The term suspension polymerization (also termed as bead or pearl polymerization) refers to polymerization in an aqueous phase with monomer as a dispersed phase, resulting in polymer as a dispersed solid phase. In general, suspension polymerization is carried out by suspending the polymer as droplets (0.001–1 cm in diameter) in water as a continuous phase. In a typical suspension polymerization, the initiator is dissolved in the monomer phase. These types of initiators are referred to as oil-soluble initiators. Each monomer droplet in a suspension polymerization is like a small bulk polymerization reactor. The suspension is maintained by agitation and the use of polymeric stabilizers. The suspension polymerization method is not used with monomers whose polymers are highly water soluble or whose homo- or copolymers have a very high glass transition temperature. The suspension polymerization technique is used to prepare polymers such as polystyrene, poly(methyl methacrylate), poly(vinyl acetate), and poly(vinyl nitrile). In other terms, suspension polymerization is essentially equivalent to bulk polymerization, but is carried out in reaction medium in which the monomer is insoluble and dispersed in droplets, with a catalyst system that generates radicals within the droplets. The highest-volume polymer made

Table 9 Typical dispersion polymerization recipe

Material	Parts (by weight)	Function
Methyl methacrylate	10	Monomer
Polyvinyl pyrrolidone (PVP)	0.55	Stabilizer
Anionic surfactant	0.06	Stabilizer
Methanol	62.5	Dispersion medium
Water	26.8	Dispersion medium
Benzoyl peroxide	0.1	Initiator

Table 10 Typical recipe: PVC polymerization by suspension polymerization

Ingredients	Amount (per 100 parts monomer)
0.03% aq. dispersing agent	200
Ferrous sulfate	0.15
Vinyl chloride	100
Lauroyl peroxide	0.2
pH adjuster (0.5% sodium hydroxide)	1.7

by suspension polymerization is polyvinyl chloride (PVC). A typical recipe for PVC polymerization by suspension polymerization is described in Table 10.

ADVANTAGES AND DISADVANTAGES OF FREE-RADICAL POLYMERIZATION TECHNIQUES

The advantages and disadvantages of several free-radical techniques discussed in the previous section are discussed in Table 11. Some common polymers produced using these processes in the chemical industry are also listed in the table.

REACTION ENGINEERING

The reaction kinetics and reaction processes described in the previous sections lead to a variety of industrial implementations and related issues with pre- and postprocessing of materials. The heat, mass, and momentum transport in the reactors, the thermodynamics of various reaction systems and their impact on the reaction kinetics have been the subject of intense study.[20]

There are three broad stages of any industrial free-radical polymerization. These include the preparation stage, the polymerization stage, and the postprocessing stage. In each of these stages, there are significant issues that need to be dealt with depending on the type of polymerization process being used.

The Preparation Stage

The preparation stage involves purification of reagents and preparation of reagent streams for addition to the reactor. The unit operations may involve removal of impurities from reagents including purging with inert gases to remove oxygen (an inhibitor). Reagent streams may be premixed by operations like stirring, homogenization, and gas sparging, depending on the type of polymerization process under consideration. For example, it is common to add certain monomer streams homogenized with a concentrated aqueous surfactant mixture called a pre-emulsion or premix. The preparation steps may also include heating or cooling certain system parts or reagents to predetermined temperatures. In addition, there are the usual setup and preparation steps to operate the banks of pumps, heat exchangers, utility streams, and other processes that go hand in hand with running an industrial polymerization process.

The Polymerization Stage

The polymerization stage deals with converting the monomer(s) to polymer and controlling the level and rate of conversion as well as the properties of the product to within desirable specifications. There are three very important parameters that change significantly with most polymerization processes. These are viscosity, density, and solubility. An increase in the amount of polymer in the reactor typically leads to higher viscosity, higher density, and lower solubility in the reaction medium. These have different impacts on different polymerization processes. There have been a variety of models and correlations that can effectively describe these changes and even relate them with some degree of confidence to the transport phenomena and the resulting impact on reaction kinetics.[20]

Higher viscosity leads to significant changes in the effectiveness of heat, mass, and momentum transport. These can result in issues like compartmentalization and localized autoacceleration in reactors resulting in localized charring or undesirable variation in product properties. Higher density leads to volume shrinkage and could have a significant impact on design issues like the location of feed lines, sampling lines, heat addition and removal equipment, and agitator configurations.

These factors have led to a variety of reactor types and designs that help control the rates of heat, mass, and momentum transport, residence time distribution of the reactor contents, and as a result the quality and consistency of the reactor product. The basic reactor types, the processes they are used for, and some of the polymers they are used to produce are listed in Table 12.

The safety of the equipment and the people operating it, as well as the environmental impact, need to be considered for the design of the equipment and processes. Other important details include the installation and utilization of appropriate sensors and measurement tools, the establishment and implementation of

Table 11 Comparison of free-radical polymerization processes

Process	Advantages	Disadvantages	Polymers
Bulk—polymerization in the absence of a dispersing or diluting medium	High reactor utilization, low separation cost, high product purity, no transfer reactions	High viscosity during the course of polymerization	Low-density polyethylene, PVC, methyl methacrylate
Solution—polymerization of monomers dissolved in solvents in which the polymer products are also soluble	Lower viscosity than bulk and better heat transfer and mixing; direct application of solution; less reactor fouling	Smaller reactor capacity than bulk; high separation cost; often inflammable and toxic solvents; lower molecular weights	SBR, polyvinyl acetate, polystyrene, acrylics
Suspension—polymerization of monomers dispersed in an inert phase with monomer-soluble initiator	Low dispersion viscosity compared to bulk; good heat transfer; high polymerization rate and high molecular weight; direct application of the latex	Smaller reactor capacity than bulk; reactor wall fouling; wastewater problems	Polystyrene, PVC, polypropylene
Emulsion—formation of small particles via micellar or homogenous nucleation	Low dispersion viscosity compared to bulk; high molecular weight; good heat transfer	Emulsifier impurity; reactor wall fouling; emulsifier impurity	SBR, polyvinyl acetate, vinyl acrylics, etc.

(From Ref.[2].)

Table 12 Reactor types classified according to their operation modes

Operations	Reactor types	Polymers
Bulk and semibatch	Stirred tank reactor	PVC, PVC (B, S, E), polyester (B), polyurethane (B)
Continuous	Continuous stirred tank reactor: loop reactor, stirred tank reactors, fluidized reactors, tubular reactors	Polyvinyl acetate, styrene–butadiene, PVC (E), polystyrene (S), low-density polyethylene (B)

B, bulk; S, solution; E, emulsion.
(From Ref.[2].)

appropriate process control schemes, and the monitoring of appropriate parameters to ensure that the polymerization process is proceeding according to specification.

Changes in reactor conditions may lead to changes in several important product properties, such as molecular weight and molecular weight distribution, copolymer composition, and the level and type of branching and cross-linking. These may have a substantial impact on the application properties of the polymer and hence need to be controlled to ensure quality.

The Postprocessing Stage

Once the reaction has been completed the reactor product typically consists of polymer with other inert or unreacted reagents. The extraction of polymer in a form that can be further utilized needs special attention. The postprocessing may be relatively simple as in the addition of residual monomer scavenging systems to solution or emulsion polymer products to get close to 100% conversion and remove residuals that could be harmful to eventual users or the environment. It may also involve complex processes like controlled coagulation of styrene–butadiene emulsions to get styrene–butadiene rubber (SBR).

The physical transport of the reactor products may also need sufficient processing. Bulk polymerizations in high-pressure extruders may be followed by dicing the product into small pellets suitable for pneumatic transport. Emulsion and solution products are usually transported as obtained and frequently used in the same mode. The design of suitable containers and transportation protocols is very important to avoid harming the product during transportation and storage. For example, special containers may be required for air-sensitive materials, or to avoid solvent or water loss from solutions and emulsions, respectively.

In some instances, undesirable products may result because of loss of reactor control or unforeseen events during the reaction. These may have a varied impact on the polymerization product and could lead to significant costs, if they occur. The design of polymerization processes, equipment, and related pre- and postprocesses needs to consider all of these factors to ensure success.

CONCLUSIONS

Free-radical polymerization continues to be one of the principal industrial routes to synthetic polymers. Every year, billions of pounds of industrial polymers are synthesized using this technique for a variety of applications. The advent of CFRP techniques promises to enhance the value of free-radical polymerization significantly from an industrial as well as an academic perspective. It promises to deliver products that will help in satisfying the increasing demands of high-performance applications in existing and emerging market segments.

Friction Materials

Sunil Kesavan
Xinming Shao
Akebono Corporation, Farmington Hills, Michigan, U.S.A.

INTRODUCTION

Friction materials are used in a variety of automotive and nonautomotive applications to control vehicle movement or for the transmission of power. This entry will limit its scope to automotive brake friction materials. Automotive friction materials are composites that are incorporated into a disk or drum brake system (a) for stopping or reducing the speed of a vehicle by converting kinetic energy into frictional heat or (b) to prevent the movement of parked vehicles.

Over the past century, a variety of brake configurations have evolved to accommodate the increasing demands placed on them. Modern vehicles use friction materials shaped for use in disk or drum brakes for dynamic braking or parking purposes. Disk brakes employing two friction pads hydraulically pressed on the faces of a rotating solid or ventilated pearlitic gray cast iron disks are used for the front or rear corners of vehicles (Fig. 1). Drum brakes use two curved brake linings pressing outward on the inside surface of a cast iron drum and are used for the rear service or parking brakes on vehicles (Fig. 2).

Original equipment (sold on new vehicles) friction materials are formulated to help the brake system meet three sets of requirements:

1. *Legal requirements*: Government requirements like the Federal Motor Vehicle Safety Standard (FMVSS) 105 and 135 in the United States and ECE R13 in Europe and South America are normally specified to cover vehicle stopping distance under cold, hot, high-speed, thermal and water fade and recovery conditions, and inoperative power assist. Additional requirements are imposed on the selection of raw materials by health, safety, and environmental regulations. These are the minimum requirements that need to be satisfied by a brake system.
2. *Vehicle manufacturer requirements*: These requirements are defined by the vehicle manufacturers and cover performance under different conditions, product piece and life cycle costs, ease of installation and servicing, health, safety, liability, and warranty considerations.
3. *Customer requirements*: Customers expect stable, smooth, responsive, reliable, and noise-free performance from their brakes in a variety of real-life terrains and seasons. In addition to performance considerations, they desire long pad/rotor life and low maintenance costs.

No single friction material can completely meet all these requirements for every vehicle. The objective of friction material formulation development is to custom design application-specific formulations whose performance is a compromise between conflicting requirements. In several countries, including North America, there are no regulations or standards governing the performance or durability of replacement friction products installed on vehicles after sale.

TYPES OF FRICTION MATERIALS

Asbestos Friction Materials

Asbestos friction materials introduced in 1908 contained up to 65% of short chrysotile asbestos fibers that served as a cost-effective, heat-resistant, insulating reinforcement and friction enhancer. Asbestos formulations were widely employed in drum and disk formulations for several decades until health and safety concerns triggered efforts to find suitable substitutes. These materials are being universally phased out in favor of nonasbestos formulations.

Semimetallics

A semimetallic formulation typically contains over 50 wt% of ferrous metal in the form of steel fiber and porous iron powder. Other typical ingredients include binder resins, abrasives, graphite and coke lubricants, rubber particles, and cashew friction dust. These materials were developed in the 1960s to meet the demands of heavy-duty and high-temperature braking. The use of semimetallic formulations for automobiles increased in popularity in the 1970s with the imposition of Federal Motor Vehicle Safety Standard 105 (FMVSS105) and the arrival of front wheel drive vehicles with their higher brake operating temperatures. Semimetallics have good wear

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007778

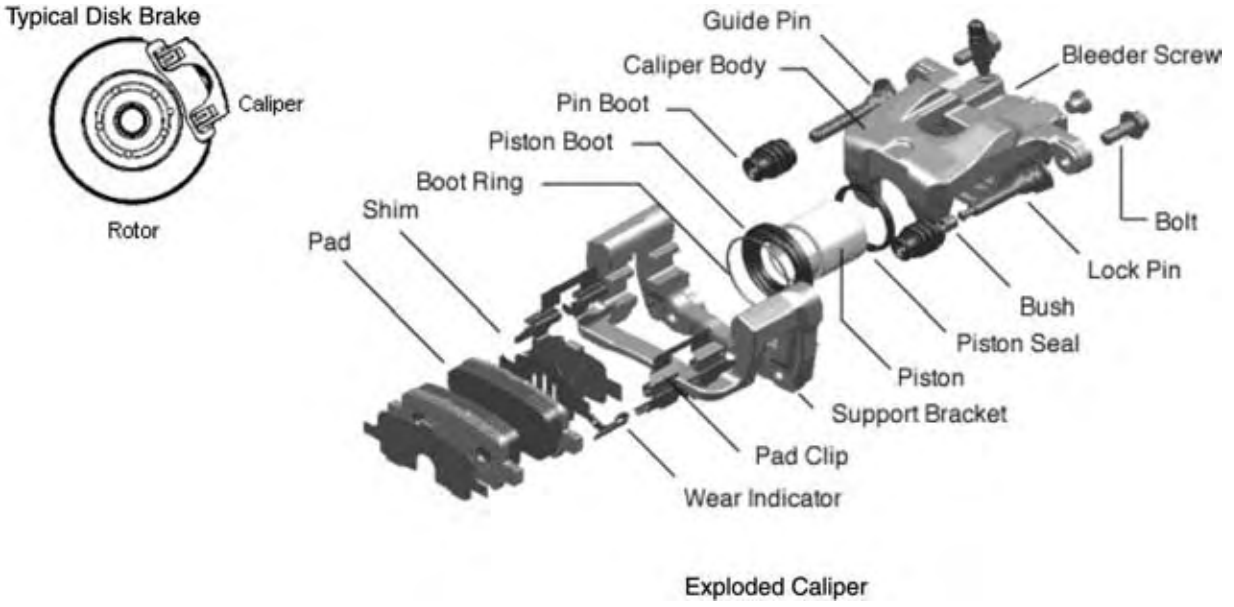

Fig. 1 Schematic of a typical disk brake showing the caliper and rotor. The exploded view of a floating single piston caliper is also shown. (Courtesy of the Akebono Corp.)

characteristics under heavy-duty and higher temperature use, but have high wear at lower temperatures and high speeds. Wear life of semimetallics in actual use is very dependent on the conditioning of the friction couple. These materials have poor friction performance under cold conditions and can also suffer from noise, vibration, and harshness (NVH) and corrosion problems. Semimetallic formulations have a relatively high thermal conductivity, which can lead to problems with brake fluid boil. Backing layers (a thin layer of friction material between the backing plates and bulk friction material) with lower thermal conductivity are sometimes used to partially offset the effect of higher thermal conductivity.

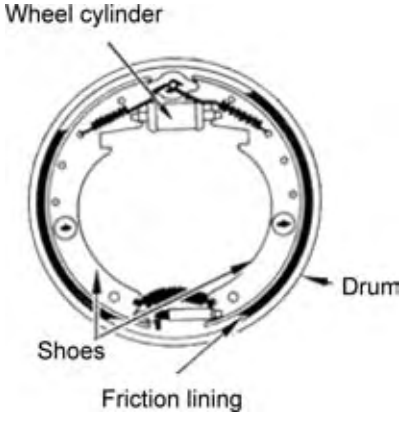

Fig. 2 Schematic of a typical drum brake.

Nonasbestos Organics

As the name indicates, these are asbestos-free formulations that use a fiber cocktail of aramid pulp, ceramic fiber, rockwool, and other fibers or whiskers for reinforcement. These fibers are mixed with binders, abrasives, lubricants, fillers, and other property modifiers. This type of formulation is available in friction levels up to about 0.40 and is best suited for light and medium duty applications. Nonasbestos organics (NAOs) show excellent wear characteristics at usage temperatures up to about 250°C. Above this temperature, pad and rotor wear tend to increase dramatically. Nonasbestos organics started replacing semimetallic formulations on automobiles starting in the early 1990s because of their superior friction stability, creep groan, NVH behavior, and low wheel dust. The so-called ceramic formulations currently marketed by some manufacturers are essentially NAOs containing heat-resistant ceramic ingredients.

Low-Metallics

These friction materials contain both ferrous and nonferrous metals and are mostly used in European friction applications. Low-metallics normally have a high friction level with the friction coefficient in the 0.40–0.50 range and good high-temperature and high-speed performance to meet European legal requirements (ECE R13). A combination of carbonaceous and

sulfide lubricants and aggressive abrasives like alumina and silicon carbide are used to achieve the desired performance. Given the aggressiveness of low-metallics, pad and rotor life are limited, with a concomitant increase in wheel dust formation. Table 1 summarizes the relative characteristics of semimetallic, low-metallic, and NAO friction materials.

Sintered Metallics and Cerametallics

These are iron- and copper-based inorganic friction materials used for severe applications like tractor clutches, train, and aircraft brakes. Sintered metallic formulations contain lubricants like graphite, abrasives, and other property modifiers held together by metal binders like copper and iron. Sintered friction materials are normally fabricated as buttons that are riveted or fused to a carrier plate or cup. These friction materials are well suited for heavy-duty applications and find use in either dry or oil-immersed applications.

Carbon–Carbon Friction Materials

These expensive carbon–carbon fiber composites are used for thermally demanding applications like aircraft and racecar brakes.[1] Typically, both pads and rotors are made of carbon composite. These friction couples have a relatively low friction level, which is insensitive to the high temperatures experienced in operation. Friction couple components are expensive to manufacture as they are fabricated by time-consuming chemical vapor deposition techniques. Carbon–carbon systems suffer from low cold friction and are best suited for hot operation.

