantially as the speed and power of processors have increased at a similar rate. Clusters of inexpensive computers can now do jobs that previously required supercomputers. In addition, new CFD software products have been introduced with limited capabilities and easy-to-use front ends. These new tools are designed to make CFD available to nonspecialists who want quick decision support for product design or troubleshooting. In this entry, the conservation equations that describe fluid motion are reviewed, and the general methodology behind CFD is summarized. The steps that are typically followed during an analysis are described and illustrated by an example of a reacting fluidized bed.

CONSERVATION EQUATIONS

Computational fluid dynamics is based on the principle of solving conservation equations for all relevant variables. The conservation equations include the transport of the variable throughout the domain, as well as either its creation or its destruction. Conserved variables include:

- Mass
- Momentum

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120016187

- Enthalpy
- Turbulent kinetic energy
- Turbulent energy dissipation rate
- Chemical species concentrations
- Local reaction rates
- Local volume fractions for multiphase problems.

The equation for conservation of mass, also termed the continuity equation, has the form:

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_i}(\rho U_i) = 0 \tag{1}$$

Here, ρ is the fluid density and U_i is the fluid velocity in the x_i direction. When an index, such as i, is repeated in the same term, it means that the term is a summation over all possible values of the index. The first term on the left-hand side describes the change in fluid density over time, and the second term describes the transport of the fluid. For incompressible fluids, which have a constant density, the continuity equation reduces to the following, simpler form:

$$\frac{\partial U_i}{\partial x_i} = 0 \tag{2}$$

The statement for the conservation of momentum, also known as the Navier–Stokes equation, is as follows:

$$\begin{aligned}\frac{\partial(\rho U_i)}{\partial t} + \frac{\partial}{\partial x_j}(\rho U_i U_j) &= -\frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j}\left[\mu\left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i} - \frac{2}{3}\frac{\partial U_k}{\partial x_k}\delta_{ij}\right)\right] \\ &\quad + \rho g_i + F_i\end{aligned} \tag{3}$$

The first term on the left-hand side describes the variation of the fluid momentum in time and the second term describes the transport of the momentum in the flow (convective transport). The first term on the right-hand side describes the effect of gradients in the pressure p; the second term, the transport of momentum due to the molecular viscosity μ (diffusive transport); the third term, the effect of gravity g; and in the last term, F_i lumps together all the other forces acting on the fluid. Techniques for solving the set of four equations (one continuity and three momentum equations) are discussed in a later section of this entry. When the flow is compressible, it is usually necessary to close the system of equations listed above using a thermodynamic equation of state (such as the ideal gas law) that calculates the density as a function of temperature and pressure.

For steady-state flows, the first term on the left-hand side is zero. For turbulent flows, which are unsteady, it saves time and computer resources to calculate a single, time-averaged flow field only, instead of solving for the full time-dependent flow field. To do this, the velocity is written as the sum of a constant and a fluctuating component $(U_i + u_i')$, and the momentum equation is averaged over time, resulting in the following modified conservation equation for momentum:

$$\begin{aligned}\frac{\partial}{\partial x_j}(\rho U_i U_j) &= -\frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j} \\ &\quad \times \left[\mu\left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i} - \frac{2}{3}\frac{\partial U_k}{\partial x_k}\delta_{ij}\right)\right] \\ &\quad + \frac{\partial}{\partial x_j}(-\rho\overline{u_i' u_j'}) + \rho g_i + F_i\end{aligned} \tag{4}$$

A new term is introduced, the so-called Reynolds stresses $\overline{u_i' u_j'}$. The overbar denotes a time average. This term is the correlation between the turbulent velocity fluctuations u_i' and u_j', and it describes the transport of momentum in the mean flow due to turbulence. This term is difficult to model, and over the years a variety of turbulence models have been developed. Turbulence models are necessary for calculating time-averaged flow fields directly, without first having to calculate a fully time-dependent flow field and then doing time averaging. The use of turbulence models is therefore much more computationally efficient. A detailed discussion is beyond the scope of this entry, but it is important to note that not all turbulence models are equally suited for all types of flow. Table 1 summarizes the most common turbulence models and their properties.

For the other conserved quantities, conservation equations of a form similar to the momentum conservation equation are solved. These usually include a time-dependent term, a convective transport term (describing the transport of the variable due to the mean flow), a diffusive transport term, and a generalized source term describing all other physical effects.

COMPUTATIONAL FLUID DYNAMICS METHODOLOGY

Overview

The general methodology followed during a CFD analysis comprises the following steps:

1. Geometry creation
2. Grid generation
3. Defining the model by specifying physical models, boundary conditions, and initial conditions
4. Specification of the numerical methods to be used for solving the model equations
5. Performing the calculation
6. Analysis and interpretation of the results.

Table 1 Summary of turbulence models

Model	Description, advantages, and disadvantages
Standard k–ε	The most widely used model, it is robust, economical, and time tested. The Reynolds stresses are not calculated directly, but are modeled in a simplified way by adding a so-called turbulent viscosity to the molecular viscosity. Its main advantages are a rapid, stable calculation, and reasonable results for many flows, especially those with a high Reynolds number. It is not recommended for highly swirling flows, round jets, or flows with strong flow separation
RNG k–ε	A modified version of the k–ε model, this model yields improved results for swirling flows and flow separation. It is not well suited for round jets and is not as stable as the standard k–ε model
Realizable k–ε	Another modified version of the k–ε model, the realizable k–ε model correctly predicts the flow in round jets and is also well suited for swirling flows and flows involving separation
Spalart–Allmaras	The Spalart–Allmaras model was developed for external flows in aerospace applications. It provides good answers for attached flows and flows with mild flow separation. It is not commonly used for process industry applications
RSM	The full Reynolds stress model (RSM) provides good predictions for all types of flows, including swirl, separation, and round and planar jets. Because it solves transport equations for the Reynolds stresses directly, longer calculation times are required than for the k–ε models
LES	Large eddy simulation (LES) is a transient formulation that provides excellent results for all flow systems. It solves the Navier–Stokes equations for large-scale turbulent fluctuations and models only the small-scale fluctuations (smaller than a computational cell). Because it is a transient formulation, the required computational resources are considerably larger than those required for the RSM and k–ε family of models. In addition, a finer grid is needed to gain the maximum benefit from the model and to accurately capture the turbulence in the smallest, subgrid-scale eddies. Analysis of LES data usually requires some degree of planning in advance of building the model.