Ceramic Friction Materials

Ceramic friction couples have been developed for use in race and high-performance Porsche and Mercedes car applications. These brakes use expensive heat and fade-resistant ceramic disks which weigh about half of conventional cast-iron disks. The disks are made from specially treated carbon fibers that are siliconized at 1700°C in a vacuum. The use of these lightweight brakes improves braking performance as well as ride quality owing to lower unsprung weight. However, their low heat capacity and thermal conductivity places high demands on the friction pads. Development of suitable friction materials for use with ceramic rotors is still work in progress.

TRIBOLOGY

Friction Coefficient

The simplest way to characterize friction materials is to use the so-called friction coefficient μ. This coefficient is defined by Amontons' law:

$$F = \mu P$$

where F is the friction force at the sliding interface acting in a tangential direction relative to the normal force P. According to the Amontons' law, friction coefficient μ is a dimensionless constant and is an inherent property of materials in contact. However, in real-world applications such as an automobile brake system, the friction coefficient is almost never a constant. In fact, it is very much dependent on the brake system and its operating conditions. Fig. 3 depicts the complex interdependence of friction behavior on various factors. This figure clearly shows why it is almost impossible to satisfactorily model the friction behavior of a brake system.

Because of the continuously changing nature of the friction process, many different mechanisms of friction and wear may operate simultaneously with one or two mechanisms dominating. The dominant mechanism is different from one friction system to another. In addition, for a given friction system, the dominant

Table 1 Comparison of the performance characteristics of various classes of friction materials

★ Excellent; ◯ good; △ fair.

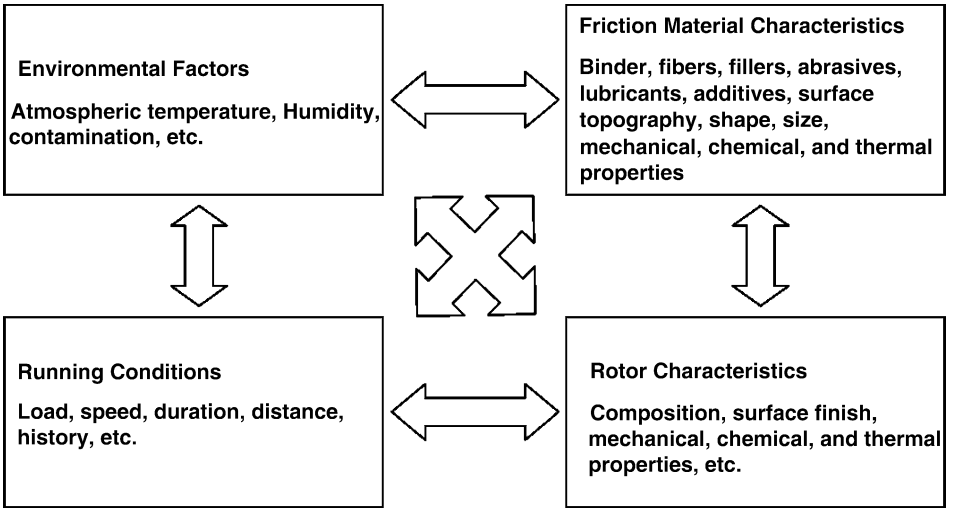

Fig. 3 Representation of the complex interdependency of friction characteristics on various factors.

mechanism can change depending on operating conditions. The key for engineering a successful friction system is to identify and analyze the dominant friction and wear mechanisms for a particular system under the operating conditions of interest to the end user.

The heat energy generated during friction is due to the work done by the friction force. In addition to energy dissipation as heat, energy is also spent to create new chemicals, form new surfaces, and in the work of plastic and viscous deformation and dislocation of surface materials. An important energy dissipation mechanism is the creation of vibration or sound energy. In automobile brake systems, generation of friction-induced vibration, groan, squeal, and other unpleasant noises has often been the most important and difficult engineering problems to solve.

Wear Mechanisms

In sliding friction systems, one or more of the following wear mechanisms come into play: abrasive wear, adhesion and tearing, thermal or ablative wear, macroshear, and fatigue.[2,3] Abrasive wear is a result of the ploughing action of surface asperities (two-body) or the hard wear particles trapped between the wear surfaces (third body; Fig. 4). Adhesive wear involves the formation and rupture of interfacial adhesion bonds. Repeated thermal and mechanical stressing of friction material surfaces results in fatigue wear. Macroshear wear results when a thermally degraded friction surface undergoes mechanical failure under severe mechanical stress. Fig. 5 shows the wear mechanisms operating under different driving conditions for automobile braking systems.

Fig. 4 schematically represents transfer layers that usually form on the friction and mating surfaces of friction couples. These complex layers are formed from inorganic and organic constituents derived from the mating surfaces. The transfer layers are formed and destroyed in dynamic fashion and contribute greatly to the friction, wear, and noise performance of friction couples. Some of the wear generated by transfer layers is of a redundant nature as material gets transferred back and forth between the mating surfaces.

In simple terms, the objective of designing friction materials is to maintain a desirable friction level while keeping friction couple wear and noise/vibration to a minimum.

PERFORMANCE CHARACTERISTICS OF FRICTION MATERIALS

Friction materials are often characterized in terms of friction, wear, and noise performance. However, as explained earlier, these are characteristics of the complete brake system and not of the friction couple alone. Friction material characterization techniques

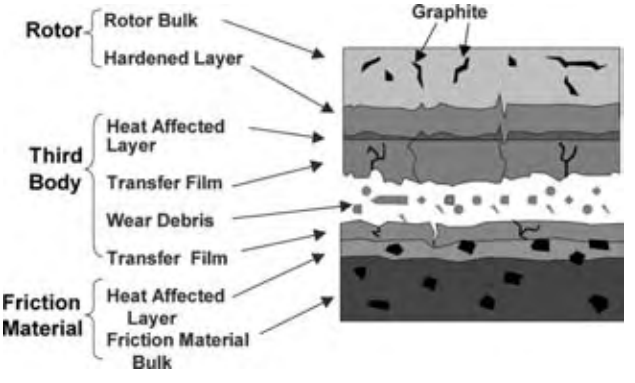

Fig. 4 Representation of the interface between friction materials and rotor/drum counterface. *(View this art in color at www.dekker.com.)*

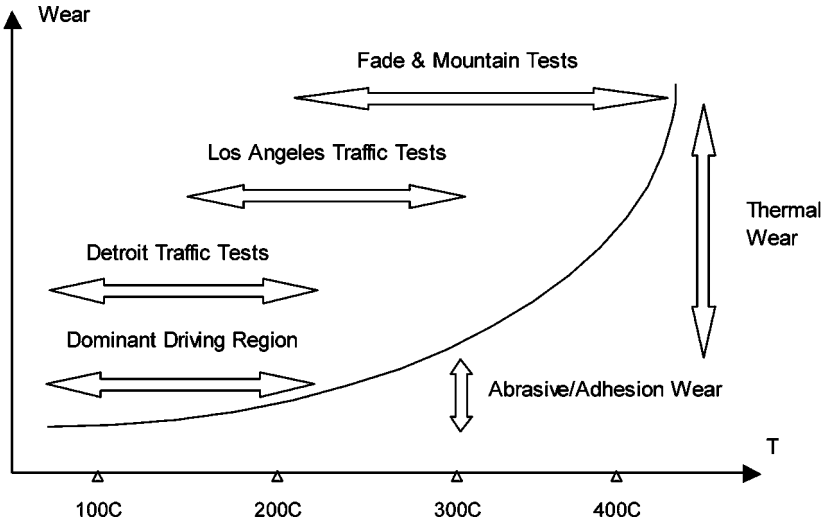

Fig. 5 Operating temperature and wear regimes for various driving conditions.

are developed based on the end-use application. As a result, there are different performance characteristics and related test techniques for automobile brake friction materials.

A typical standard friction performance (effectiveness) test for a passenger car brake usually includes the following measurements: green and burnished effectiveness; thermal fade and recovery; speed, pressure, and temperature sensitivity; water fade/recovery; moisture sensitivity; cold and static friction. These aspects of friction performance are discussed elsewhere in some detail.[4] The performance of an ideal friction material will be immune to changes in braking conditions.

Wear: Wear behavior of friction materials and their mating surfaces is an economic consideration. Although it is desirable to minimize wear, a certain amount of wear is needed to satisfactorily remove corrosion products and material transfer at the interface. As in the case of the friction coefficient, wear depends on brake system and operating characteristics. Accelerated dynamometer tests are routinely used to characterize the temperature dependence of wear rate. These tests are best suited for judging the relative wear performance of materials. More meaningful predictions of lining and rotor life are derived from vehicle road tests that include a large number of stops designed to emulate real-life driving conditions. For most friction materials, wear rate increases with temperature (Fig. 5).

NVH: As mentioned in the section on Tribology, some braking energy is converted into vibration and sound energy. Just as in the tests used for wear characterization, several dynamometer and vehicle tests have been developed to characterize the NVH-generating tendency of brake systems. Dynamometer tests are conducted with the brake corner or a whole vehicle mounted in a controlled environmental chamber. Noise and vibration measurements are made with microphones and accelerometers. Sometimes, sophisticated instruments like laser vibrometers are used for NVH work. Common noise fixes include cutting slots and/or chamfers on the brake pads and linings, the application of constrained layer damping noise insulators to the back of the brake pad shoe plates, and detuning the resonant frequency of mechanical brake corner components.

EVALUATION EQUIPMENT

Laboratory evaluation equipment for testing brakes are designed to evaluate brakes under the widest possible sets of simulated real-life conditions to look for performance flaws or behavioral inconsistencies that can lead to end-user dissatisfaction. Laboratory evaluation equipment can be tailored for either the component or the system level. For component level evaluations, a variety of laboratory evaluation methods have been devised. The custom-designed equipment for this kind of work ranges from small-scale evaluation equipment to large, full-scale inertial dynamometers. Of all available evaluation equipment, full-scale inertial dynamometers come the closest to simulating real-life use. Fig. 6 is a schematic representation of a full-brake dynamometer that is used for evaluation of friction materials. These machines simulate vehicle braking by testing a complete brake-assembly mounted on a rotating shaft loaded with inertia weights chosen to simulate actual road inertia. Table 2 summarizes the commonly used laboratory-scale testing machines.

In addition to laboratory tests, vehicle road tests are used for the evaluation of the whole brake system in various terrains and seasons. The evaluation system

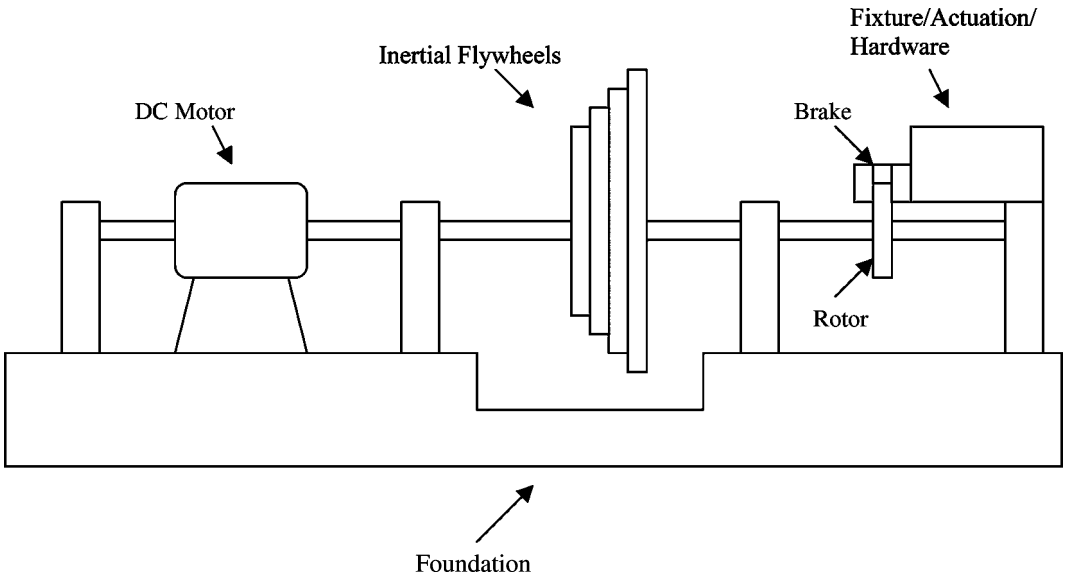

Fig. 6 Schematic representation of a brake dynamometer that is used for evaluation of friction materials.

should include the vehicle with the appropriate end-use brake configuration. The test vehicles are instrumented to acquire information on brake temperature, line pressure, deceleration, noise, vibration, etc. Vehicles can either be driven on roads or run automatically on a vehicle dynamometer.

In addition to the tests mentioned above, there are many standardized pieces of equipment for physico-chemical characterization of friction materials. Table 3 summarizes the different physical and chemical tests that are generally used to characterize friction materials for performance evaluation/prediction or product quality control. Additional information on some of these test procedures is given elsewhere.[5–7]

FORMULATION DEVELOPMENT

As no single raw material can meet all the requirements expected of a friction material, friction linings are

Table 2 Sample and full-scale dynamometers used for characterization of friction materials

Equipment	Characteristics	Application
FAST (friction assessment and screening test) machine	Small friction material specimens dragging for 90 min on the circumference of a test ring at constant torque	Used for quality assurance only
Chase machine	Friction sample (~25.4 mm square pad) rubbing against the inner diameter of a rotating drum	Used to conduct SAE J661 tests for friction edge code determination
Subscale custom testing machines	Usually custom-built for a specific purpose (vibration, fade, thermal stability, friction, wear stability, etc.) with well-designed control systems	Cost-effective tools for simulation and studying the fundamental performance of friction materials
Full-size inertial dynamometers	Uses a motor and shaft-mounted inertial weights to provide energy for friction testing. Brake-specific hardware is mounted on these machines for evaluation	Extensively used for evaluation and problem solving in friction material and brake component development

Table 3 Summary of various tests used in friction material manufacturing for raw material and finished product quality assurance

Raw material tests	Finished product tests
Visual checks	Specific gravity

complex composites that contain anywhere from about 6 to over 20 raw materials. Friction material companies use iterative development techniques to develop proprietary formulations customized to their end-use applications. Formulation development is both an art and a science as very little is known about fundamental tribological processes and their dependence on ingredient properties. Intuition and past experience have proven to be the best tools in the evolutionary process of friction material development.

In addition to the characteristics of the myriad raw materials, processing parameters also have an important role in determining the performance of the compounded product. Given the limitless ingredient and process combinations possible, formulation by trial and error proves to be a laborious and expensive process. Some effort has been made in recent years to use artificial intelligence tools to shorten the development cycle time and to remove human bias from the development process.

RAW MATERIALS

Raw materials can be classified under four broad categories with some overlap: binders, reinforcements, friction modifiers, and fillers.

Binders

Both organic and inorganic binders are used to hold the various ingredients together in a friction material formulation. Unmodified and organic/inorganic modified phenolic resins are the most widely used binders in friction materials because of their easy processing, heat stability, high char yield, and relatively low cost. Organic modifiers typically used for phenolic resins are nitrile, silicone and chlorinated rubbers, cashew and vegetable oils, epoxy, cresol, alkylphenol, and phenoxy groups. Typical inorganic modifiers are phosphorus, boron, and silicon. Liquid resole resins are used either alone or in combination with powdered phenolic resins. Water, alcohol, and other solvents are sometimes used to intimately disperse the powdered resins in friction material mixes. The physicochemical characteristics of binder resins like flow distance, B-time (time needed for the resin to pass through a rubbery stage where the resin is insoluble and almost infusible), hexamethylene tetramine content, and type of modification can be tailored to obtain the required processing and end-use friction material characteristics.

Unmodified or rubber-modified liquid cashew resins have been used to make wet drum lining mixes. These resins are inexpensive and help to improve product

flexibility, but do not confer the mechanical properties and heat resistance provided by powdered phenolic resins.

Green rubber is sometimes used as a primary or secondary binder in disk and drum formulations. Nitrile, styrene–butadiene and chlorinated rubbers have been used for this purpose. These rubbers are intimately mixed with curatives and other ingredients in intensive mixers.

Metal powders and fibers like iron, tin, copper, brass, and bronze are used as binders in sintered formulations. Powder metallurgy processes are used to fabricate these friction materials.

Reinforcements

Chrysotile asbestos fibers that were widely used as reinforcement in friction materials in the past are being replaced by a combination of fibers. Although being phased out for health and safety reasons, asbestos is well suited for use in friction materials because of its strength, thermal stability, flexibility, briquettability, ease of processing, and low cost.

No single fibrous reinforcement embodies all the desirable characteristics of asbestos fibers. Combinations of organic and inorganic fibers are used in friction materials to achieve the desired effect. Given the past experience with asbestos, end-users of fibrous reinforcements have to insure that the materials do not cause cancer, fibrotic lung disease, or pulmonary dysfunction.

Organic fiber reinforcements

Fibrillated aramid (Kevlar® and Twaron®) pulps are widely used as a moderately heat-resistant reinforcement in friction formulations. Aramid pulps provide briquettability for preforms, improve friction and wear characteristics, help modify compressibility, and aid in noise damping. However, these fibers are one of the most expensive raw materials used in friction materials.

Polyacrylonitrile pulp is used in some friction materials as a processing aid and to help improve the briquettability, ingredient retention, and green strength of preforms. Various forms of cellulose pulp or fiber derived from recycled clothing, printed matter, and natural sources (flax, hemp, and sisal) are also used in friction materials. Cellulose does not possess heat resistance but helps to hold ingredients together. Sometimes cellulose fiber is added to formulations to provide porosity when burned off during oven curing.