Preprocessing

The first two steps, geometry and grid creation, are also referred to as preprocessing. In the first step, geometry creation, a computer model is created of all flow passages and of those solid components that need to be included in the heat transfer analysis. The geometry is created in a way that is similar to three-dimensional solid model creation in computer aided design (CAD) software, and in software used for structural analysis. In fact, it is becoming more and more common to import CAD geometries into the CFD preprocessor instead of creating the whole geometry from scratch using the preprocessor. An important difference between the computer models constructed for structural analysis applications and those constructed for CFD is that the former requires details of the solid parts, whereas the latter requires details of the flow passages or of the space enclosed by the solid parts. Hence, when CAD models are imported into CFD preprocessing software, new volumetric entities for the flow passages usually have to be created from the imported solid surfaces. Furthermore, certain geometric details that can be present in the CAD model (e.g., boltheads, weldlines, and flange details) but not relevant to the CFD analysis can (and should) be removed.

Although it is common to use three-dimensional geometries, some problems can be solved suitably in two-dimensions. For example, the flow in a straight circular pipe in the absence of gravity or asymmetric heating is independent of the angular position. In such cases, it is sufficient to create a two-dimensional geometry, taking into account the axial and radial directions, but ignoring the circumferential (''tangential'') coordinate.

Once the geometry has been created, a computational grid, or mesh, has to be generated. During grid generation, the flow domain defined in the geometric model is subdivided into a large number of computational cells. The CFD solver will later solve conservation equations inside each computational cell, keeping track of what enters and leaves through each of the cell faces. Generating a suitable grid is therefore of utmost importance for the success of the model calculations. Different cell types with different shapes can be used to this effect. For two-dimensional boundary layer flow, for example, it is better to use up to 10 layers of quadrilateral cells than triangular cells in

the near-wall region. To accurately capture a two-dimensional jet entering a plenum, at least 10 cells should be used for the jet cross section to avoid excessive spreading. These guidelines can be extended to three-dimensional cases, and depend on the overall dimensions and requirements of the case at hand. In most software, the initial grid can be refined or coarsened during the course of the solution, to better resolve gradients or capture other effects, if needed. Fig. 1 shows some of the most commonly used types. The corner points of the cells are referred to as nodes. For two-dimensional models it is common to use triangular or quadrilateral cells. For three-dimensional models it is common to use hexahedral, tetrahedral, prismatic, or pyramid cells. Of course, these are not all of the possible cell types. For example, clipping corners of hexahedral cells can create other cell shapes. To accommodate such shapes, some CFD software allows the use of arbitrary polygonal cells, with any number of faces.

There are different ways in which the cells can be distributed throughout the domain. When the mesh consists solely of quadrilateral or hexahedral cells distributed throughout the domain in a regular, stacked pattern, such as that shown in Fig. 2, the mesh is referred to as a structured mesh. The use of such structured meshes, in which all cells are referenced by an i, j, k index in the computational domain, was common in the past because of the advantages it offered in the form of simplified programming and straightforward data interpolation routines. The main disadvantage of using structured meshes lies in the difficulties they pose in representing complex shapes. Now it is more common to use unstructured meshes, such as that shown in Fig. 3. In unstructured meshes, cells can be arranged in an arbitrary fashion. The user can choose the cell arrangement that is most suitable for reproducing the details of the geometry. Unstructured meshes can use only one cell type (e.g., all hexahedral or all tetrahedral), or mix different cell types as shown in the mesh in Fig. 3. Meshes that combine different cell types are usually referred to as hybrid meshes.

For very complex geometries, meshing can be simplified by subdividing the flow domain into different volumetric zones that can be meshed independently, choosing the best mesh type for that particular zone. The meshes for the different zones then can be combined into one mesh, usually called a multiblock mesh. When combining the meshes for the different zones, the cells and the nodes at the shared faces do not necessarily have to be lined up exactly. Multiblock meshes are called conformal meshes when the nodes at the shared faces do line up, and when they do not line up they are called nonconformal meshes.

Model Definition

Once the mesh has been created, the scope of the problem to be solved has to be specified. This step includes specifying the material properties, defining the physical models, setting the boundary conditions, and specifying the initial conditions.

A wide range of physical models is available in most commercial CFD software. At a minimum, the flow field will be calculated by solving the conservation equations for mass and momentum. In addition to flow, many of the problems encountered in the process industry involve heat transfer also. For such applications, the temperature field can also be calculated, which is commonly done by solving a conservation equation for enthalpy. For problems involving chemical reaction, the transport equations for the chemical species involved in the reaction(s) will be solved. The creation and destruction of the species due to the reaction are modeled by means of source terms in these equations. The reaction rates determining these source terms are calculated locally, based on the values of species concentrations and temperature at each

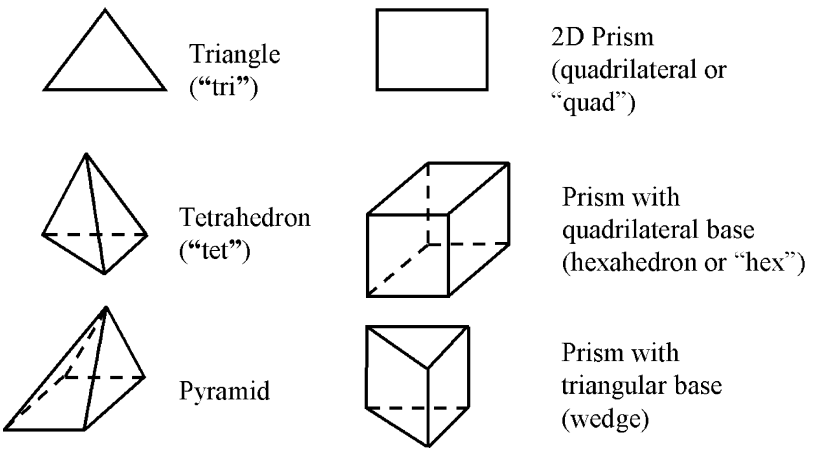

Fig. 1 Examples of three-dimensional element shapes that can be used in CFD simulations.

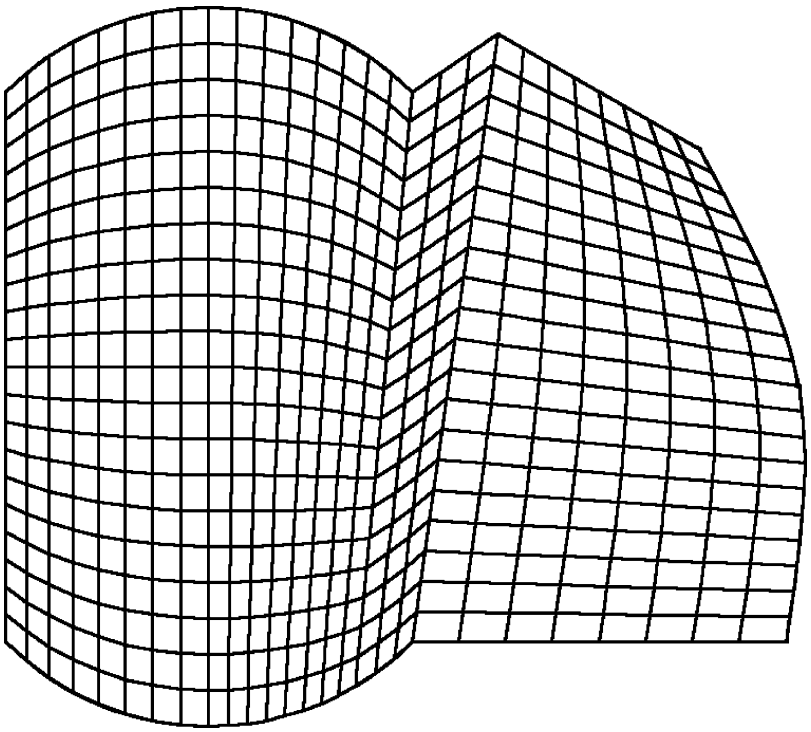

Fig. 2 An example of a two-dimensional structured grid.

variable storage site (a point at the center of each computational cell). The quality of the CFD predictions for reacting systems depends largely on the availability of accurate reaction rate constants. Many real-life systems involve a number of main reactions and also a number of side reactions that progress at much slower rates. When the total number of reactions is very large, or when the reaction constants for the less important side reactions are not known, the reaction model is often simplified to include only the most important reactions.

Multiphase flows are common in many types of process equipment. In such equipment there is usually one main continuous phase (a primary phase), and one or more dispersed (or secondary) phases. Multiphase flows can be modeled in a number of different ways. The most straightforward method is to calculate a single-phase flow field and then to calculate the trajectories of a finite number of particle streams for the dispersed phase that include the effects of drag, buoyancy, and turbulence. (Here, the term particle is used in the most general sense; it includes drops and bubbles also.) This so-called Lagrangian particle tracking calculation shows how the particles are dispersed throughout the domain. Physical phenomena such as particle evaporation, boiling, or surface reaction can be included in the tracking algorithm as well. The effect that the particles have on the flow field can be modeled by including particle trajectory-dependent source terms in the momentum (or other) equations for the fluid. Particle tracking models are best suited for systems with low volume fractions ($<10\%$) of the dispersed phase. Examples of systems that are commonly modeled using this method are spray dryers and liquid fuel or coal combustors.

Eulerian multiphase flow models work differently. Rather than compute individual particle trajectories, the primary and secondary phases are modeled as interpenetrating continua using separate sets of conservation equations. In addition to a set of momentum and continuity equations for each phase, a volume fraction equation for each secondary phase is also solved. Momentum exchange terms are included, which depend on the buoyancy, drag, and lift of the secondary phase particles. Computational fluid dynamics predictions are for the flow fields for both phases, which are usually different, depending on the system characteristics. Eulerian multiphase flow models can be formulated for any number of phases. Breakup and coalescence can be included for droplets or bubbles, along with mass transfer between the phases. When one of the secondary phases consists of a granular material, a maximum packing density can be prescribed for that phase, and a special treatment is used for the granular viscosity and granular pressure. Eulerian multiphase flow models are commonly used for fluidized beds, stirred vessels, and bubble columns.

Other types of multiphase flows are free surface flows, where there is a well-defined interface between two continuous phases. Examples of such flows can be found in liquid separators, unbaffled mixing vessels where surface deformation occurs when a central vortex forms, mold filling applications, and blow

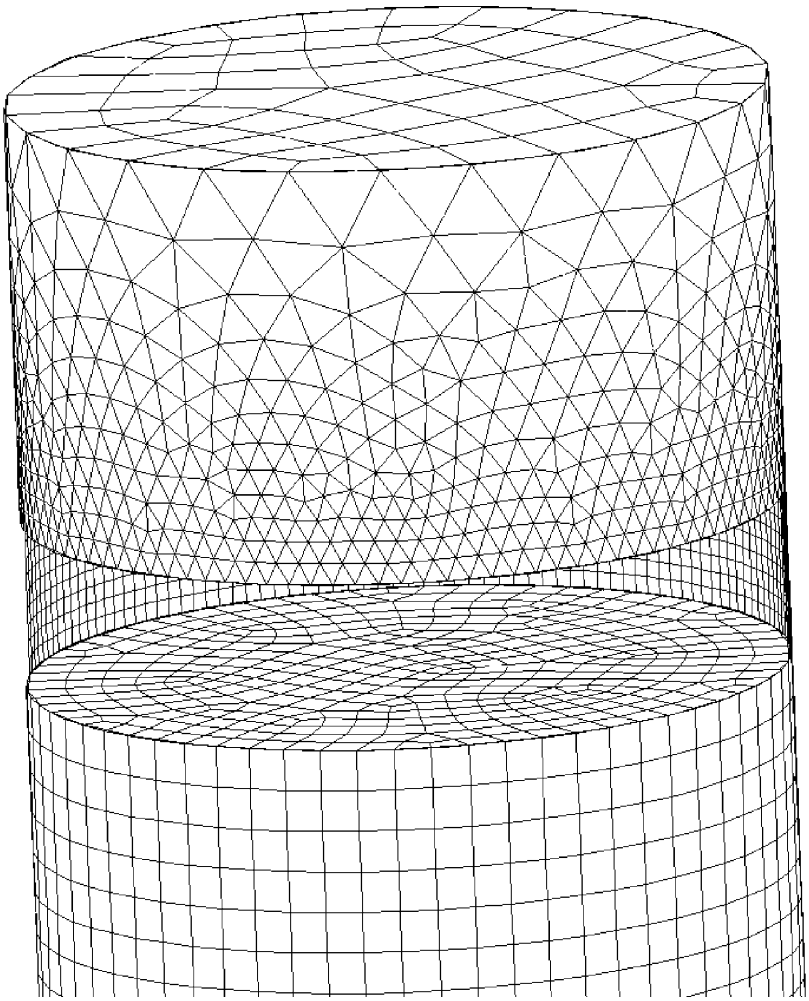

Fig. 3 An example of a three-dimensional unstructured grid.