Inorganic fiber reinforcements

Chopped strands (1/8 to 1/4 in.) of silanized E-glass fibers are used as reinforcements in some formulas. Glass fibers provide excellent thermal reinforcement but tend to be aggressive on the mating surfaces. Dispersion of glass fibers in dry mixes can be problematic as overmixing of fibers can result in the formation of undesirable fiber balls.

Man-made mineral fibers (MMMFs) are widely used to provide high-temperature reinforcement for friction materials. Mineral wool fibers are short (with diameters around 5–6 μm and lengths up to 650 μm) calcium–alumino silicate fibers produced from raw materials like slag, rock, and basalt. Mineral wool is not as effective as chopped glass in providing thermal reinforcement but provides sufficient reinforcement in a cost-effective manner. Also, low-shot (shot is the term used for unconverted raw material present in the final fiber product in the form of small beads) mineral fiber can cause less rotor/drum wear than glass fibers. Another type of MMMF is vitreous ceramic fiber based on combinations of calcia, alumina, magnesia, silica, and zirconia that have a higher melting and softening temperature than mineral wool. Ceramic fibers are generally more expensive than mineral wool. Recently, fiber manufacturers have introduced biosoluble grades of MMMFs to address health and safety concerns associated with respirable fibers.

Chopped carbon fibers derived from either pitch or polyacrylonitrile are also used to provide reinforcement in friction materials but their lubricating tendency lowers the friction level. Although prices have come down in recent years, these reinforcements are quite expensive as a friction material ingredient.

Different grades of chopped low-carbon steel fibers are used as reinforcements and friction enhancers in formulations. Steel fibers have good reinforcing properties and thermal resistance but high density, poor corrosion resistance, and high thermal conductivity. Chopped stainless steel fibers have found limited application in friction materials and backing layers. Some manufacturers have developed annealed and softer grades of steel fiber to reduce rotor and drum wear.

Wollastonite is a natural calcium metasilicate mineral with an acicular structure. Silanized and uncoated versions with maximum fiber lengths up to 25 μm are used as inexpensive secondary reinforcements in friction materials. Short fiber attapulgite clays have also been developed as secondary reinforcements.

Potassium titanate whiskers were found to improve the tribological properties of NAO friction materials.[8] These soft, synthetic refractory materials stabilize friction level, reduce pad wear, noise, fade, thermal conductivity, control porosity, and provide thermal reinforcement. Fibrous potassium titanates are being replaced by platelet and powder versions because of health concerns associated with respirable fibers.

These platy and powder titanates help to improve friction stability, wear and noise performance, but do not provide the thermal crack resistance or porosity control characteristics of fiber versions of titanate.

Friction Modifiers

Friction modifiers are ingredients used in friction materials to alter the friction, wear, and noise behavior. Some friction modifiers also serve as fillers for reducing product cost.

Abrasives are universally used in friction materials to provide the desired friction and wear characteristics. Abrasives also help to clean up corrosion products and other deposits that form on the rotor. The most widely used abrasives are metal oxides and silicates. Examples of abrasives are finely divided magnesium oxide, iron oxides, alumina, chromia, zircon, zirconia, mullite, tin oxide, iron chromite, and silicon carbide. Harder and larger size abrasive particles are used in aggressive formulations that exhibit higher friction level. Finer and softer abrasives are gentler to the rotor and, in general, generate lower friction levels, wear, and noise. In addition to particle size and hardness, morphology also plays a large role in determining the function of an abrasive. Many friction formulations use a combination of abrasives to achieve the desired end-use performance.

Carbonaceous lubricants are used in most friction materials as a cost-effective way to control friction material performance, wear, and NVH characteristics. Commonly used carbonaceous lubricants are natural and synthetic graphites and metallurgical and petroleum cokes.

Fibers and chips of nonferrous metals and alloys like copper, brass, aluminum, zinc, and bronze are used in friction materials to provide the desired friction and wear performance. Porous and solid metal powders like tin, brass, copper, bronze, and iron are also used in some products. As mentioned earlier, some metal powders are also used as binders in sintered formulations.

A variety of metal sulfides and their mixtures have been employed to improve the friction stability, wear, and noise characteristics of friction materials.[9] Commonly used sulfides are antimony trisulfide, molybdenum disulfide, tin sulfides, zinc sulfide, copper sulfides, titanium sulfide, and bismuth trisulfide. Sulfide lubricants are usually used to complement carbonaceous lubricants. Fluoride and molybdate additives are sometimes used to enhance the action of carbonaceous and sulfide lubricants. Examples of fluorides are calcium fluoride and cryolite. Sodium and calcium molybdates have been used in small amounts.

Friction dusts are cured coarse powders composed of polymerized cashew nut shell liquids. These materials are added to friction materials to confer friction stability, resiliency, and noise damping. Rubber and abrasive modified friction dusts are also available. Friction dusts tend to absorb solvents, causing the friction material to spring back after forming. This limits the use of cashew friction dusts to dry mixes or solvent-free wet mixes.

Rubber particles of various origins are used in friction materials to provide friction and wear improvement, noise damping, and as a cost-reducing filler. Powders made from tire peel and other recycled rubber products and partially cross-linked acrylonitrile powders are the most widely used products in friction materials.

Examples of other property modifiers are silicone powder and liquids, fluoropolymer powders, Promaxon® (processed calcium silicate), mica, vermiculite, and waxes.

Fillers

Inexpensive, finely ground minerals like barium sulfate (barytes), dolomite, limestone (whiting), clays, and silica are widely used to provide bulk and reduce the cost of friction material formulations. These materials also act as friction modifiers and alter the performance of the end product. Other less commonly used fillers are hollow and solid organic and inorganic microspheres and fly ash.

MANUFACTURING

All friction material manufacturing processes can be subdivided into the following stages: mixing of proportioned raw materials, forming of friction material under heat and pressure, oven curing to complete cross-linking of thermosetting binder resin, mechanical finishing to final configuration, and packaging.

Mixing

In the mixing process, the proportioned friction material ingredients are intimately mixed under wet or dry conditions. A variety of mixing equipment is used in the friction industry depending on the nature of the ingredients and the desired final product. Several suppliers have developed custom-made mixers suited for the friction industry. Mixers supplied by Littleford (Fig. 7), Lödige, Eirich (Fig. 8), Henschel, and MTI are widely used in the friction industry. These mixers are basically static or rotating cylindrical containers with heavy-duty mixing and chopping blades designed to open fibers and disperse ingredients uniformly.

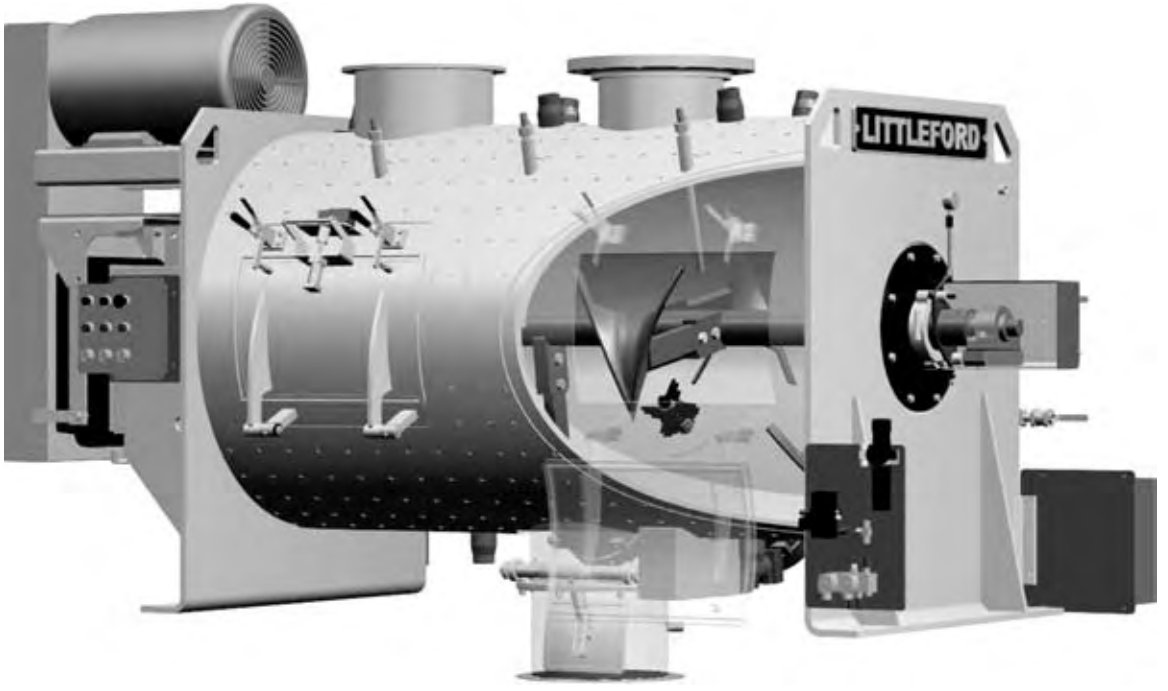

Fig. 7 Cutaway view of a Littleford ploughshare mixer. (Courtesy of Littleford Inc.)

Some mixers are provided with temperature control jackets for heating or cooling. Solvents or liquid resins can be introduced into the mixers through spray nozzles during the mixing cycle. Littleford and Lödige ploughshare mixers use mixing ploughs mounted on a horizontal shaft running in a cylindrical shell. A chopper with a variety of different blades is mounted on the mixer wall. The Eirich mixer uses a mixer blade that rotates in a tilted cylindrical shell. The MTI mixer uses a mixer blade in the bottom of a vertical cylindrical mix chamber with a chopper mounted in the wall.

Various mix parameters can be changed to control the dispersion of ingredients and the ''fluffiness'' of the mix: 1) mixing time: good opening of fibers and dispersion of ingredients requires an appropriate mixing duration—mixing for too long can cause agglomeration and/or degradation of fiber length; 2) adjusting mixer load; 3) changing chopper configuration and speed; and 4) order of addition of ingredients.

Fig. 8 Cutaway view of an Eirich mixer showing mixing action. (Courtesy of Eirich Machines.)

Rubber premixes made using bale rubber are processed in high-intensity Banbury mixers that are widely used in the rubber processing industry. The mixer uses two heavy-duty counterrotating mixer blades to intimately mix fillers and fibers into the rubber. The product of Banbury mixers are either directly formed in a cure press or used as an ingredient in a friction formulation after size reduction.

Preforming

Many manufacturers preform the dry or wet mix into briquettes prior to press curing. The preforms are usually made by briquetting mixes at room temperature. Although an additional step in the manufacturing process, preforming is used to improve utilization of the cure presses. Some manufacturers bypass the preforming step by producing a granular, free-flowing mix that can be directly metered into the cure press molds.

Friction Material Forming

Disk pads

In the integral molding process for fabricating disk pads, the preforms or loose mix is molded onto a shoe

or metal backing in a press under high pressure and at temperatures ranging from room temperature to around 150°C. Prior to molding, the friction material side of the shoe or metal carrier plate surface is coated with an adhesive after a surface treatment designed to promote adhesion. Some products designed for heavy-duty applications use a mechanical attachment technique instead of adhesive attachment. Depending on the temperatures used, the pressing process is classified as cold, warm, or hot pressing. In the past, disk pad shapes molded without a backing plate were riveted onto a backing plate. This process is generally being replaced by the integral molding process.

Drum linings

For riveted and bonded linings, the drum friction material segment is first formed into shape by either positive molding or extrusion techniques. In the positive molding process, drum linings are formed under heat and pressure from a dry mix in either flat or curved molds. If a flat sheet fabrication method is used, the formulation is only partially cured so as to allow subsequent forming on a mandrel into a curved shape. Extrusion forming is a low-cost manufacturing process for bondable drum linings where a granulated mix is extruded through a rectangular orifice. Liquid phenolic or cashew nut shell resins and rubbers with or without solvents are used to produce an extrudable mix with sufficient tack. The mix is forced into the nip between forming rollers that extrude the friction material in strip form. Some manufacturers embed a wire backing into the extruded strip to provide strength during process handling and service use. The strips are then either formed into rolls or cut into the desired length and cured in confined preforms to confer the curved shape required in use.

Postcuring

A final oven cure cycle is needed to complete the cure of the binder resin started in the molding process and also to develop the maximum heat resistance of the friction material. Both batch and continuous ovens using convection or infrared heating are used in curing friction materials. Typical oven cure cycles can range from 1 to 16 hr depending on the cured product. Both disk and drum linings can be cured either free or confined by steel plates under pressure. Although confined curing is more expensive than free curing, it reduces the chance of delamination or debonding during oven cure. After postcuring, the inner and outer surfaces of the formed linings are finish ground to the desired thickness. For bonded applications, adhesive is applied on the inner surface before the lining is bonded under pressure and heat onto the carrier shoe. In riveted

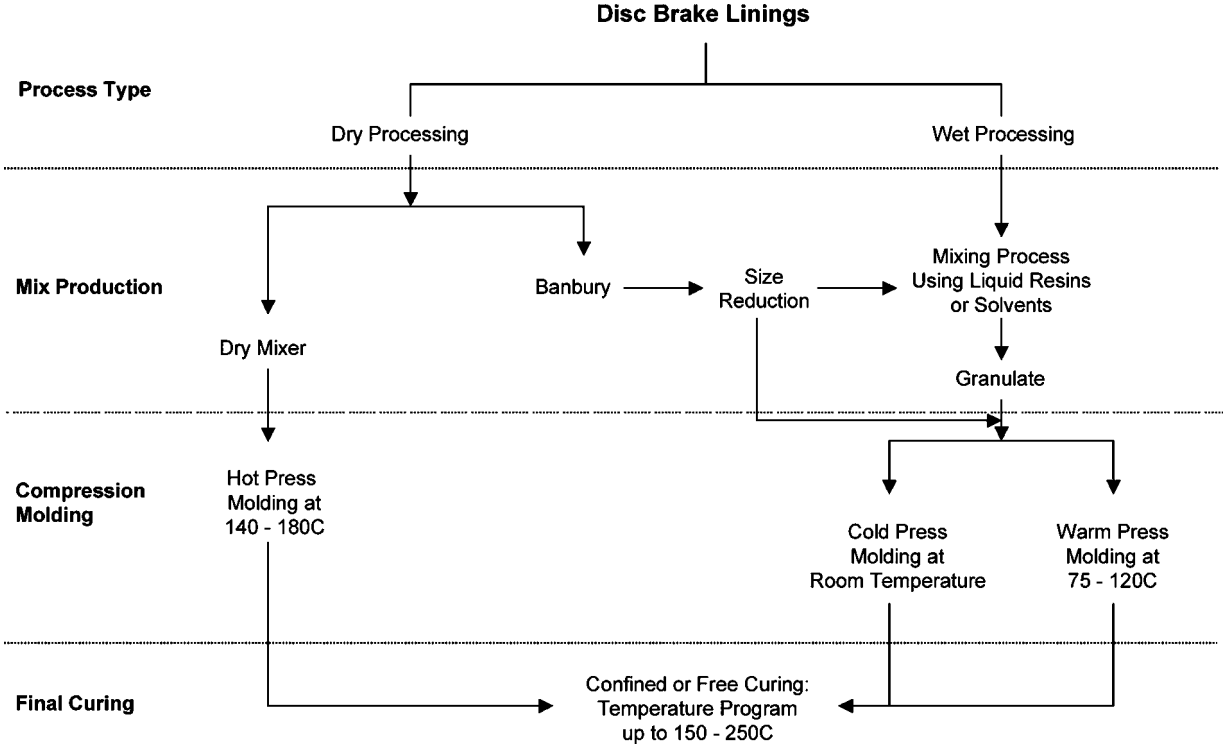

Fig. 9 Disk brake pad production processes.

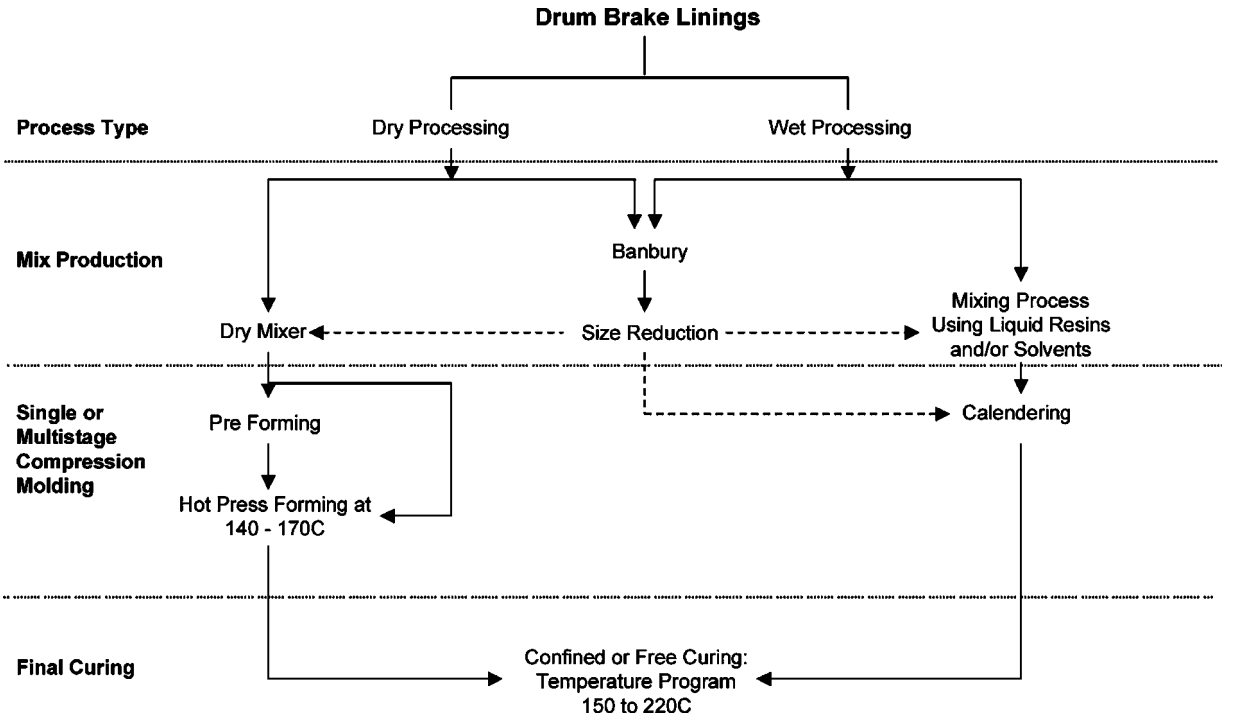

Fig. 10 Drum brake lining production processes.

applications, the drilled linings are riveted onto the carrier shoe with multiple metal rivets. Some manufacturers use integral molding onto a carrier shoe to produce drum linings designed for thermally demanding applications. Figs. 9 and 10 summarize the various disk pad and drumlining manufacturing processes.