molding applications. With free surface flows, mass and momentum conservation equations are solved, along with an equation that describes the movement of the interface.

The material properties that have to be specified depend on the physical models chosen. For flow field calculations only, it is usually sufficient to specify the density and the viscosity. The fluid can be incompressible (constant density) or compressible (a compressible liquid or an ideal or nonideal gas). The viscosity can be either Newtonian or non-Newtonian (independent or dependent on shear rate, respectively). Any type of non-Newtonian fluid can be modeled, including shear-thinning fluids, yield-stress fluids, and viscoelastic fluids, assuming that the viscosity behavior is known. Unfortunately, this is not always the case. For fluids with complex rheological behavior such as paper pulp, dough, and other viscoelastic fluids, it is often difficult to determine the rheology. In such cases, simplified rheologies often have to be used, and it is not uncommon to model the fluid as Newtonian using an effective average viscosity that is known to give good results for such quantities as pressure drop or torque predictions in rotating equipment.

When heat transfer is involved, the density and viscosity can be functions of temperature, and the thermal properties of the fluid have to be prescribed as well. These properties include heat capacity, thermal conductivity, molecular weight (for gases), and thermal expansion coefficient. For problems involving chemical species, all physical properties have to be specified for all of the species along with a method to calculate the average property for mixtures in each cell using the properties of the component species.

To complete the model specification, boundary conditions have to be specified. These describe the flow conditions at the domain boundaries. At flow inlets one can usually specify the fluid velocity, a mass flow rate, or an inlet pressure. Depending on the problem definition, the inlet temperature, species concentrations, turbulence properties, and volume fractions of any secondary phase must also be supplied. At flow exits, one usually specifies an outlet pressure, and if entrainment through a flow exit is anticipated, the exit

should be moved downstream or have boundary conditions carefully specified for the entrained flow. For problems with only a single flow exit—far from recirculation zones—no such boundary conditions are required. One can also set guidelines regarding how much of the mass entering the domain from the inlet(s) exits through each of the outlets. At the domain walls, the wall can be prescribed to move at exactly the same velocity as the adjacent fluid with no imposed frictional drag (a so-called slip condition), or the wall can be assigned the more common no-slip condition, where a constant wall velocity (tangent to the fluid flow), usually zero, is set. The shear stress at the wall can also be prescribed. When the problem involves heat transfer, boundary condition options include a specified heat flux (which can be zero to model well-insulated, or adiabatic, walls), a specified temperature, or an external heat transfer boundary condition that may include heat losses due to radiation.

For problems involving repeating geometry and flow conditions, it is often sufficient to model the flow in only one section of the domain, which is identical to that in other sections of the same size. At the appropriate boundaries of that section, either periodic or symmetric boundary conditions can be prescribed.

For problems where the fluid behavior is steady and the final solution is independent of the initial conditions, calculations can usually be carried out in a steady-state fashion. For problems that describe transient behavior or that require a time-marching solution technique, initial conditions must be supplied in addition to boundary conditions. These include the state of the flow field, concentration fields, and temperature fields at time zero at all locations in the domain.

As part of the specification of the physical models and boundary conditions, the user has to specify the body forces on the fluid. Body forces are those forces that act on the entire volume of fluid throughout the domain. These forces include gravity, electromagnetic forces (if relevant), and the Coriolis force for rotating domains.

Numerical Methods

There are a variety of numerical methods available to solve the conservation equations. The most commonly used method in commercially available CFD software today is the finite volume method. Excellent descriptions of this method can be found in Refs.[1,2]. With the finite volume method, an integral form of the conservation equations is solved by performing a mass and momentum balance over all faces of each computational cell. There are, however, many other methods available, such as the finite element method (where the equations are solved in differential form instead of in integral form), vorticity-based methods (where conservation equations for vorticity are solved instead of those for momentum), and spectral element methods (where the equations are transformed into Fourier space before being solved). The main advantage of the finite volume method over other methods is that it conserves mass on coarse as well as fine meshes, including those with large numbers (tens of millions) of computational cells, and performs well for turbulent flows.

One disadvantage of the finite volume method, however, is that because velocities and other variables have to be interpolated from the cell centers (the storage sites) to the cell faces so that face fluxes can be computed, a certain amount of numerical error is introduced. These errors tend to have the effect of decreasing the sharpness of gradients in the flow when compared to real life, similar to how diffusion smoothens out gradients in all scalar fields. This error is therefore termed numerical diffusion, and it is present in all CFD simulations performed using the finite volume method. It can be minimized by using meshes that are finer in regions where steep gradients in the flow occur, and by choosing accurate interpolation methods (also called numerical schemes) that result in a small error (usually at the expense of increased computation time). However, for flows where gradients tend to be relatively small, such as in time-averaged turbulent flows, the numerical diffusion may be insignificant. The finite element method is not as prone to numerical diffusion, and therefore tends to give solutions that are more accurate for a given number of cells for flows that have sharp gradients. Examples of such flows are laminar flows at very low Reynolds numbers. The finite element method is not as computationally efficient as the finite volume method for turbulent flows or for meshes with large numbers of cells. Most applications in the process industries involve turbulent flows in complex geometries that require fine meshes. The finite volume method is used, therefore, for most applications. The finite element method tends to be the better choice for applications involving very viscous fluids, such as those encountered in blow molding and extrusion processes.

Solution

Once the solution method has been chosen, the actual calculations are performed using an iterative procedure. The solution procedure is as follows. Starting with an initial solution provided by the user (which may be a value of zero for all variables throughout the domain), the solver determines the error in the mass and momentum balances for each computational cell. This error is also known as the residual. Based on

that error, the solver determines what adjustments need to be made to various variables to improve the balances for each cell. These adjustments are applied to all cells in the domain, and the procedure is repeated until the error in the solution is smaller than a preset tolerance specified by the user. At that time, the solution is considered converged and the calculation is halted. There are many different ways in which this concept can be implemented, and many mathematical techniques are available to enhance the rate of convergence and to improve the solver's ability to converge to a stable and accurate solution. A discussion of these techniques is beyond the scope of this entry.

Postprocessing

The final step in a CFD simulation is to analyze and interpret the results, a step also referred to as postprocessing. Typical CFD results include values for the pressure, the three velocity components, turbulence properties, temperature, and species concentrations at all grid cells in the domain (which is typically on the order of several hundred thousand in today's applications). The total amount of available data is thus extremely large and detailed. To be useful to an engineer the data have to be presented in an understandable way.

The objective of the simulation might be to obtain quantitative estimates for certain global variables, such as an overall reaction rate, the temperature at a certain location, or the pressure drop across the domain. These can be calculated from the CFD solution in a relatively straightforward manner. The results also can be presented graphically, and there are many options available for doing so.

Iso-surfaces can be constructed by connecting all points in the flow domain that have exactly the same value of a given variable. These surfaces can be colored by the contours of any other variable. Iso-surfaces are useful to visualize certain flow-field features, such as the central vortex in the cyclone separator shown in Fig. 4. Contour plots can be used to show the local values of scalar variables. A cross section of the flow domain is created and colored by the local value of the variable of interest, e.g., temperature. A color scale is used indicating how each color corresponds to a certain value of the variable. Such plots can be used to quickly see the variation of important variables throughout the domain. An example of a contour plot is found in Fig. 5, which is described in the example in the following section.

A commonly used graphical visualization of the flow field is through plots of velocity vectors. An example, also taken from the simulation described in the following section, is shown in Fig. 6. The velocity vectors point in the direction of the fluid flow where the vector originates. The length of the vector can be made proportional to the local velocity magnitude, such that longer vectors indicate higher velocities. The vectors can also be colored by the velocity magnitude, or by any other variable, as desired.

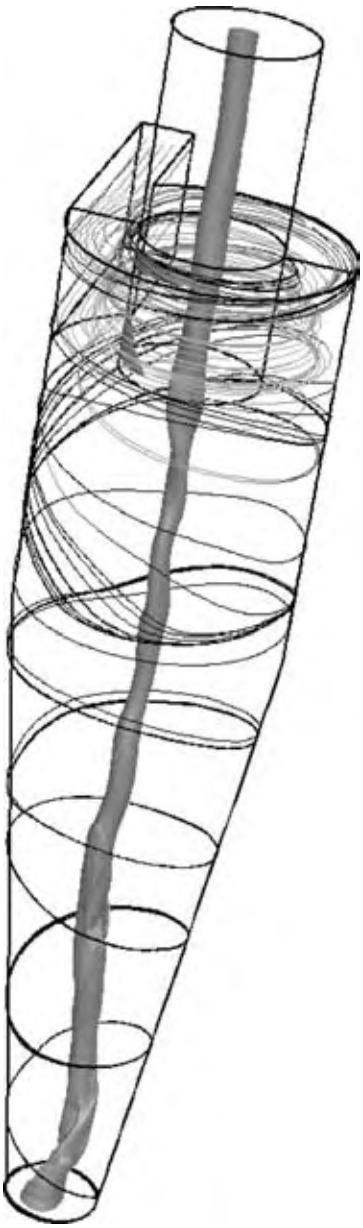

Fig. 4 An iso-surface of axial vorticity in a cyclone, colored by velocity magnitude, is used to show the central vortex; pathlines are used to show the swirling flow. *(View this art in color at www.dekker.com.)*

Other methods to visualize the flow field make use of flow lines, of which different types are available. Streamlines are useful in two-dimensional simulations. They are curves that are tangent to the flow field and whose spacing is such that a fixed mass of fluid passes between any pair of lines. For three-dimensional

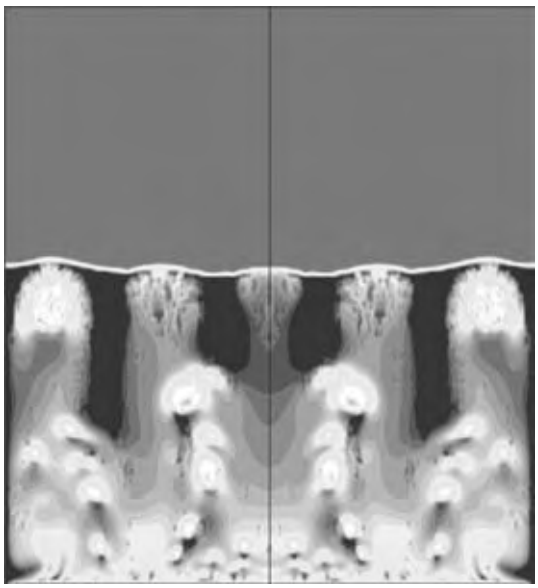

Fig. 5 Gas volume fraction in a reacting fluidized bed 0.6 sec after the operation begins. *(View this art in color at www.dekker.com.)*

geometries, pathlines can be constructed by calculating the trajectories of massless particles that follow the mean flow. Streaklines are formed by a series of particles that are continuously injected into the flow from a number of fixed locations. For steady two-dimensional flows, streamlines, pathlines, and streaklines are the same. However, for unsteady (time varying) flows, they can be very different.

Other types of flow lines also can be used. Oil-flow lines are pathlines that are constrained to a given boundary surface. When calculating the pathline, velocity components that are tangent to the given boundary surface are included and normal velocity components are ignored. This is useful for visualization of the flow field over an object. Timelines are formed by placing a series of particles along a line in the flow field at time zero. The particles are tracked for a given amount of time, and the curve connecting the particles is redrawn. Timelines also are called material lines, and they are commonly used to study the amount of stretching and deformation that occurs in mixing applications.