Postcure finishing

Disk brake pads and drum linings are finish ground to the final dimensions after the oven cure process. Sometimes, the surface of disk pad products are scorched or seared under the influence of heat applied in the 250–700°C range. This burns off the organics in the pad surface and helps the initial friction properties of brake pads. Scorching can be accomplished by a variety of methods—direct gas flame, contact with an electrically heated hot plate, or radiant heat from a heated surface. Subsequently, the parts are painted and stenciled with product information prior to packaging.

CONCLUSIONS

Friction material technology has gradually evolved over the past century driven primarily by increasing demands on end-use performance or environmental considerations. The recent introduction of FMVSS 135 has placed increased demands on automobile brake friction materials. In addition to higher friction performance, a more general requirement exists for increasing product life to help extend maintenance periods. These requirements are in addition to the basic requirements of excellent NVH performance at the lowest product cost.

The main limitation in developing friction materials that satisfactorily meet customer needs is the lack of basic understanding of complex relationships between various friction material structures and compositions, and their interactions with brake system hardware and operating conditions. These areas offer major opportunities for research in addition to an understanding of basic third-body tribological mechanisms. A better understanding of the correlation between friction material composition and characteristics and dynamometer/vehicle performance will help in increasing the efficiency of the friction product development process. Artificial intelligence and other computational productivity tools have been playing an increasing role in complementing conventional compounding techniques to give companies a competitive edge.[10,11] Improved and efficient bench tests, which better correlate with vehicle performance, are needed to speed up screening of formulations.

In addition to product improvements, continuous improvement of processes to reduce scrap, improve quality, and reduce production time and energy requirements is essential to insure future competitiveness

among friction material manufacturers. Several companies are aggressively applying lean manufacturing and six-sigma techniques to stay competitive.

In the longer term, alternative automotive braking methods may play an increasing role. Examples of such technologies are electric and/or magnetic brakes. The increased adoption of electric and hybrid propulsion systems will greatly influence braking requirements. The need to develop cost-effective friction material solutions for these applications will pose further challenges.

Fuel Cell Membranes

Andrew M. Herring
Department of Chemical Engineering, Colorado School of Mines, Golden, Colorado, U.S.A.

INTRODUCTION

One of the driving forces of the recent interest in proton exchange membrane (PEM) fuel cells (FCs), is the dramatic improvement in performance that has been achieved in commercially available PEM. The membrane in PEM FCs must allow the transport of a high flux of protons while having low reactant crossover, be stable to oxidative attack, be electrically insulating, and be of desirable mechanical properties. Fast start-up and high current densities of several amperes per square centimeter are easily achieved with lifetimes of over 60,000 hr of operation. Platinum must currently be used as the catalyst for both the anode, fuel oxidizing, and the cathode, oxygen reducing electrodes, at these low operating temperatures. Because some oxygen crossover is inevitable, oxygen reacts at both the electrodes to form hydroxyl radical as a by-product. The resultant hydrogen peroxide produced at the membrane electrodes is thus significant and so the materials from which the membrane can be constructed are limited to oxidatively stable fluorinated and fully aromatic polymers. The current state-of-the-art membranes are fabricated from perfluorinated sulfonic acid (PFSA) polymers, such as Nafion®. High proton fluxes are obviously achieved by manufacturing membranes as thin as possible, and thus most state-of-the-art membranes are reinforced with inert fillers or scaffolds. These materials only have useful, high proton conductivities when fully hydrated limiting their usefulness to temperatures below 100°C. These hydrated sulfonated systems are well understood in terms of proton transport, water diffusion, and electro-osmotic drag (transport of water with the protons under FC operation). Ion transport between sulfonic acid groups is highly dependent on the bound and free water associated with those sites and may be described in terms of both a proton hoping, Grotthus mechanism and a Vehicle mechanism in which the protons move in association with one or more water molecules leading to electroosmotic drag. Water management issues with these materials are therefore crucial to a successful FC design as water is being constantly transported from the anode, which tends toward dry-out, to the cathode where it is being produced by the electrochemical reaction leading to flooding. Other desirable properties of an ideal PEM would include the ability to operate at moderately elevated temperatures, 120–200°C, with no external humidification, and to be manufactured inexpensively. Operation of the PEM FC at temperatures above 100°C is desirable as the platinum catalyst is severely poisoned by carbon monoxide, a by-product of reforming hydrocarbon fuels to hydrogen, below 100°C. Current research therefore is focused on developing PEM capable of operation at these moderately elevated temperatures in the absence of external humidification. Other active areas of research at the current time are concerned with maximizing the lifetimes of PEM and reducing their cost of fabrication. Further resources describing this topic area are available.[1–6]

MEMBRANE CHARACTERISTICS

The initial membranes developed for PEM FC were for space applications where the emphasis was solely on performance and durability.[7] The recent excitement with PEM FC is that they may one day be widely be applied in automotive applications, where in addition to high performance and durability, the membrane must also be inexpensive.[4,5] The current well-developed PEM FC technology is based on PFSA polymer membranes as the electrolyte. All the currently used PFSA membranes are composed of carbon–fluorine backbones with pefluorinated ether side chains containing sulfonic acid groups. (Table 1).[8] The processes occurring in a PEM FC are shown in Fig. 1. The power produced by a FC is a product of the cell voltage and the current produced. The ideal standard voltage of a H_2/O_2 FC is 1.229 V at 298 K. In reality various losses determine the current that can be drawn at useful power densities (Fig. 2). The biggest single loss in the system is attributed to slow reaction rates at the platinum cathode. The catalytic activity of oxygen reduction is high in the PFSA electrolyte because the sufonic acid groups do not adsorb on the platinum surface.[8] Fast reaction kinetics at both the electrodes is also enhanced as long as the coating electrolyte film is optimized because the solubility of the reactant gases, H_2 and O_2, are high in the electrolyte. Losses attributable to the membrane are reactant crossover and short-circuit voltage losses as

well as ohmic losses associated with membrane and membrane catalyst's interface resistances.

Proton Transport

In an idealized PEM FC only protons would be transported across the membrane (Fig. 1). Proton conductivities of membranes are measured in siemens per centimeter and are typically on the order of 0.1 S/cm for fully hydrated PFSA membranes.[2,3] High proton conductivities of membranes depend on a high ion exchange capacity, which is expressed usually as the inverse equivalent weight that ranges from 1100 to 1000 or less; this is equivalent to an ion exchange capacity of 0.8–1.1 meq/g. The other critical factor for high proton conductivity is the membrane thickness, the thinner the membrane the higher the flux of protons. A typical unsupported PFSA membrane used in an FC membrane electrode assembly (MEA) is 150–170 μm in thickness. Water content is also critical, the water content of the membrane is expressed as λ, the moles of water per mole of acid group, and is typically 21–23 for Nafion.[9] Two mechanisms of proton transport have been differentiated: in the first, the so-called, Grotthus mechanism, protons hop between fixed acid sites; in the second, the so-called, Vehicle mechanism, protons move through the membrane with associated water molecules. It is this Vehicle mechanism which is important to fully hydrated PFSA membranes.

Water Management

The transport of the water associated with protons is called electroosmotic drag and typical coefficients of H_2O/H^+ for PFSA membranes are 3 and 4 at 80°C (Fig. 1).[10] Electroosmotic drag is independent of the membrane thickness, proportional to the current density, and induces a water concentration difference between the anode and the cathode.[11] The electroosmotic drag coefficient, K_{drag}, increases with the membrane water content (Fig. 3).[6] At the high current densities at which PEM FC are run; therefore, significant amounts of water are being removed from the anode and transported to the cathode. As the PFSA membrane must be fully hydrated, this leads to significant water-management issues. One advantage of thinning the membrane is that back diffusion of water from the relatively wet cathode to the relatively dry anode will increase (Fig. 1). The diffusional flux of water, j_{H_2O}, from cathode to anode may be derived from Fick's law

$$j_{H_2O} = -D_{H_2O} \frac{C^c_{H_2O} - C^a_{H_2O}}{\Delta x}$$

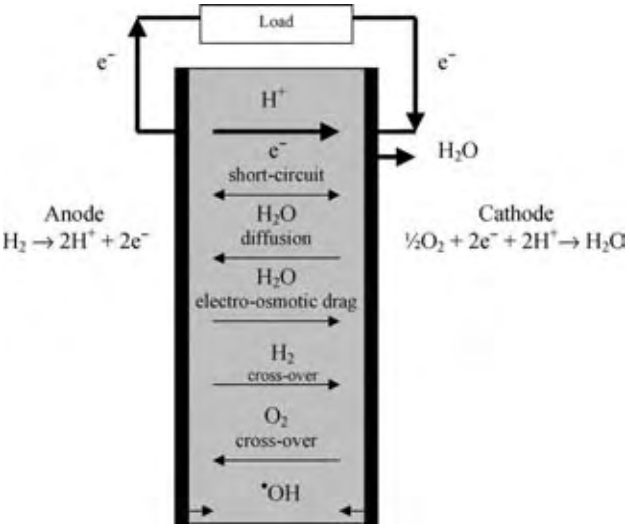

Fig. 1 Membrane processes occurring in a polymer electrolyte FC.

where $C^{c}_{H_2O}$ and $C^{a}_{H_2O}$ are the membrane water content at the anode and the cathode, respectively, Δx is the membrane thickness, and D_{H_2O} is the water diffusion coefficient in the membrane.[11] D_{H_2O} can be assumed to be a linear function of the water content λ, so that $D_{H_2O} = 7.1 \times 10^{-7} \times \lambda\,cm^2/sec$.[11] The thinness of FC membranes cannot be solely designed based on the need for high proton fluxes and high back diffusion, as thinner membranes will not be structurally robust, although state-of-the-art membranes are reinforced. As the membrane thickness is decreased reactant crossover increases. The permeability of oxygen and hydrogen is 10^{-11} and 10^{-10} mol/cm/sec/atm, respectively, corresponding to a loss of 1–10 mA/cm^2 or 1% for Nafion 117.[3,8] Both crossover and electrical shortening lead to decreases in cell efficiency, which are manifested in decreases in the open circuit voltage of the cell. These factors limit the practical thickness of a PEM. It is therefore necessary to humidify the PFSA membrane by methods other than back diffusion. The most common method of humidifying the membrane is to humidify the reactant gases using bubble humidifiers. Care must be taken to not over humidify the cathode, as too much water will result in liquid water flooding the electrode leading to transport losses (Fig. 2). Various internal humidification schemes have been proposed to transport water from the cathode to the anode, such as using porous carbon bipolar plates, current collectors, as were used in the phosphoric acid FC, and sewing wicks into the membrane to wick the water back to the anode. It has also been proposed to impregnate the membrane with Pt nanoparticles, which would catalyze the production of water from the crossover H_2 and O_2.[12] This has the added advantage of increasing the open circuit potential of the cell, but not the cell's efficiency. The Pt nanoparticles might also decompose hydroxyl radical (see below).

The most widely used model of the structure of water-swelled Nafion is that of Gierke.[13] In this model the polymer is assumed to form reverse micelles of radius 20 Å connected by small cylindrical pores 10 Å in length and 5 Å in radius. This model breaks down for all swelling states of the membrane and although modified to include more ordered structures, it has only been recently that a new more comprehensive picture has emerged from extensive small angle X-ray scattering (SAXS) and small angle neutron scattering (SANS) studies. It is now proposed that the structure comprises cylindrical or ribbon-like polymeric aggregates surrounded by ionic groups and water molecules.[14] In general, compared to other ionomers, Nafion has relatively wide, more separated, and less branched channels with good connectivity, small sulfonate separation, and a pK_a of ~6 (Fig. 4).

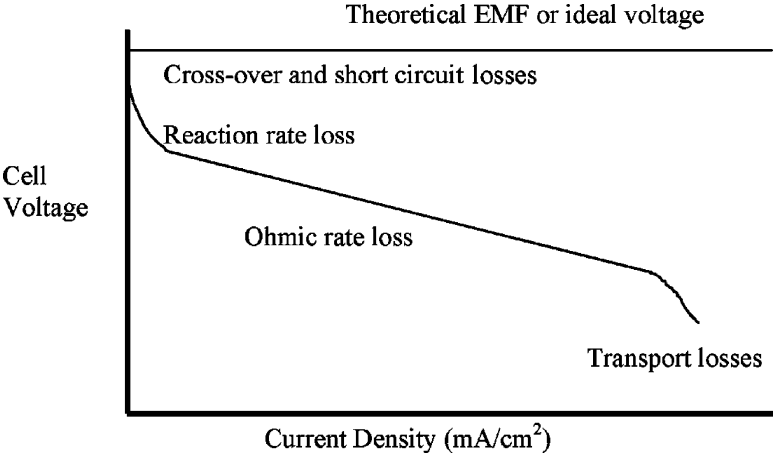

Fig. 2 Polarization curve for a realistic polymer electrolyte FC.

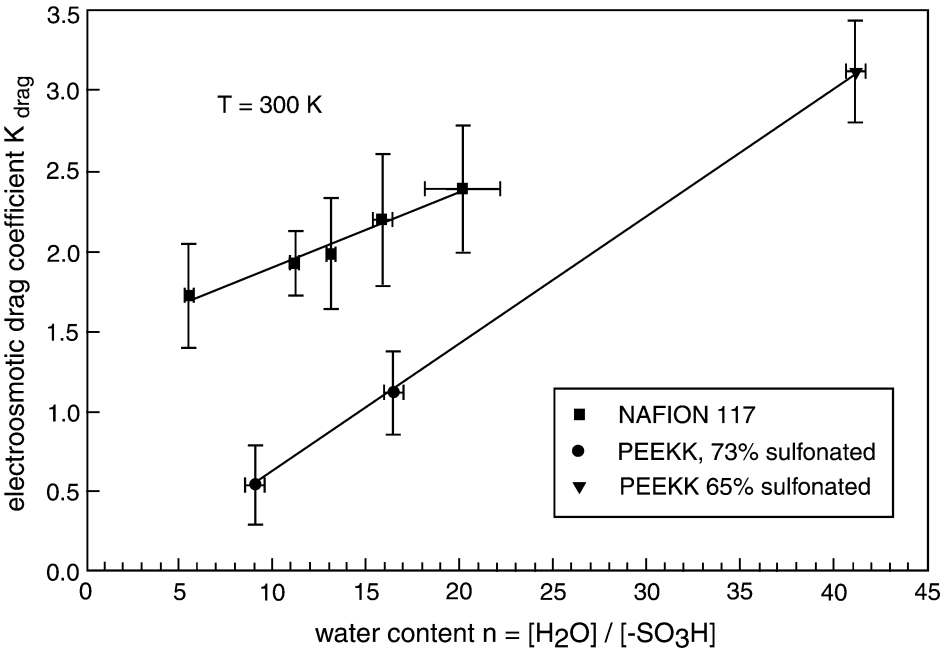

Fig. 3 Electroosmotic drag co-efficient obtained by electrophoretic-NMR as a function of the water content, $n = [H_2O]/[-SO_3H]$. (From Ref.[6].)

Oxidative Stability

Although the anode side of a PEM FC may be considered to be operating under reducing conditions, the cathode side is severely oxidizing. Not only is oxygen present and activated by the catalyzed cathode electrode, but a key intermediate in the reduction of oxygen, hydroxyl radical, is released at the cathode; additionally, as oxygen does diffuse across the membrane, hydroxyl radical is also formed at the anode. The PEM is therefore subjected to very harsh oxidizing and acidic conditions. This is the biggest limitation on the choice of materials that may be used to fabricate a PEM FC. A PFSA membrane can be imagined to decompose in the presence of hydroxyl radical by the following three idealized steps:[15]

$$R_f{-}CF_2COOH + {}^{\bullet}OH \rightarrow R_f{-}CF_2^{\bullet} + CO_2 + H_2O$$

$$R_f{-}CF_2^{\bullet} + {}^{\bullet}OH \rightarrow R_f{-}CF_2OH \rightarrow R_f{-}COF + HF$$

$$R_f{-}COF + H_2O \rightarrow R_f{-}COOH + HF$$

It should be noted that the products of this decomposition are water, carbon dioxide, and HF. While PFSA membrane FCs have been demonstrated for many thousands of hours, the flux of HF is significant enough so that uncoated metallic bipolar plates are precluded. Hard to machine graphite bipolar plates must be used or an electrically conducting corrosively resistive coating must be developed for easily fabricated metal bipolar plates. Lifetime studies of PEM FC membranes are usually expressed in terms of the decay in cell voltage while under operation. As the membrane is corroded by the harsh conditions of the cell, pinholes will inevitably develop leading to reactant crossover and decay in the cell voltage. Decay rates of less than $6\,\mu V/hr$ can now be obtained with state-of-the-art PFSA membranes.[16] Metal ion impurities in the membrane, such as iron or cobalt, dramatically affect the life of the membrane, as supplied Nafion is always boiled in nitric or sulfuric acid, to also ensure it is in the acid form, hydrogen peroxide, and DI water to clean the material prior to use. To test for oxidative stability, membranes are routinely boiled in Fenton's reagent in which an iron compound is used to generate a large concentration of hydroxyl radical. While PFSA membranes survive this test, many experimental membranes currently under consideration do not, and while the test is useful, it represents an unrealistically high concentration of hydroxyl radical than would be found in a FC. Another related failure mode of anhydrous Nafion is that it loses sulfonic acids groups above 165°C.

Mechanical Attributes

The membrane must be mechanically robust and also suitable for manufacture. One of the consequences of the need for a fully hydrated membrane is that the membrane will shrink and swell between operation and resting. This can have dire consequences for an FC stack that must be sealed if the membrane dimensions are radically changing between on and off conditions. So, ideally the membrane should not

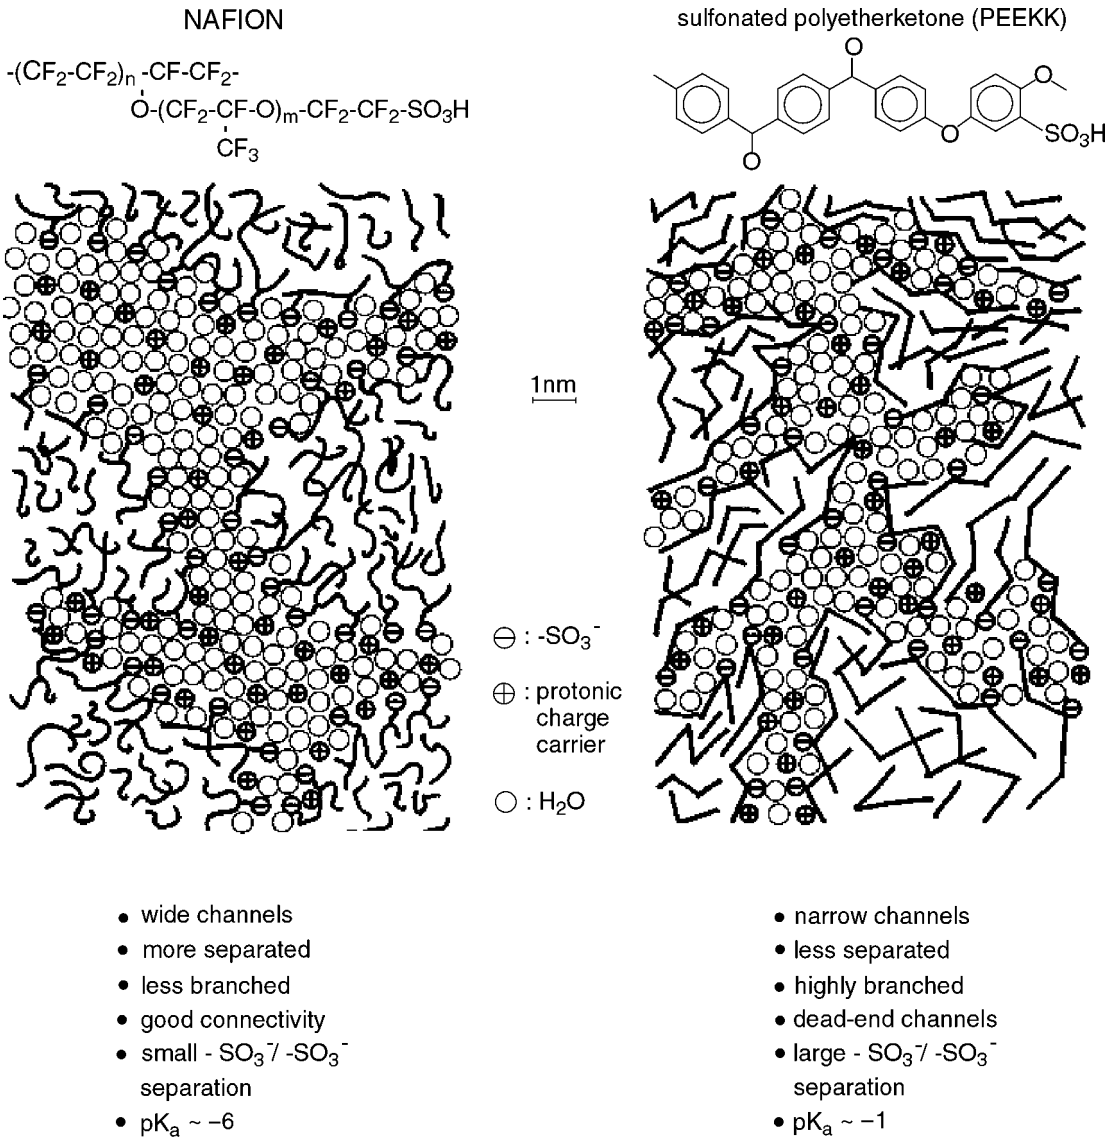

Fig. 4 Schematic representation of the microstructures of Nafion and a sulfonated PEK (derived from SAXS experiments) illustrating the less pronounced hydrophobic/hydrophilic separation of the latter compared to that of the former. (From Ref.[6].)

change dimensionally between water swollen and dry states. Nafion 117 typically shrinks 10% between wet and dry states.[17] Water also acts as a plasticizer in PFSA lowering the T_g and the tensile strength of the material. Nafion loses half of its tensile strength between dry and fully hydrated states.

HISTORY OF PEM FC

The proton membrane FC was discovered in the late 1950s at GE; the first PEM FC was constructed using phenol–sulfonic ion exchange membranes. The cells operated at 15 mA/cm^2 at 0.6 V for 500 hr.[7] The next significant breakthrough that came in the 1960s for the Gemini space program was the development of sulfonated polystyrene resins. After optimization, these membranes were capable of 300 mA/cm^2 at 0.6 V and 4000 hr of operation.[7] These membranes were limited in the oxidizing environment of the FC as the methylene CH bonds were too susceptible to oxidation. The next improvement was the introduction of Du Pont's Nafion PFSA membrane, which gave an operating time in excess of 10,000 hr. NASA funding for PEM FCs ended in the mid-1970s and while interest continued to grow in the intervening decades, large increases in performance have only begun to be achieved in recent years as the emphasis and interest has switched to the potential for PEM FCs in automotive applications. Currently, the biggest barrier to commercialization is cost, while no FCs are currently mass produced and so it is hard to get a true idea of what a realistic cost would be,

FCs must cost around \$45/kW to be competitive with the internal combustion engine. Perfluorinated sulfonic acid membranes currently cost \$100–200/KW resulting in PEM FC prices estimated to be of the order of \$1000/KW.

MEMBRANES FOR HIGH-TEMPERATURE AND HIGH-PERFORMANCE OPERATION

There is considerable interest in developing PEM that will allow FC operation at elevated temperatures, 120–200°C. The two primary reasons are to allow the use of carbon monoxide contaminated H_2 from reforming hydrocarbons and to facilitate heat transfer. The platinum catalyzed anode is poisoned by as little as 20 ppm of carbon monoxide at 80°C, but can tolerate 1000 ppm at 130°C and 3% at 200°C.[3,8] Very pure hydrogen for PEM FC operating at 80°C is produced via a costly multistep process. In fact, the reformer costs as much as the FC. Raising the temperature of operation of the FC to 120°C or above will dramatically decrease the complexity and expense of the reformer. An FC run at 120°C will seamlessly fit into the existing automotive radiator technology facilitating cooling. At these and higher temperatures, stationary combined heat and power applications become attractive. Other advantages of higher-temperature operation include faster electrode kinetics because of enhanced gas transport, and higher reliability due to system simplification with only one phase of water. As can be seen from Fig. 5, no polymer seriously outperforms Nafion below 100°C and only phosphoric acid-doped benzimidazole and polybenzimidazole (PBI) have appreciable proton conductivity at higher temperatures. The field of emerging materials for higher PEM FC operation has been recently reviewed.[2,6,8] In addition to the high temperature limitations of PFSA, the cost of fluorinating the polymer has often been invoked as the reason for the materials relative expense. The manufacturers obviously dispute this quoting the relatively low volumes of material as the reason for the high cost. Fluorination remains a process of environmental concern and the search is on for a greener PEM.

Reinforced Perfluorosulfonic Acid Membranes

Perfluorinatedsulfonic acid membranes are limited to temperatures of operation below 100°C because they must be fully hydrated. By reinforcement, PFSA membranes may be made much thinner allowing enhanced back diffusion of water. Perfluorinatedsulfonic acid membranes enforced with polytetrafluoroethylene (PTFE) or Teflon® are used in industrial electrochemical membranes, but these are much too thick for FC applications. Goretek® is stretched PTFE, which forms the basis for the Gore-select® membranes in which Goretek® is impregnated with Nafion. Gore-select® membranes are transparent and have ionic conductivities

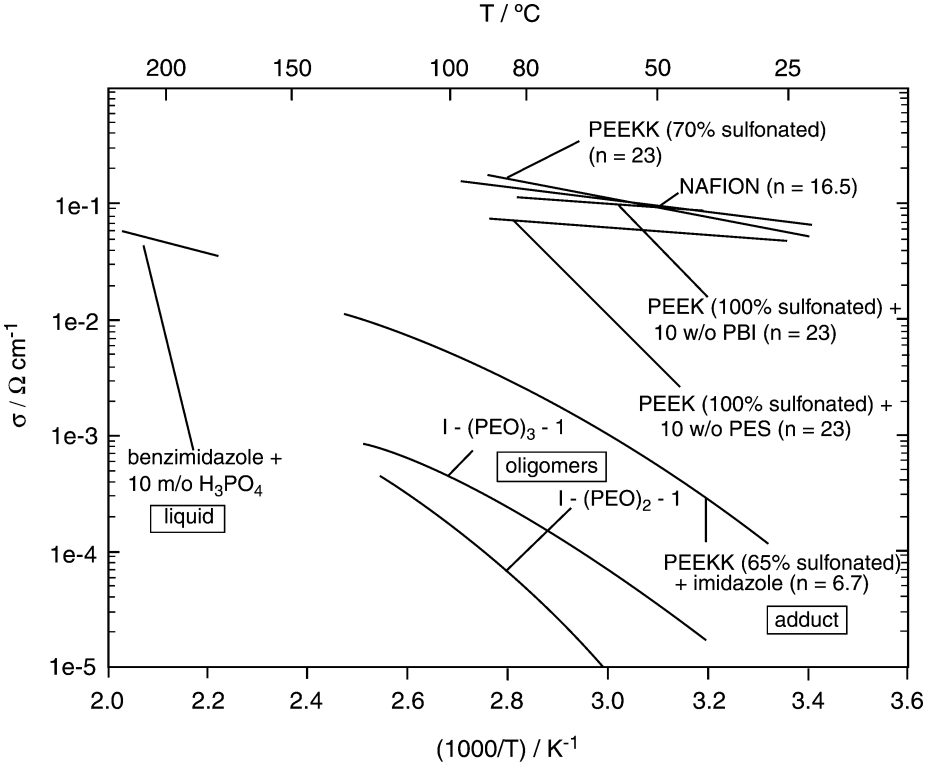

Fig. 5 Proton conductivity of different fully hydrated acidic polymers and a liquid, an adduct, and an oligomer containing heterocycles as proton solvent. (From Ref.[6].)

and equivalent weights comparable to Nafion while being an order of magnitude thinner, on the order of 5–20 μm. In addition, the gore-select membranes are dimensionally stable between wet and dry states shrinking only 2% and losing little tensile strength.[17] Recent advances with these membranes resulted in significant stabilization to peroxide attack. The membranes do indeed perform well under relatively dry conditions showing little degradation in performance at 80°C or 95°C with relative humidities decreased from 100% to 30%. A Gore MEA has been demonstrated at 120°C giving a current density of 250 mA/cm^2 at 0.6 V compared to 20 mA/cm^2 for Nafion 117 under the same conditions. Asahi Glass has developed a reinforced Flemion using 2–5 wt% dispersed PTFE fibrils.[3,8] This reinforcement again allowed improved mechanical strength of the membrane and decrease in thickness of the membrane from 100 to 50 μm. Du Pont has made available a PTFE reinforced PFSA, Nafion 324 and 417, for many years for industrial electrochemical applications but these materials are too thick for FC applications. Du Pont is now offering a strengthened thinner Nafion for FC applications, but little is known about this new ionomer.

Modified PFSA Polymers

Various additives have been added to PFSA membranes to either replace the water or to retain the water at higher temperatures. Nafion has been swollen with phosphoric acid and a conductivity of 0.05 S/cm has been achieved at 150°C. Unfortunately, the anode fails after a short period of time in these membranes so no successful FC tests have been run.[8] 1-Butyl,3-methyl imidazolium triflate and tetrafluoroborate have also been used to swell Nafion giving a conductivity of 0.1 S/cm at 180°C. Nafion has also been swollen with heterocycle solutions, imidazole, and imidazolium salts in trifluoroacetate and trifluoro methane sulfonate solution, although the reported conductivities are more modest, 10^{-3} S/cm at 100°C.[8] Acetic acid and tetra-*n*-butylammonium chloride solutions of the heteropoly acid (HPA), 12-phosphotungstic acid (PTA), have all been used with Nafion giving improved FC performance at 110°C and 120°C, respectively, vs. the undoped PFSA.[18]

As mentioned above, platinum nanoparticles have been used to generate water in the membrane in situ from hydrogen and oxygen crossover. TiO_2 and 3 wt% SiO_2 nanoparticles have also been used to retain water in the membrane under hot and dry conditions. There has been considerable interest in composite recast PFSA membranes using inorganic super acids and oxides. The HPAs are a large and diverse set of super acid inorganic oxides of which a few can be obtained commercially and have been extensively studied. It should be pointed out that the generalizations in the literature to date are only based on the three or four commercially available HPAs and not on the many hundreds of structures that have been reported in the literature since the late 19th century. The common commercially available HPAs, PTA, 12-sillicotungstic acid (STA), and 12-phosphomolybdic acid (PMA), have the Keggin structure (Fig. 6).[19] The theory is that if the pK_a of the nonvolatile acid is higher than the pK_a of the PFSA electrolyte, it will solvate the proton of the stronger sulfonic acid, creating the ionic network clusters for conduction.[2] In addition, the free acids in the electrolyte pores will also conduct protons through self-ionization. Recast HPA-composite membranes are fabricated as follows. A commercial 5% Nafion solution is reduced by 50% and mixed with the appropriate concentration of HPA. Cast membranes are then produced by evaporation of the solvent from various amounts of solution to give membranes of thickness 15–500 μm. The films are then dried at 45–60°C for 24 hr and then in an oven at 130–170°C for 4 hr. The resultant films were peeled off the casting plate and washed and stored in deionized water.[2] All the HPA/Nafion composite membranes swell more in water than in Nafion in the order Nafion 117 (27%) < Nafion/STA (60%) < Nafion/PTA (70%) < Nafion/PMA (95%) at 90°C. The ionic conductivites are also greater than for Nafion in the order Nafion 117 (1.3×10^{-1} S/cm^2) < Nafion/PMA (1.5×10^{-1} S/cm^2) < Nafion/PTA (2.5×10^{-1} S/cm^2) < Nafion/STA (9.5×10^{-1} S/cm^2) at 90°C. The FC currents at 0.6 V increase in the order Nafion 117 (640 mA/cm^2) < Nafion/STA (695 mA/cm^2) < Nafion/PTA (810 mA/cm^2) < Nafion/PMA (940 mA/cm^2) at 90°C. These membranes show less deformation than Nafion, but the tensile strength of the membranes is, however, compromised.[2] Further improvements have been achieved in the Nafion/STA by the use of thiophene. Heteropoly acids have also been immobilized in silica; a PMA/silica Nafion-composite membrane has been reported to have a proton conductivity >0.3 S/cm^2 at 90°C.[8]

Another inorganic proton conductor, zirconium phosphate, $Zr(HPO_4)$ has also attracted considerable interest in Nafion composite membranes. Zirconium phosphate, a very hydroscopic insoluble solid, has been electrochemically and chemically precipitated in the pores of PFSA membranes as well as recast from Nafion solution containing zirconium ions.[2] The preparation of recast Nafion zirconium phosphate membrane involves swelling a membrane with a 1 : 1 methanol–water solution, which is then dipped in zirconylchloride followed by rinsing and storing in 1 M phosphoric acid. Current densities using Nafion 115 of 1.5 A/cm^2 at 130°C and 3 bar pressure using H_2/O_2 have been achieved with these membranes. These

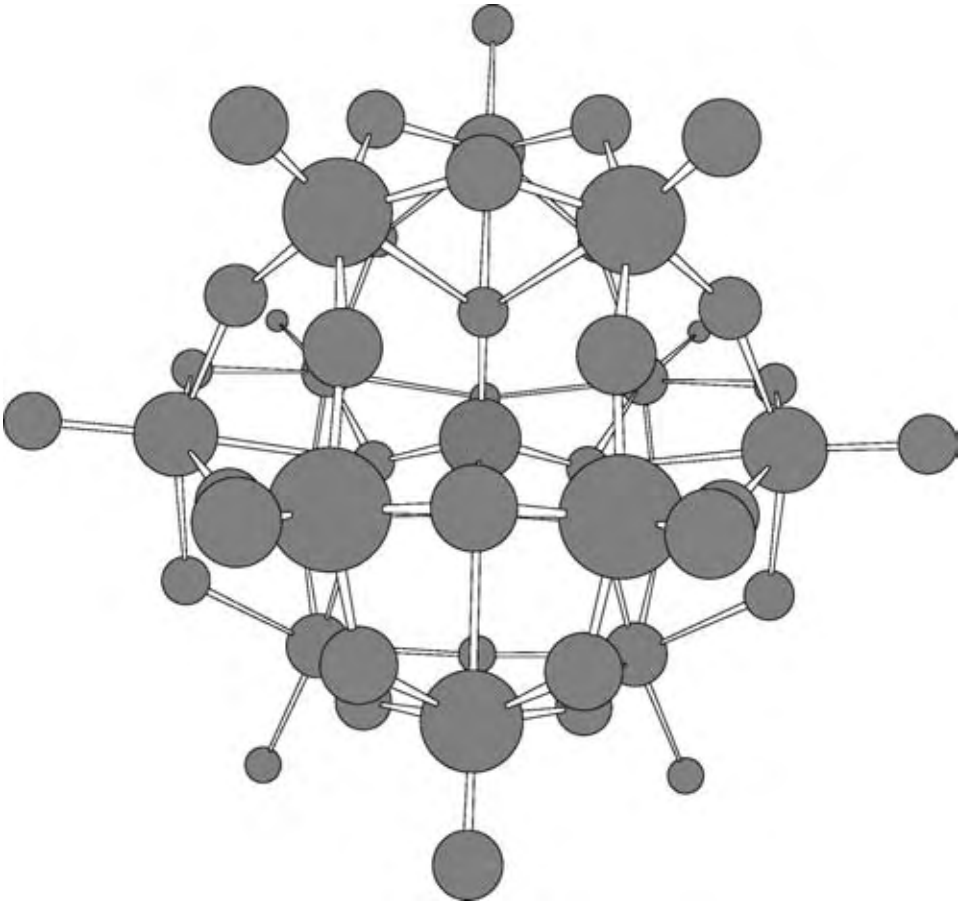

Fig. 6 Keggin anion structure, $[XM_{12}O_{40}]^{(3 \text{ or } 4)-}$ (X = Si(4–) or P(3–), M = W or Mo), atomic co-ordinates. (From Ref.[28].) *(View this art in color at www.dekker.com.)*

improvements have been attributed to the hydroscopy of the zirconium phosphate and the reduction of free spaces in the pores of the PFSA promoting capillary condensation and thus water retention.