REACTING FLUIDIZED BED

One example that illustrates many of the concepts described in this entry is the conversion of ozone to oxygen in a fluidized bed. The particles in the bed serve as a catalyst where surface reactions take place. To model this complex process, the commercial software FLUENT is used. The fluidized bed is simulated using the Eulerian granular multiphase model, and a reaction is specified in the bed to account for the decomposition of ozone and subsequent production of oxygen.

A two-dimensional axisymmetric model of a column 0.23 m in diameter and 0.25 m high is used.[3] At rest, the bed is 0.12 m high, and contains sand particles impregnated with iron oxide, 117 μm in diameter with a density of 2.65 g/cm^3. Two gas phase species (ozone and oxygen) are specified. Ozone enters from inlets at the base of the bed at speeds that range from 4 to 14 cm/sec. The gas lifts and separates the particles in the bed, allowing for better interaction between the ozone and iron oxide at the particle surfaces. The decomposition rate is expressed as

$$K = 1.57\alpha[O_3] \tag{5}$$

where α is the volume fraction of the catalyst and $[O_3]$ is the concentration of ozone. After the reaction has

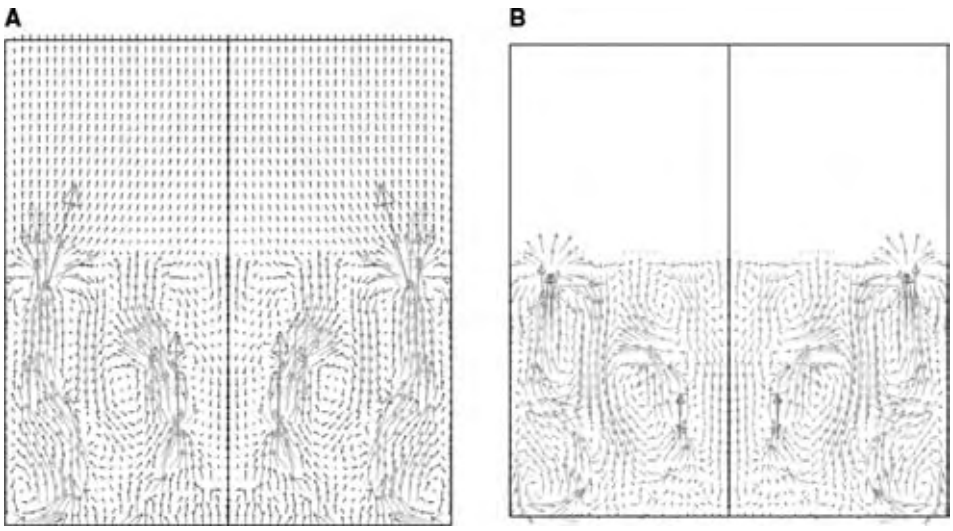

Fig. 6 Velocity vectors of (A) the gas phase and (B) the granular phase (sand) in a fluidized bed after 0.6 sec of operation; the sand motion is different from that of the gas, and is restricted to the bed region. *(View this art in color at www.dekker.com.)*

taken place, a mixture of ozone and oxygen exits through the top of the column. Of particular interest are the conversion characteristics of the bed, where conversion is defined as

$$1 - \frac{C_{\text{out}}}{C_{\text{in}}} \tag{6}$$

where C_{out} and C_{in} are the outgoing and incoming concentrations of ozone, respectively. If $C_{\text{out}}/C_{\text{in}}$ is small, conversion is high and the bed is operating efficiently.

Fig. 5, discussed earlier, shows contours of the gas volume fraction 0.6 sec after the flow is initiated. Light gray (or red) indicates regions of pure gas, and dark gray (or blue) indicates regions where the sand volume fraction is maximum. The flow field is the same whether the reaction in the gas phase takes place or not. Bubbles are formed near the bottom of the bed and migrate upward. The simulated bubble shape and size are grid dependent. If a coarse mesh is used, the bubbles are fewer in number and rounder. On finer meshes, the bubbles are denser and more irregular. The number and size of the bubbles have a significant impact on the conversion. The more bubbles in the domain, the greater the interaction between the ozone and sand particles, so the higher the conversion.

Fig. 6 illustrates the velocity fields for the gas (left) and granular (right) phases after 0.6 sec of operation. The vectors are plotted on every fifth grid cell to make the display easier to read. The velocity fields are different in several ways. First, there is no granular motion on the top of the bed, where only the oxygen and ozone gases are escaping. Second, while some of the larger flow features are the same for both phases, some of the smaller ones are not. For example, a rather large recirculation pattern dominates the gas flow on either side of the bed. In the sand phase, perhaps owing to the increased inertia of the material, the recirculation patterns are not as strong, and have slightly different shapes.

In Fig. 7, curves for $C_{\text{out}}/C_{\text{in}}$ (pink) and gas holdup (red) are plotted as functions of the gas velocity. The gas holdup is defined as the ratio of the gas volume in the bed to the total volume of the bed. The figure shows that the gas holdup increases with gas velocity up to a point, after which saturation occurs. This is because at the low end, the increasing gas velocity forces the bed to lift more. When saturation occurs, the bed can no longer rise and hold additional gas.

The curve of $C_{\text{out}}/C_{\text{in}}$ is in good agreement with data from Ref.[3]. The results follow the trends in the gas holdup. At low gas speeds, the residence time is long, so there is more time for the ozone to come into contact with the particles. $C_{\text{out}}/C_{\text{in}}$ is small, so conversion is high. At high speeds, the residence time reduces, and the rate of conversion tends toward a constant value.