A major modification to the PFSA electrolyte polymers is the replacement of the sulfonic acid group with a bis[(perfluoroalkyl)sulfonyl] imide acid group, i.e., $-SO_3H$ is replaced with $-SO_2NHSO_2CF_3$. This modified acid group is more thermally stable and has greater gas phase acidity than the sulfonic acid group. This ionomer can be copolymerized with tetrafluoroethylene to produce a structure very similar to Nafion except with a different proton conducting functionality. The observed dependencies on water absorption and ionic conductivity on RH and EW for the bis[(perfluoroalkyl) sulfonyl] imide polymers are similar to Nafion.[2]

Sulfonated Aromatic Polymers

Partially perfluorinated polymers

The first PEM were constructed from sulfonated polystyrene, but these materials were not of sufficient oxidative stability to survive the FC environment. Chemically, the bond strength for C–F is 485 kJ/mol higher than for C–H bonds (typically 350–435 kJ/mol). Ballard has developed a series of membrane materials based on sulfonated copolymers incorporating α,β,β-trifluorostyrene known as Ballard advanced membrane third generation (BAM3G). These materials have low EWs 320–920 g/mol and have very high water retentions. Composite BAM3G membranes have been fabricated using sulfonated BAM3G incorporated into a porous film with ion exchange and ethylene-based monomeric units. This should improve the membranes mechanical and dimensional stability but no information is available.[2] Perfluorinated grafted membranes may be prepared by radiation grafting. The perfluorinated film is irradiated and reacted with a sulfonated polystyrene to produce the electrolyte membrane. In a similar approach, trifluorovinyl aromatic monomers may be grafted to a preformed polymeric base film and modified to incorporate ion exchange groups.

Nonperfluorinated composite membranes

The basic idea of these membranes is to take a polymer that has been developed for use in extreme temperatures, atmospheres, or corrosive environments and to convert it into a PEM usually by sulfonation (Fig. 7). Sulfonation may be accomplished as follows: 1) by

direct sulfonation in sulfuric acid or chlorosulfonic acid; 2) by lithiation–sulfonation–oxidation; 3) by chemically grafting a group containing a sulfonic acid to a polymer; 4) by graft copolymerization using a high-energy radiation source; and 5) by synthesis using monomers bearing sulfonic acid groups. Purely hydrocarbon polymers, such as poly-*p*-phenylene, have excellent resistance to oxidation and thermal stability but are stiff-ridged rod polymers that are hard to process. However, polyelectrolytes based on poly-*p*-phenylene have recently appeared.[8] More often, aromatic polymers with –O–, polyether; –(C=O)–, polyketone; –S–, polysulfide; or –(SO_2) –, polysulfone linkages are employed, as these materials are more easily processed into membrane films (Figs. 7A–D). Ether linkages are particularly flexible and are the most widely used. Polyetheretherketones (PEEK) are thermoplastic polymers with an aromatic backbone in

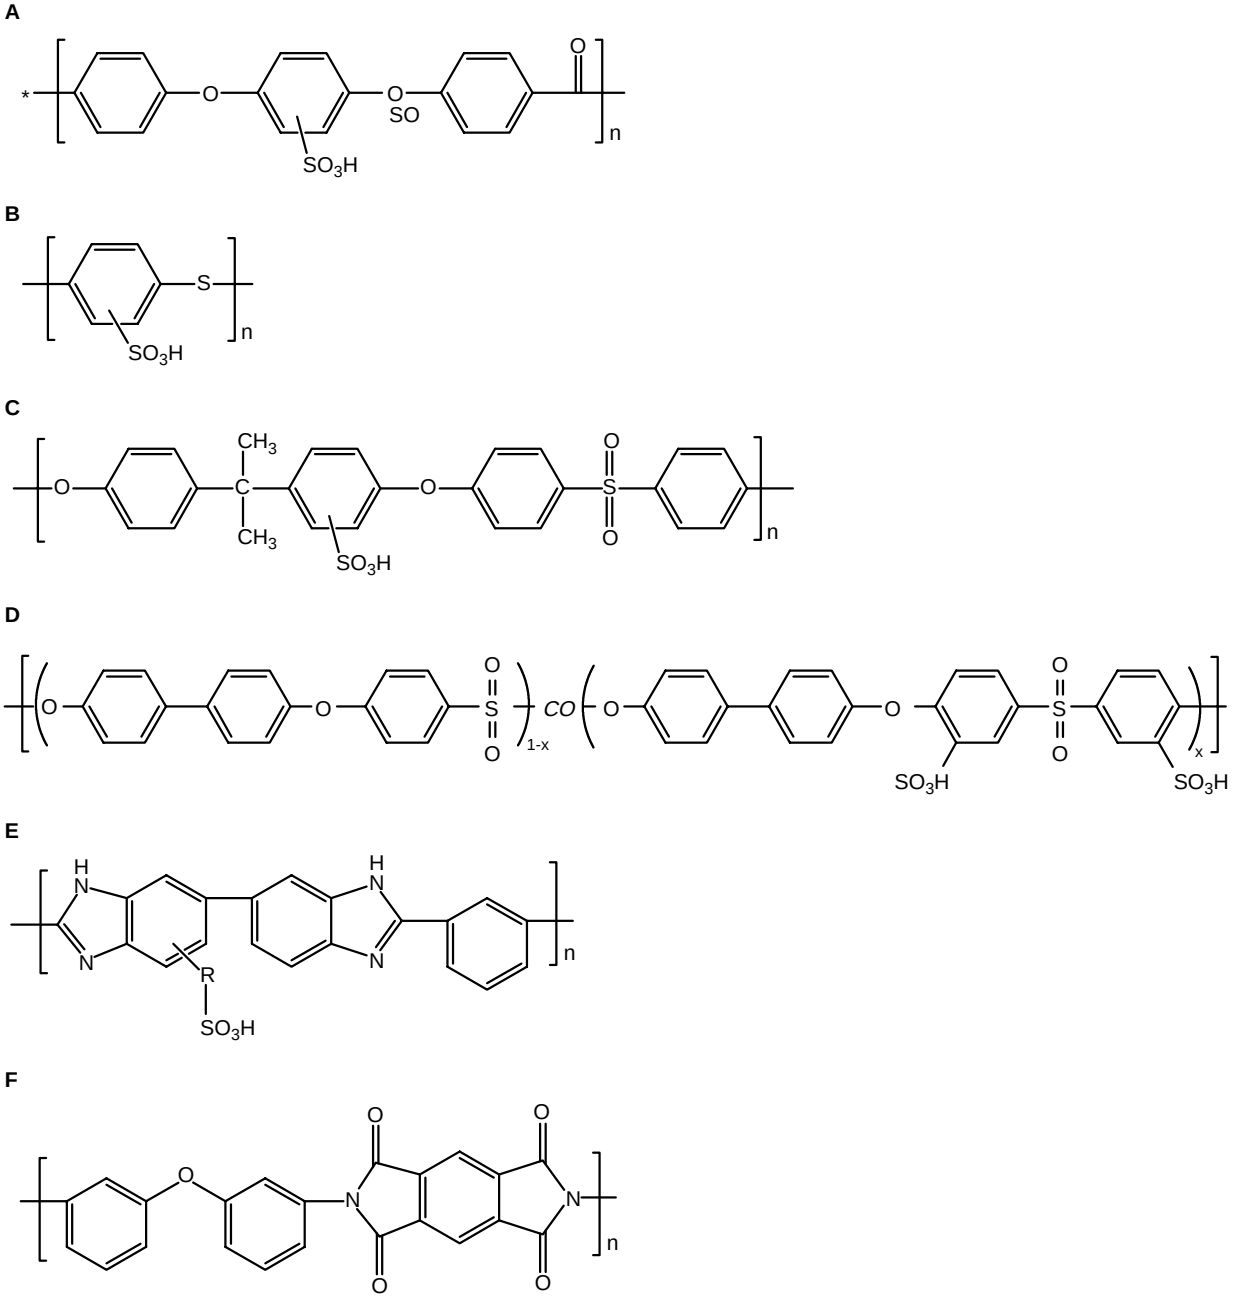

Fig. 7 Chemical structures of some sulfonated polymers and a polyimide: (A) sulfonated polyetheretherketone, PEEK, PSF; (B) sulfonated polyphenylenesulfide, PPS; (C) sulfonated polysulfone; (D) poly(4,4′-biphenol) (4,4′-dichlorodiphenyl sulfone), BPSH–XX (XX is mol% of disulfdonated units); (E) sulfonated polybenzimidazole, PBI; (F) polyimide.

which 1,4-disubstituted phenyl groups are separated by –O– and –CO– linkages.[2] Various other configurations, such as polyetherketone (PEK), polyetherketoneetherketone, or polyetheretherketoneketone (PEEKK), are also available with similar properties. These polymers are easily sulfonated up to 60% by treating, e.g., PEEK, with concentrated sulfuric acid with a SO_3 concentration of 82.4% at room temperature to give sulfonated-PEEK (SPEEK). Membranes can be cast from a *N*-methylpyrrolidone solution prepared at 130°C under vacuum. The membranes are reinforced with glass fiber. The conductivities of SPEEKK and SPEEK approach those of Nafion (Fig. 5). Sulfonated-PEEK loses water and when dehydrated, like all sulfonated polymers is susceptible to loss of sulfonic acid groups, limiting its use in high-temperature FC. A current density of 620 mA/cm^2 at 0.6 V has been achieved for a woven SPEEK membrane at 110°C.[2] In general, comparison to Nafion, SPEEK has relatively narrow, less separated, and highly branched channels with many dead-end channels, large sulfonate separation, and a pK_a of ~1 (Fig. 4). Composite SPPEK/inorganic membranes have been prepared using HPAs, boronphosphate, zirconium phosphate, sulfenylphosphonate, and aminophenyl functionalized silica in an effort to increase the conductivity of the material.[2] Proton conductivities of 0.1 S/cm at 100°C have been achieved with SPEEK–HPA composite films. Poly-*p*-phenylene sulfone has too high a softening point, 520°C to be processable, but the use of an ether linkage as in the Udel polysulfone brings the T_g to 190°C (Fig. 7C). There is a lot of recent interest in a class of block copolymer polysulfones in which a sulfonated aromatic group is used as a monomer to form a copolymer, such as BPSH-40 (Fig. 7D). The reason for this is that postsulfonation occurs at the most reactive, least stable site, so by using a sulfonated monomer in which the sulfonate group is in the most stable least reactive position the hope is to make more stable sulfonated polysulfones for high-temperature PEM applications.[20] Furthermore, the block polymers morphology is controlled such that there are hydrophobic regions and hydroscopic regions. This morphological control is used to design a polymer with desirable mechanical properties and greater oxidative stability. Proton conductivities as high as 0.17 S/cm have been obtained with sulfonation rates as high as 60%, but these materials swell excessively in water so the optimum 40% sulfonation, hence BPSH-40, is being further developed, which takes up 40 wt% water. Composites of both PTA and zirconium hydrogen phosphate have been made for high-temperature applications.[21] While these inorganic super acids improve the materials morphological, dimensional, and thermal stability, only PTA improves the materials proton conductivity, but its retention in the structure is not optimum.

Polybenzimidazole is a polymer used to fabricate fire resistant clothing as well as a membrane for use in blood dialysis and reverse osmosis in high-temperature and harsh environments (Fig. 7E). The material is a basic polymer, pK_a = 5.5, with excellent thermochemical stability, mechanical properties, low hydrogen permeability, and is of relatively low cost. Direct sulfonation of PBI results in a brittle material. Polybenzimidazole may be sulfonated by first deprotonanting a nitrogen in a benzimidazole ring followed by reaction with aryl or alkyl sulfones. The longer the alkyl linking group the higher the water uptake of the sulfonated PBI; when the alkyl chain is propyl, the conductivity of the material is maintained above 100°C, but, of course, the methylene hydrogens would not be expected to survive a working FC environment. Polyimides are also basic thermoplastic polymers that may be sulfonated (Fig. 7F). These materials show very little sensitivity to external conditions, the number of water molecules per ionic group is independent of equivalent weight, the conductivity is not related to the water content, the monomers contain an internal structure of ionic domains, and the microstructure of the polymer is not spherical ionic domains as in other ionomers.[2]

Acid Doped Basic Polymers

Another way to create a polymer PEM from a basic polymer is to dope it with an amphoteric acid, which acts as both a donor and an acceptor in proton transfer and therefore allows proton migration.[8] The most widely studied of these materials are the phosphoric acid-doped PBI membranes. Phosphoric acid-doped PBI has been shown to exhibit high conductivities up to 200°C, low gas permeabilities, excellent oxidative and thermal stability, and nearly zero electroosmotic drag as the proton conduction is by the Grotthus, proton hoping, mechanism. H_3PO_4–BPI membranes are cast from phosphoric acids solution to give 5 mol of H_3PO_4 per PBI repeat unit.[8] H_3PO_4 interacts only with the imidazole group but does not protonate it.[2] Polybenzimidazole may be doped with other acids the conductivity follows the order $H_2SO_4 > H_3PO_4 > HCO_4 > HNO_3 > HCl$. Recently, new H_3PO_4–BPI materials have been synthesized by the use of polyphosphoric acids (PPA) as both solvent and polycondensation reagent in a process in which the PAA polymerization solution is directly cast without isolation are followed by a sol–gel transition induced by the hydrolysis of the PPA into H_3PO_4.[22] These PPA–PBI materials have 15–25 mol of H_3PO_4 per PBI repeat unit, yet still have 1.0–2.5 MPa tensile strength. All acid-doped PBIs have high proton conductivities at higher temperatures, >140°C, but relatively low conductivities at ambient temperatures, the conductivity rapidly rising

between 80°C and 140°C. This apparent slow cold start problem and the still not fully understood effects of water on the material are major hurdles to the widespread use of these membranes in PEM FC; even so the performance of the PPA–PBI as shown by proton conductivity of 0.21 S/cm and 500 mA/cm at 0.6 V in a H_2/O_2 FC is impressive.