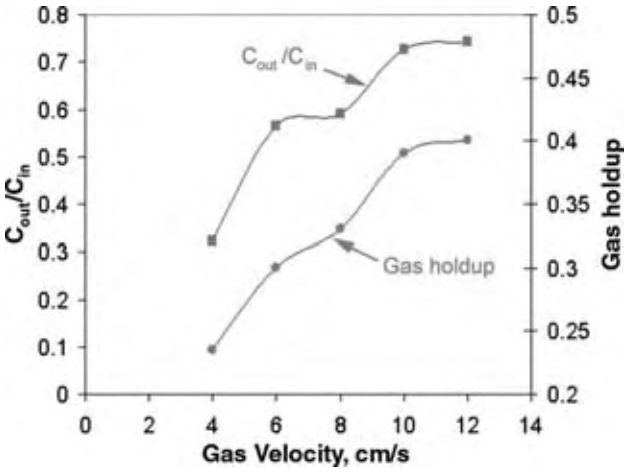

Fig. 7 Ozone conversion (pink) and gas holdup (red) as functions of gas velocity for the fluidized bed. *(View this art in color at www.dekker.com.)*

CONCLUSIONS

Before embarking on any CFD simulation, it is important to realize that the care that goes into the setup of the model is directly related to the quality of results that are obtained. The grid should be fine enough and of optimal quality to capture the flow details of interest. The choice of physical models, for turbulence or multiphase, for example, should be based on the flow regime and expected flow features. Boundary conditions and physical properties should be chosen carefully so that they represent the full range of anticipated behavior. Approximations—what to keep in the model and what to neglect—can also play a significant role in the type of effects that the simulation can capture. Finally, once the setup is complete and the simulation is running, it is important to make sure that proper convergence has been obtained before using the results for any type of careful analysis.

If these issues are heeded, the potential benefits that can be extracted from a simulation are numerous. With the computational resources available today, both in terms of speed and power, engineers are more able to use high-density grids and multiple, detailed physical models than at any time in the past. In the years to come, computing power will only continue to increase, so CFD results will become more and more accurate as turnaround times shorten. Interoperability between CFD and other computer-aided engineering packages is on the rise. In many industries, this has led to a recent expansion of CFD from its use in the analysis and design departments to being a major contributor to automated plant operation and process optimization.

Computer-Aided Process Engineering

Andrzej Kraslawski
Lappeenranta University of Technology, Lappeenranta, Finland

INTRODUCTION

This entry presents the structure of computer-aided process engineering (CAPE) from the perspective of activities, problems, and methods. More detailed information is presented on process synthesis and chemical product development. Future prospects of process and product design are mentioned briefly.

BACKGROUND

CAPE develops methodologies and their implementations for designing activities and processes that enable the manufacturing of products from raw materials. The manufacturing process is realized by a chain of physical, biological, and chemical processes. Other functions of CAPE stress on process modeling or decision making in chemical supply chain. The term ''process systems engineering'' (PSE) is sometimes used instead of CAPE.

CAPE concentrates on finding a representation of problems, generation of several alternative solutions, and selection of an appropriate solution. Majority of the problems handled by CAPE is NP-hard. This means that the computation time increases exponentially with the problem size. It is an illustration of the fact that the design is usually ill defined (no clear information about its goals) and open ended (usually a few equally good designs exist). NP-hard problems are the main reason for the generation of several alternatives instead of providing straightaway optimal solution.

CAPE uses methods and tools developed in chemistry, physics, biology, mathematics, economics, and systems engineering, and applies them to products and production methods in process industries. Its original contribution is in the development of new representations for the description of the problems in process industries as well as that in computationally efficient solution methods and tools.

This entry gives an introduction to the history of CAPE, general characteristics, and, structure. It describes in more detail the most significant and characteristic branch of CAPE—process synthesis, and introduces the most important new area of CAPE applications—product design. A few conclusions and ideas about the future development of CAPE are also provided.

HISTORY

The development of chemical industries is characterized by the following main phases: first, extraction and purification of useful materials (metals from ores, dyes from plants and insects, etc.); next, production of naturally existing chemicals from various raw materials (acetic acid, furfural, and vanillin, to name a few); and finally, synthesis of chemicals that are not available naturally (nylon and other polymers). The degree of complication of the production processes increased in every phase. It was manifested by the fact that more and more equipment had to be used in the production to perform the so-called unit operations. The first design issue related to process synthesis was how to combine those unit operations to get products of good quality, in a short time, and at a reasonable cost. The advent of computers and scientific insights have resulted in treating the problem of connecting the equipment for realization of various unit operations as a mathematical programming problem,[1] and as such to be tractable by computers. Historically, the first applications of CAPE were in process design for petrochemical industry in the late 1950s.

The first conference on computer-aided design was organized in 1972.[2] Now there are cyclic conferences for the presentation of new results, namely, ESCAPE, PSE, FOCAPD, and FOCAPO. CAPE is also very educative for chemical engineers. Important journals on CAPE are *Computers and Chemical Engineering*, *AICHE Journal*, *Industrial & Engineering Chemistry Research*, *Chemical Engineering Science*, *Chemical Engineering*, and *Processing and Chemical Engineering Research and Design*, while the most popular textbooks are Refs.[3–6].

GENERAL CHARACTERISTICS

The activities and processes of CAPE are interdisciplinary, multiobjective, complex, uncertain, as well as dynamic.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120030505

Typical activities are analysis of the consumer needs; its translation into technical specifications of the product; generation of ideas on how to produce such a material; synthesis of the production scheme, e.g., flowsheet; design of the process, its operation, and control; waste treatment; planning and controlling of the flow of raw materials, utilities, and final products; and analyses of the market response leading to the changes of the actual products. The interdisciplinary nature of CAPE results from the need of applying technical, scientific, economic, and management data, information, and knowledge to deal with the above-mentioned activities.

The multiobjective nature of the activities covered by CAPE results from the fact that production processes are dependent on technical, economic, environmental, and social systems. Each has its own priorities and objectives (e.g., technical—maximizes yield and purity; economic—maximizes profit; environmental—minimizes the amount of wastes and use of natural resources; and social—full employment for the workforce). Moreover, there are often several objectives inside the systems themselves. Usually there are conflicts between these objectives with their role being twofold. On one hand, they introduce serious constraints and limitations leading to the search of trade-offs between the objectives and finally Pareto optimal solutions. On the other, attempts to remove these conflicts could lead to the generation of highly innovative technical, economic, and organizational solutions.