Inorganic Proton Conductors

There have been an increasing number of reports of using HPAs as the proton-conducting element in PEM. Solid HPA exhibit proton conductivities of 0.2 S/cm at room temperature, but this value rapidly falls with increasing temperature for HPA, which do not readily retain water. The HPA are water soluble and so must be immobilized in a matrix. Sol–gel approaches using hybrid organosilanaes have been used to produce membranes with conductivities as high as 10^{-2} S/cm at temperatures up to 160°C and temperature stability up to 400°C.[23] The group of compounds $M^{IV}(RXO_3)_2 \cdot n$S where M is a tetravalent metal such as Zr, Ti, Ce, Th, or Sn; R is an inorganic or organic group; and S is a solvent of which $Zr(HPO_4)_2$ is a member and exhibits good proton conductivity up to 300°C.[8] These materials may be cast as glassy plates or films and the conductivities may be enhanced with silica or alumina. Organic derivatives of α- or γ-zirconium phosphates where the HPO_4 group of the α- is replaced with a O_3POR group and the $O_2P(OH)_2$ group of the γ- is replaced with a O_3POR or $O_2PR'R$ group are being developed for PEM FC applications when the R group contains a proton-generating function, such as –COOH, $–PO_3H$, $–SO_3H$, or NH_3^+.[24] Conductivities of 2×10^{-2} S/cm at 105°C and 85% RH have been achieved with α-$Zr(O_3PC_6H_4SO_3H) \cdot 3.6H_2O$.[24] Another group of inorganic proton conductors that has recently been demonstrated impressively in an elevated PEM FC are the hydrogen sulfates, $MHXO_4$, where M is a large alkali metal, such as Rb, Cs, or NH_4^+, and X is S, Se, P, or As.[1,25] $CsHSO_4$ exhibits an ordered arrangement of hydrogen bonds at room temperature and on slight heating becomes structurally disordered and transforms from a monoclinic to a tetragonal structure at 141°C. Accompanying this transformation is an increase in proton conductivity of two to three orders of magnitude reaching values as high as 10^{-2} S/cm.[25] A current density of 50 mA/cm^{-2} at 0.6 V has been achieved at 235°C over 100 hr of operation using humidified H_2 and O_2.[25]

MEMBRANES FOR DIRECT METHANOL FC

Methanol as a liquid is an ideal fuel for an FC, but unfortunately its reaction at the anode is slow so power densities from DMFC are typically low. However, the lower temperature DMFCs are attracting considerable interest for portable applications. The anode reaction of the DMFC is:

$$CH_3OH + H_2O \longrightarrow 6H^+ + 6e^- + CO_2$$

The reaction produces $6e^-$ for every mole of methanol, but the methanol must be mixed with water. Water management in DMFCs is challenging because electroosmotic drag will take substantial amounts of water across the membrane from the anode to the cathode. In a portable device this water must be pumped or wicked back from the cathode to the anode to ensure that concentrated aqueous methanol is used so that the device can achieve a high power density. Fuel crossover is also much worse with methanol than hydrogen as the fuel is absorbed into the membrane resulting in further efficiency degradations.[26] In PFSA membranes the methanol crossover rate is 10^{-6} mol/cm^2/sec corresponding to a loss of current density of 50–100 mA/cm^2.[8] Much effort in commercializing PFSA-based materials as the electrolyte for DMFC is currently under way, which primarily involves engineering around these problems. Membrane development for DMFC focuses on minimizing crossover and electroosmotic drag. A number of modifications to PFSA membranes are under consideration. By operating the FC at 140°C and using a silica/Nafion composite membrane, methanol crossover can be diminished.[5] Nafion has been treated with phosphoric acid, doped with cesium ions, and impregnated with polymer precursors to produce polymers, such as poly(1-methylpyrrole), in situ.[27] A number of recent publications describe barrier strategies to the development of new polymer electrolyte membranes, including using plasma polymerization, layering solution cast PBI films with Nafion, using a sulfonated polyvinyl alcohol barrier, creation of a three-layered laminar electrolyte, combining a palladium membrane with Nafion, use of low-dose electron beam exposure to modify the Nafion surface structure, and creating a thin methanol impermeable barrier at the film surface.[27,28] While PFSA remains the benchmark for DMFC a number of other materials are being developed for DMFC, such as SPEEK, H_3PO_4–PBI, zirconium phosphate doped BPSH-40, and sol–gel HPA membranes.

CONCLUSIONS

Fuel cell membranes are close to optimization with PFSA materials. These materials give excellent performance when fully humidified and have adequate oxidative stability. These materials limit the temperature of operation of the FC to <100°C and have unacceptably high methanol crossover for direct methanol

FCs. For the further development of FCs, membranes must be fabricated that allow FC operation at temperatures at or above 120°C. While direct methanol FCs are close to commercialization, membranes with lower methanol crossover and electroosmotic drag coefficients would greatly facilitate their wider use.

Functional Biomaterials

Chun Wang
Department of Chemical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, U.S.A.

INTRODUCTION

The term ''functional biomaterials'' is a broad definition of biomaterials that carry biologically relevant function(s). These may include all the contemporary biomaterials used in medical implants and devices and are classified traditionally as metals, ceramics, composites, and polymers. As the development of biomaterials relies more and more heavily on the understanding and adaptation of principles in biology, functional biomaterials often refer to materials that combine biological molecules, such as proteins, peptides, and nucleic acids, forming systems that actively interact with biological entities (such as cells) and modulate biological processes. Functional biomaterials are also responsive materials that are able to recognize signals in biological environment, change their structures, and carry out their functions accordingly.

The layout of this entry is structured around ''biologically relevant functions,'' which specifically refer to the ability of recognizing cells and regulating cellular activities and the ability of delivering biologically active substances precisely. Topics discussed in detail include material surfaces functionalized with biomolecules that bind to cells and support cell growth in 2-D, material matrices that encapsulate and support cell and tissue growth in 3-D, ''intelligent'' materials and material surfaces that respond to biological signals, and materials that control specific delivery of genetic therapeutics to cells in vivo. Preparation, processing, and functionalization strategies are described for synthetic polymeric biomaterials, synthetic systems combined with biomolecules, and biopolymers that are derived naturally or synthesized de novo.

FUNCTIONAL BIOMATERIALS THAT PROMOTE CELL ADHESION

Inside the human body, cell adhesion to foreign biomaterial surfaces is mediated by a layer of proteins found in the blood or serum. Biomaterials that are able to control the adsorption of blood proteins will be able to control selectively the adhesion of cells. This function underlies the so-called ''biocompatibility'' of biomaterials and is ultimately responsible for the success or failure of medical implants and devices in vivo.[1]

Minimizing Nonspecific Cell Adhesion

Functional biomaterial surfaces that absorb proteins minimally are desirable in prolonging the lifetime of medical implants and providing a clean background for introducing specific cell adhesion functionalities.[1] Nonspecific protein adsorption occurs in various degrees to all surfaces, but more readily to hydrophobic and positively charged surfaces. To date, the most effective way to minimize nonspecific protein and cell adhesion is to use surfaces comprised of chains of polyethylene oxide (PEO; also named polyethylene glycol, or PEG).[1]

PEG chains are extremely flexible and hydrophilic. Protein adsorption to a PEG-surface restricts the freedom of the PEG chains and is therefore thermodynamically unfavorable. The effectiveness of reducing protein adsorption depends on the length of PEG—longer chains are more effective than short ones at any given surface coating density. PEG chains can be chemically coupled at one end to many biomaterial surfaces bearing reactive groups such as amines and carboxylates. Block copolymers of PEG, such as di- or tri-block copolymers of PEG and polypropylene oxide (PPO), known as Pluronics® or Poloxamers®, and PEG graft copolymers, can be used to physically coat hydrophobic material surfaces such as polystyrene beads or dishes. PEG-based polymer networks, or hydrogels, are well known to absorb proteins minimally and are often used to coat otherwise protein-absorbing surfaces. Gold surfaces can be similarly passivated through forming self-assembled monolayers (SAMs) of alkanethiols terminated with oligoethylene glycol chains. Recently, a new approach to more stable surface coating was developed[2] combining thiol–gold interaction with PEG block copolymers (PEG-polypropylene sulfide-PEG). The free-ends of surface-bound PEG chains can then be used to attach cell adhesion motifs to facilitate specific interactions with cells on top of a nonadhesive ''low-noise'' background.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120037175

In addition to PEG, certain polysaccharides, such as hyaluronic acid (HA) and dextran, have been used as low protein-adsorption, low cell adhesion surface coatings. Synthetic polymer surfactants consisting of poly(vinyl amine) with dextran and alkanoyl side chains, which mimicks the glycocalyx—negatively charged sugar layer outside cell membrane, are also shown to reduce protein adsorption to hydrophobic graphite surface.[3]

Surface Immobilization of Cell Adhesion Motifs

Early attempts to functionalize biomaterial surfaces with biological molecules[1] were focused on improving blood compatibility of cardiovascular devices, such as the artificial heart and synthetic blood vessels, by immobilizing heparin or albumin on polyurethane or Dacron®. To enhance cell adhesion to biomaterial surfaces, entire extracellular matrix (ECM) proteins, such as fibronectin and laminin, have been used directly as coatings. However, because of the nonspecific manner of whole protein adsorption, most of the cell binding capability is often lost. Using a molecular templating technique, it may be possible to select which protein(s) to absorb on biomaterial surfaces.[4]

It was found that ECM proteins contain short stretches of amino acids (peptides) that bind specifically to a group of receptors on most cell surface, the integrin receptors, which triggers intracellular events that lead to various kinds of cell behavior. These cell adhesion peptides have been immobilized on synthetic biomaterial surfaces to promote specific attachment of selected cell types, which is desirable in many tissue engineering applications. Comparing with ECM protein adsorption, immobilizing cell adhesion peptides can be done in a much better controlled fashion with higher cell binding functionality.[5]

A common method to graft cell adhesion peptides on biomaterial surface is chemical end-coupling, attaching reactive amino acid residues in the peptides to reactive groups on the surface. If the biomaterial surface does not naturally contain reactive groups, they can be generated either chemically or by radiation (UV, plasma gas discharge, etc.). A linker or ''arm'' is often bridging the peptide and the surface to enhance the freedom and activity of the adhesion motif.[1]

One of the most prevalent cell adhesion peptides is the tripeptide arginine–glycine–aspartate (RGD) from fibronectin.[5] This tripeptide has been used extensively to promote adhesion and spreading of many cell types. For example, polyurethane surface can be activated and coupled to RGD via the carboxy terminus. Surfaces containing photo-activable groups, such as benzophenone or aryl azide, can be modified easily with RGD by UV radiation. This tripeptide and other similar adhesion peptides have also been grafted to activated PEG surface, which supported long-term highly specific cell adhesion and spreading. Through copolymerized lysines, RGD has been immobilized on biodegradable polymers of the poly(glycolic acid) and poly(lactic acid) families. Glass surface can be silylated by trialkoxysilanes to couple with adhesion motifs bearing amines, hydroxyls, or carboxyls. In addition to peptide motifs, monosaccharides, such as glucose and lactose have been used to functionalize polystyrene surfaces to enhance hepatocyte binding.[5]

Immobilization of cell adhesion motifs using physical interactions is more straightforward than chemical attachment.[5] One of the earlier reports on the practical application of RGD involved peptide adsorption to many polymer and inorganic surfaces via a hydrophobic tail of oligoleucine. Polymeric surfactants such as the PEG block copolymers can be modified to display RGD on the end of the hydrophilic block and coat hydrophobic substrates. Alkanethiols bearing cell adhesion peptides form SAMs on gold surfaces. Peptide amphiphiles containing RGD and other sequences on one end, and long alkyl ester lipid tails on the other, have been shown to self-assemble on hydrophobic surfaces and used to probe specific cell adhesion.[6]

The strength and the specificity of cell adhesion by surface-functionalized biomaterials are dependent on the density, composition, and 2-D distribution of the immobilized adhesion motif.[5] It is generally accepted that there is a trade-off between cell affinity and cell mobility, with the optimal cell mobility achieved at an intermediate ligand density. The explanation is that low ligand density does not provide enough adhesion sites and strength, whereas high density creates too much adhesion, limiting mobility. Cell adhesion motifs with different chemical composition mediate adhesion and spreading of different cell types. For example, a peptide derived from laminin, isoleucine-lysine-valine-alanine-valine (IKVAV), mediates neurite extension, whereas the RGD peptide attaches to most cell types. The combination of cell adhesive surfaces with non-adhesive surfaces makes it possible to generate 2-D patterns that lead to cell attachment to selected and predetermined areas on biomaterials. Micropatterning techniques such as photolithography and microcontact printing (or soft lithography) have been applied[7] either to create patterns of large populations of one or multiple cell types or to control the shape of cells, which adopt the shape of the ''adhesive islands.''[8] The ability of organizing cells spatially is of interest in tissue engineering applications, and cell shape control serves an excellent model for elucidating the biology of mechanotransduction.

It has long been realized that the surface topography of biomaterials plays a very important role in addition to the cell adhesive motifs effecting cell

attachment and spreading. Texture of biomaterial surfaces, such as micrometer-size grooves, influences cell behavior through contact guidance.[5] Recently it became clear[9] that nanometer-size topographic features are more important than micrometer-size features; however, the exact mechanism of contact guidance remains unclear. The design of next generation functional biomaterial surfaces for controlling cell behavior must take into account both the chemical signals (the cell adhesion motifs) and the topographic cues.

Besides solid material surfaces, functional water-soluble polymers have also been created to promote cell–cell adhesion in aqueous media. For example, cell adhesion peptides of RGD or tyrosine–isoleucine–glycine–serine–arginine (YIGSR) have been attached to the ends of biofunctional PEG and shown to induce neural cell aggregation in culture media.[10]

Responsive Material Surfaces

Functional biomaterial surfaces have been created to change between being hydrophobic and hydrophilic, in response to external signals, such as differences in temperature, solvent environment, light, or electrical current.[11] Temperature-sensitive poly(*N*-isopropylacrylamide) (PNIPAm)-coated substrate is hydrophobic at a cell culture temperature of 37°C that favors cell adhesion and becomes hydrophilic at a lower temperature of 20°C, causing the detachment of cell sheets.[12] These reversible responsive surfaces have been used to culture and harvest layers of endothelial, epithelial, lung, liver, cardiac, and kidney cells, and could eventually enable assembly of complex tissues and organs.

FUNCTIONAL BIOMATERIALS THAT PROMOTE CELL AND TISSUE GROWTH IN 3-D

Functional biomaterials that support growth of cells and tissues in 3-D are divided into two categories: polymeric scaffolds and hydrogels. These structures not only provide mechanical support of cells, but also provide necessary chemical and biological signals to allow cell attachment, migration, proliferation, and differentiation.

Material Processing for Cell Macroencapsulation

The inclusion of cells into functional biomaterial scaffolds carries several critical requirements. During and after the macroencapsulation process, cells must remain viable and physiologically functional. It is desirable to encapsulate as many cells as possible and have them distributed evenly throughout the scaffolds, because the mass and the structure of the tissue product depend on the initial cell number and distribution. For in vivo applications, it is often necessary to perform cell encapsulation quickly inside body cavities with irregular shapes and sizes. These requirements demand special processes for material preparation and scaffold formation.

There are generally two approaches for cell macroencapsulation. One is to fabricate the scaffold first, followed by cell seeding. The other approach is to combine cells with a mixture of precursors in a liquid state and form the scaffold structure around cells, or in situ. The first cell seeding approach requires scaffolds with high porosity, so that large numbers of cells could be introduced into the scaffold interior with ease. One way of generating porous polymeric scaffolds is by solvent casting in the presence of porogens such as PEG or salt crystals.[13] The polymer is first dissolved in an organic solvent and cast into a mold. The solvent is then removed, followed by the removal of the porogens, leaving pores in the polymer bulk. Other pore-generating techniques for water-insoluble polymer scaffolds such as poly(lactic acid) (PLA) have also been developed, using gas-foaming and supercritical carbon dioxide.[13] Polymer fibers can also be woven into porous structures as cell scaffolds. The in situ encapsulation approach usually requires the chemistry of scaffold formation to be triggerable externally, such as photo-initiated polymerization and gelation of precursor molecules, temperature-controlled reversible sol–gel transformation, or mixing-controlled chemical coupling of two activated polymer precursors. Scaffold formation and cell encapsulation can also be driven by self-assembly of molecules such as block copolymers, peptides, proteins, and polysaccharides, into supra-molecular structures such as fibers and gels.

Synthetic Biodegradable Polymers

Biological functionalization of synthetic biodegradable polymers as 3-D scaffold for cells involves grafting ECM proteins or cell adhesion motifs such as the RGD peptide. One example is introducing reactive groups such as amines into the polymer backbone through copolymerization and using these groups later for peptide conjugation, as in the case of poly(lactic acid-*co*-lysine).[14] Other scaffolds of biodegradable polymers may be treated to reveal reactive groups by plasma, by surface-restricted controlled hydrolysis (by, e.g., sodium hydroxide), or may be blended with another functional polymer near the surface for peptide conjugation. Surface treatment involving breaking polymer chains should be done carefully, because of the risk of compromising the mechanical strength

of the scaffold as a result of excessive polymer chain scission.[1]

Most of the commonly used degradable polymer scaffolds are mechanically strong, but for certain applications such as engineering muscles and tendons, which require considerable elasticity, these polymers are not optimal. Novel biodegradable polyesters have been developed with superior elasticity and strength that resemble vulcanized rubber and are hence termed as "biorubber."[15] Scaffolds made with these mechanically functional materials may be useful especially in engineering elastic tissue such as muscular-skeletal tissues and blood vessels.