The complexity of the activities and processes where CAPE is involved is a consequence of new economic, technical, scientific, and social opportunities. The first of these is manifested by such phenomena as mergers and acquisitions of companies as well as emergence of new markets. This has led to new problems related to the complicated supply chain and knowledge management in heterogeneous organizations. It resulted in the need for analysis and synthesis of multiscale systems. The maturity of the chemical industry has resulted in its shift from being process based toward product based. New challenges emerged in the development and operation of processes as well as in the design of products. On one hand, a lot of efforts have to be taken to improve the existing processes (usually running in nearly optimal state), and on the other to develop new products characterized by complex structural properties and unconventional formulations.

The complexity in CAPE applications also results from new opportunities offered by proteomics, materials science (self-assembled materials, nanomaterials, biomimetic materials), and pharmaceutical science (combinatorial design of molecules, drug delivery systems).

Social changes like new beauty standards and food habits resulted in the development of new industries that produce highly complex products (e.g., cosmetics, food products with long shelf life, etc.).

The dynamic aspects related to CAPE applications result from the earlier needs of process control to run the processes in unsteady state and control them, as well as from new requirements like the shortening of the life cycle of products or management of abnormal situations.

STRUCTURE

The structure of CAPE is complex because of the broad spectrum of the problems that are solved and the variety of methods applied. Structuring can be done from the various classifications presented in Table 1.

From the viewpoint of scientific methodology there are three main tasks in CAPE: representation of the problem, generation of several alternative solutions, and selection of the best one. These tasks correspond to the activities realized in four phases of any scientific method: analysis (description of the problem and identification of the objectives), hypothesis (generation of solutions), synthesis (comparing the solutions), and validation (formulation of conclusions). The activities realized in the last two phases correspond to the selection task in CAPE.

The CAPE activities specified from the point of view of realization of any industrial project are product design, process synthesis, process design, process operation, and process decommissioning. Looking from the historical perspective, the economic interest and R&D activities in particular phases of an industrial project development and realization have been changing depending on the economic factors in the world. The social, political, and technological changes in the last 20 years have been manifested by the growing demand for new products. This trend has resulted in the mergers and acquisitions of many businesses at a scale not observed earlier. Changes in the way businesses are organized have very deeply influenced the manufacturing and processing industries. The main consequences have been low profit margins of commodities, growing pressure on environmental aspects of production and conservation of raw materials, very high costs of R&D, significance of the low-tonnage and high value-added products, growing importance of the customer-oriented products, reduction of time from the development stage to the market, shortening of the life cycle of the products, and issues related to the intellectual property rights.

All these factors have caused the shift from process-oriented to product-centered businesses in processing industries. Consequently, the most interesting economic and scientific activities are now realized in

product- and process design, with particular stress on the development of new products, intensification of the existing processes and their integration into the operation of bigger systems, as in a whole division of industry, or the natural and social environment.

The classes of problems to be identified in the contemporary CAPE concern the problem of conceptualizing change of scale, intensification, and integration. There are two main subjects of conceptualization. The first one is generation of alternatives and selection of appropriate one for the identification of the chemical path that transforms the given raw materials into the required product. The second is identification of the structure of the flowsheet, i.e., what units are to be used to produce the required material and how they should be connected. More detailed information about the solvents and the control structure is also decided in the conceptualization phase.

The problems of change of scale result from extending the applications and research in CAPE to micro- and macroscales. As shown in Fig. 1, the activities of CAPE are no longer limited to mesoscale (unit operations and processing units). The research in microscale, in terms of dimensions of the object as well as duration of the phenomena, is characteristic of the activities in the field of product design. The CAPE activities in macroscale correspond to applications at the company, industry, or even global scale.

The intensification in CAPE concerns the changes and improvements of equipment and flowsheets, modifications of control procedures, as well as new approaches to organization and management of large-scale activities in process industries.

The integration activities have been mainly related to heat and mass exchangers. However, there are many more popular applications related to integration of flowsheet creation with simultaneous consideration of safety aspects. The design of control system is also beginning to be integrated with process synthesis and process design. The large-scale integration is aimed at combining technical and business decisions to optimize the value chain in the company.

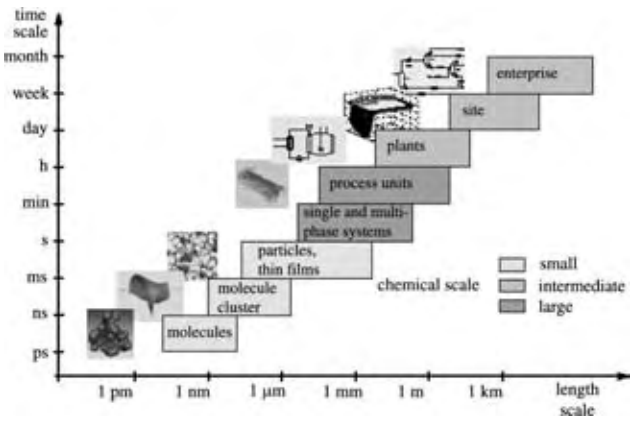

Fig. 1 Scales in process engineering. (From Ref.[43].)

The method-based classification of CAPE identifies the following main groups: optimization, modeling and simulation, search, and selection. Most R&D activities involve the first two. The methods of search and decision support relating to artificial intelligence seem to get less attention than they had in the 1980s and 1990s.

The tools used in CAPE could be specified as solvers, simulators, databases, equipment designers, and decision support systems. Several tools, such as simulators, databases, and decision supporting systems, are often embedded as one computing environment, e.g., ASPEN or ICAS. A few examples of the existing programs and environments are given in Table 1.

Process Synthesis

The most characteristic task of CAPE and historically the most popular is process synthesis.[7,8] The development of process synthesis is confirmed by the use of a very broad spectrum of methods for building a process flowsheet.

A quite common approach to solving the synthesis problem is application of optimization methods.[9] Optimization-based methods use not only traditional algorithmic approaches, such as mixed-integer nonlinear programming (MINLP), but also stochastic ones, e.g., simulated annealing and evolutionary algorithms.[10] Two common features of these methods are the formal, mathematical representation of the problem, and the subsequent use of optimization. The advantage of this approach is the provision of a systematic framework for handling a variety of process synthesis problems and the more rigorous analysis of features such as structure interactions and capital costs. An important drawback of optimization-based methods is the lack of ability to automatically generate a flowsheet superstructure. Another disadvantage is the huge computational effort required, and the fact that the optimality of the solution can be guaranteed only with respect to the alternatives that have been considered a priori.