Synthetic Polymer Hydrogels

Because of the excellent biocompatibility and hydrophilicity of PEG and well-known chemical derivatizations of PEG end groups, PEG and PEG-based copolymer hydrogels are used extensively to encapsulate cells in tissue engineering.[16] PEG containing terminal acrylates and α-hydroxy acid can be photopolymerized to form hydrogels. Cross-linkers containing peptide sequences have been introduced into these gels, which are susceptible to degradation by specific enzymes secreted by cells. These systems have been explored to mimic the cell-initiated remodeling of natural ECM, allowing cell migration, degradation, secretion of natural ECM, and releasing growth factors on demand.[17] They have also been used to form protective layer of endothelium to block restenosis, the unwanted clogging of blood vessels after balloon angioplasty.[5] Another synthetic pathway of PEG hydrogels uses Michael-type addition reaction between a nucleophile such as a thiol group and an acrylate or acrylamide. Peptides containing terminal cysteines can crosslink branched or multiarmed (or star-shaped) PEG upon simple mixing and form hydrogels in minutes with encapsulated cells under room temperature.[18] In addition to peptide-cross-linkers allowing biodegradation, PEG hydrogels can also be modified with sugar residues to enhance adhesion to certain cell types. Extensive work has been reported on tailoring the bioadhesive, mechanical, and degradation properties of PEG hydrogels to achieve better tissue engineering outcomes.[19]

PEO-PPO-PEO triblock copolymers (Pluronics or Poloxamers) form reversible physically cross-linked hydrogels under certain concentration range and temperature. The use of this system in tissue engineering is scarce because of its inability to degrade. Di- or tri-block copolymers of PEG with PLA have been developed to overcome this problem. Multiple blocks of PEG and PLA, synthesized by condensation reaction of L-lactic acid in the presence of succinic acid, can also form reversible hydrogels near body temperature. Cells may be combined with the block copolymers in the liquid state at a lower temperature and can be subsequently injected into the body where gels are formed. Biodegradation occurs later through the PLA segments.[19]

Poly(vinyl alcohol) (PVA) has tunable hydrophilicity and water-solubility through controlling the extent of hydrolysis of its precursor, poly(vinyl acetate), and its molecular weight. It can be chemically cross-linked into gels by glutaraldehyde or epichlorohydrin, which are highly toxic small molecules. Alternative methods of gelation have been developed using a repeated freeze/thaw method or using an electron beam. Because of its low degradability in vivo, PVA has been primarily used as a long-term or permanent scaffold material or as blends with other degradable polymers.[19]

Polyphosphazene is a class of organometallic polymer that contains alternating phosphorus and nitrogen atoms with two side groups attached to each phosphorus atom. It is synthesized by a substitution reaction between poly(dichlorophosphazene) and alcohols or amines. The backbone of the polymer is hydrophilic. The two side groups on the phosphorus atom can take on various structures and properties, which potentially can be modified to create biofunctionalities. Cross-linked polyphosphazene gels have been investigated for skeletal tissue regeneration.[19]

Poly(2-hydroxyethylmethacrylate) (HEMA) hydrogels were developed initially as soft contact lenses. Macroporous polyHEMA gels have been prepared by freeze/thaw method or salt leaching technique and used for nondegradable cartilage replacement. The modification of polyHEMA gels by dextran enables enzymatic degradation of the scaffolds. A novel cross-linking chemistry of polyHEMA with grafted enantiomeric oligo(L-lactide) and oligo(D-lactide) has been developed, allowing in situ formation of polyHEMA hydrogels, which are potentially useful in cell encapsulation.[19]

Owing to their temperature-sensitive sol–gel transition behavior, PNIPAAm and copolymers with acrylic acid or acrylamide can be used to encapsulate cells. Chondrocytes have been successfully encapsulated without using any organic solvent or toxic compound. The application of these systems as injectable bioadhesive (RGD) scaffold for cartilage tissue engineering is being explored. Degradability can be introduced into the otherwise nondegradable polymer system by peptide- or polysaccharide-based cross-linkers.[19]

Poly(propylene fumarate-*co*-ethylene glycol) (PF-*co*-EG) is a hydrophilic block copolymer that can be cross-linked chemically or by UV light. When used as an injectable cell scaffold in bone and vascular tissue engineering, this block copolymer degrades through the ester bonds in the PF blocks.[20]

To afford biological functionality to the otherwise inert synthetic polymer hydrogels, cell adhesion peptides are either incorporated as cross-links or attached to pendant polymer chains in the bulk or on the surface. Biologically active growth factors, such as TGF-β, bone morphogenetic proteins (BMPs), and VEGF, have been incorporated in hydrogels through covalent tethering, physical tethering, or entrapment, as stimuli for cell growth and differentiation.[20]

Natural Polymer Hydrogels

Collagen is a major component of the ECM in many tissues, such as bone, cartilage, and skin. Collagen forms thermal reversible gels physically and gels cross-linked by dialdehyde or diazide chemically. Collagen contains numerous cell adhesion motifs and sequences that are degradable by specific cell proteases. Collagen gels are often modified to include other biomolecules such as fibronectin, chondroitin sulfate, or hyaluronic acid. Although there are large variations of collagen extracted from natural sources, it serves as an excellent functional biomaterial matrix for engineering tissues and organs such as liver, skin, blood vessel, and small intestine. Single-stranded partial degradation product of collagen is gelatin, which also forms gels and is used in various tissue engineering applications.[19]

Silkworm silk has a long history of medical use as degradable sutures with good biocompatibility. Recently, the mechanism of natural processing to create high strength silk fibers was elucidated. Water-soluble silk fibroin protein extracted from silkworm silk has been processed into hydrogels with or without PEG by varying temperature, pH, and salt concentration. Because of its long degradation time, silk protein may be especially useful in reconstructing tissues requiring relatively stable scaffolds.[21]

Hyaluronic acid (or hyaluronate) is a giant molecule of glycosaminoglycan found in natural ECM and is especially important in wound healing. Hydrogels of HA can be prepared by cross-linking HA chains with hydrazide derivatives or by polymerization of glycidyl methacrylate-containing HA macromers, and HA gels are degraded by a natural enzyme in the body, hyaluronidase. Applications of HA gels include artificial skin, wound dressing, and soft tissue augmentation. Blending with synthetic polymers is often necessary to enhance the relatively weak mechanical properties of pure HA gels.[19]

Fibrin is the major protein component of blood clots and is formed by enzymatic cleavage and polymerization of fibrinogen. Because of its important role in natural wound healing process, fibrin is an attractive functional material for tissue engineering. Additional cell binding peptides, such as RGD, have been incorporated into fibrin using transglutaminase factor XIIIa activity. The resulting fibrin gels have been shown to promote neurite extension. Other applications of fibrin gels include engineering skeletal muscles, smooth muscles, and cartilage.[19]

Alginate is a natural polysaccharide obtained from brown algae. Divalent ions such as Ca^{2+} cross-link alginate into physical gels, which are used for microencapsulation of chondrocytes, hepatocytes, and islet cells to treat diabetes. Ionically cross-linked alginate gels degrade in vivo by losing the ions, and the degradation is difficult to control. Covalent cross-link of alginate has been achieved using adipic dihydrazide or bifunctional PEGs. It is possible to control alginate-PEG hydrogel formation, swelling properties, mechanical properties, and degradation. To incorporate cell binding ability, alginate gels have been modified with sugar-binding lectin and RGD and have been used to culture skeletal muscle cells.[19]

Agarose is another polysaccharide extracted from algae, and it forms thermally reversible gels. The concentration of agarose determines the pore size and stiffness of agarose gels and has been shown to influence cell migration. Agarose gels covalently modified with chitosan have been used to promote neurite outgrowth. Certain cell adhesion peptides have also been coupled to agarose gels.[19] Recently a method was developed to enable 3-D spatially controlled coupling of cell adhesive RGD within agarose gels, and directed growth of neurites has been demonstrated.[22]

Chitosan is a cationic polysaccharide derived from chitin, which is most abundant in crab shells. Because of its insolubility in neutral buffers and most organic solvents, chitosan has to be chemically modified to increase its solubility. Chitosan gels can be prepared by ionic crosslinking or chemical crosslinking by glutaraldehyde. Azide derivatives of chitosan can also be gelled by UV light. Chitosan gels have been modified with sugar moieties to interact with hepatocytes and with natural proteins such as collagen, gelatin, and albumin for neural regeneration.[19]

Genetically Engineered Protein Polymers

Recombinant DNA technology and bacterial fermentation techniques have enabled the design of artificial genes and the production of artificial protein materials. Typically a peptide repeating sequence is designed and translated into a DNA sequence. The DNA monomer is chemically synthesized and enzymatically polymerized and cloned into a bacterial vector or a plasmid, which is later transferred into a bacterial host to express the coded protein polymer. Because the protein products are genetically coded in the DNA sequences,

it is possible to produce protein-based biomaterials with precisely defined molecular weight, composition, biologically functional domains, and molecular assembly properties.[5,14]

Natural silk proteins constitute long repeated sequences of alanine–glycine (AG), which form aligned, stacked, antiparallel β-sheets. Hydrophilic amino acids such as glutamic acid have been placed with regular distances from one another, creating β-turns. It has been shown that the thickness of the β-sheet crystals can be precisely controlled and that non-natural amino acid residues can be placed precisely at one face of the crystals. Cell adhesion peptides, such as RGD and YIGSR, have been incorporated into these structures to be exposed at a particular crystal surface. These materials have been used to coat polystyrene substrates, exposing the cell adhesion motifs as support for cell culture.[5]

Elastin is an amorphous natural protein that affords elasticity to the ECM and connective tissues. It contains a five-residue repeat of glycine–valine–glycine–valine–proline (GVGVP), which has been polymerized genetically to yield elastin-analogs. These protein materials display distinct temperature-dependent phase transition, and the transition temperature is determined by the sequence of the elastin repeating unit and the substitution of the proline residue. Elastin polymer gels have been prepared by gamma-radiation or chemical cross-linking at precisely positioned lysine residues. Cell adhesion peptides such as RGD and others have been incorporated genetically into the elastin polymer at predetermined places. Elastin hydrogels are being evaluated for engineering vascular graft and cartilage tissue. Hydrogels based on elastin polymer grafted with PEG can be formed by photopolymerization, which, along with the temperature-triggered sol–gel transition behavior, is being exploited to encapsulate cells in situ.[5,14]

Block protein polymers containing hydrophilic segments and self-associating α-helical segments form reversible hydrogels spontaneously under certain temperature and pH conditions.[23] Natural and synthetic α-helical coiled coil protein segments have been combined with a synthetic copolymer of *N*-hydroxypropylmethacrylamide (HPMA) to create hybrid gels with unique responsive properties.[24] These gel systems have the potential of acquiring biofunctionalities that are relevant to tissue engineering, and they are being developed to control cell behavior.

Self-Assembling Peptides

Short peptide sequences containing alternating positively and negatively charged amino acid residues have been discovered serendipitously from a natural DNA-binding protein and found to self-assemble in salt-containing water into nanofibers, membranes, and gels.[25] Because of the high hydrophilicity of the sequences and the nanofiber-woven structure, these peptide hydrogels contain extremely high water-content (close to 99.5%). Salt-triggered gelation enables in situ encapsulation of cells into hydrogels, which have been shown to support growth of several types of cells and tissues including cartilage, liver cells, and neuronal cells.[25] Similar high water-content hydrogels have been created from chemically synthesized amphiphilic block copolypeptides. Toxicity of such materials to cells depends on the amino acid sequences of the polypeptides.[26]

Peptide amphiphiles containing an amino-terminal nonpolar hydrocarbon tail and a hydrophilic peptide head self-assemble into similar nanofibers, which subsequently form 3-D hydrogels. By incorporating a phosphorylated serine residue in the peptide region of the amphiphiles, calcium deposition and mineralization of hydroxyapatite can be initiated, forming bone-like structures. More recently, by incorporating cell adhesion peptide IKVAV into the amphiphile, neural progenitor cells cultured within these hydrogels differentiated into neurons, instead of astrocytes, owing to the specific binding and signaling of the IKVAV peptide.[27] This initial demonstration of how biomaterial matrix alone can be tailored to steer the fate of progenitor cells suggests the possibility of using these materials in vivo to promote regeneration of damaged tissues.

FUNCTIONAL BIOMATERIALS IN GENE DELIVERY

Functional Requirements for Biomaterials in Gene Delivery

Gene therapy is broadly defined as supplying the patient's cells with genetic materials, which prevent or correct a disease directly, or do so through their protein products. These genetic therapeutics include DNA (both large and small) and RNA. Genetic materials such as DNA plasmids can also be used as vaccines, if the plasmids encode antigenic proteins. The ability to deliver genetic therapeutics and vaccines specifically to target tissues and cells is crucial for the success of gene therapy, which promises to revolutionize modern medicine.[28]

There are two classes of gene delivery vehicles, or vectors, that are based on viruses or nonviral biomaterials. The viral delivery approach is limited by potential toxicity, immunogenecity, lack of targeting, production and packaging problems, and high cost. Nonviral vectors, on the other hand, have the potential to

overcome these limitations of viral vectors.[28] Unlike delivery of small molecular drugs, peptide, or protein drugs, gene delivery presents unique challenges and demands biomaterials assisting delivery to be equipped with specific biological functions.

Barriers to gene delivery are categorized into two levels: systemic and cellular. The systemic barrier is the reticular endothelial system (RES) of the body that includes liver, spleen, and phagocytic cells, which capture and clear any foreign material such as an exogenous DNA. Unwanted delivery to nontarget tissues and cells is also undesirable. At the cellular level, there are multiple barriers for DNA uptake, escaping endosomes following endocytosis, nuclear targeting/entry, and DNA unpackaging to allow transcription.[28] Functional biomaterials are expected to overcome these barriers, in addition to having excellent biocompatibility.

Targeted Gene Delivery to Cells

One way to localize gene delivery to a particular site in the body is using controlled release materials, mainly biodegradable polymers.[28] Microparticles of polymers based on poly(lactic-*co*-glycolic acid) (PLGA) have been extensively used to deliver DNA in vivo after local injections. By tuning particle size to the micrometer range, it is possible to passively target phagocytic cells such as macrophages and dendritic cells, which could be advantageous in DNA vaccine delivery. Recently, microparticles of novel poly(ortho ester) polymers have been developed[29] to accelerate degradation and DNA release in response to intracellular pH. DNA can also be tethered to or entrapped in a solid substrate, such as a tissue engineering scaffold, and be released to specific cells upon cell-initiated substrate degradation.

Prolonged systemic delivery of DNA can be achieved by coating the delivery vehicles with PEG, which avoids nonspecific cell adhesion by being ''stealth.'' Various biologically specific targeting ligands have also been coupled to delivery vectors.[30] These include transferrin, monoclonal antibody, mannose, galactose, lactose, folic acid, low-density lipoproteins, and RGD peptides. By binding to cell surface receptors, these targeting strategies enable DNA to enter target cells through receptor-mediated endocytosis. Recently, it is discovered that certain cationic peptides, such as a segment of the HIV Tat protein, when conjugated to a gene delivery vector, can enter cells directly and rapidly without relying on endocytosis. The benefit of direct cell entry by a gene delivery vector is that it bypasses the barrier of endosomal membrane.

Gene Condensation

Genomic DNA in the cell nucleus is highly condensed by cationic proteins such as histone, so that it can be packaged within a compacted organelle. Gene delivery also requires condensation of the exogenous DNA, because for the highly negatively charged hydrophilic DNA molecules it will otherwise be extremely difficult to cross the cell membrane. This is often accomplished by cationic vectors that neutralize the negative charges on the DNA, resulting in small complexes less than 200 nm in size.

Since the early 1970s, one of the first gene delivery systems useful in vivo was developed based on lipids of cationic *N*[1-(2,3-dioleyloxy)propyl]-*N,N,N*-trimethylammonium chloride) (DOTMA) and dioleoylphosphatidylethanolamine (DOPE), known as Lipofectin. Other commonly used cationic lipids include 2,3-dioleyloxy-*N*-[2-(spermine-carboxamido) ethyl]-*N,N*-dimethyl-1-propanaminium trifluoroacetate (DOSPA), dioctamido-decylamidoglycylspermine (DOGS), 1,2-dimyristyloxypropyl-3-dimethylhydroxyethyl ammonium bromide (DMRIE), 1,2-bis(oleoyloxy)-3-(trimethylammonio) propane (DOTAP), and 3β-(*N,N*-dimethylaminoethane) carbamoyl cholesterol (DC-Chol).[30] DNA is compacted and encapsulated in these cationic lipid vesicles, or liposomes, which enter cells by endocytosis.

Cationic polymers, such as poly(L-lysine) (PLL), polyethylenimine (PEI), chitosan, polyamidoamine (PAMAM) dendrimers, poly(2-dimethylamino) ethyl methacrylate, and polyphosphoesters, condense DNA to form compacted polyplexes.[30] The size and the stability of polyplexes depend on the ratio of cations vs. anions, temperature, ionic strength, and the solvent. Stability of polyplexes can be enhanced by conjugating PEG to the polycations or by using PEG-containing block or graft polymers that form micelles. Small cationic peptides are also able to condense DNA, however, six-consecutive-cations is the minimal requirement to achieve this effectively.

Subcellular Transport Processes

Endocytosed DNA/vector complexes end up in the endosomal compartments, which are filled with digestive enzymes in a slightly acidic microenvironment. Therefore, it is crucial for the DNA to be removed from that environment, which can result in DNA degradation and loss of activity. Polymers such as PEI and polyhistidine are thought to mediate the endosomal escape process by a hypothesized ''proton sponge'' mechanism—tertiary amine groups in the polymers buffer the acidic pH in endosome, causing it to burst or leak owing to osmotic effect.[30] Small

''fusogenic'' peptide sequences derived from virus such as influenza are known to change their conformation at endosomal pH and fuse with endosomal membrane. Similar peptides have been conjugated to cationic polymers and shown to enhance transfection efficiency of the exogenous DNA, presumably because of enhanced endosomal escape capability.[29] Synthetic anionic polymers such as poly(2-alkylacrylic acid) behave similarly to the fusogenic peptides in mediating pH-triggered release of DNA from endosome into the cytoplasm.

Once in the cytoplasm, the DNA or DNA/vector complex has to be transported to and enter the cell nucleus for gene transcription. This process is thought to be facilitated by specific peptide sequences termed nuclear localization signals (NLS).[29] In fact, it was shown that one NLS peptide appears sufficient for transporting a DNA plasmid to the nucleus. NLS peptides are frequently coupled to cationic vectors to aid in nuclear transport of DNA/vector complexes. Interestingly, it is reported recently that PEI/DNA complexes can be localized readily to the cell nucleus without using any NLS. Further elucidation of the transport mechanism inside cells should lead to better strategies of designing functional gene delivery materials.

Gene Unpackaging

To be transcriptionally active, the DNA must recover from its condensed form and be separated from its cationic carrier.[29] Disintegration of DNA/vector complex can be engineered by using disulfide crosslinks that are reduced in the cytoplasm by glutathione activity. The cationic polymer carriers (such as poly[α-(4-aminobutyl)-L-glycolic acid], and poly(4-hydroxy-1-proline ester)) can be programmed to degrade overtime by hydrolysis, releasing uncomplexed DNA for transcription.[30]

CONCLUSIONS

This entry focuses on biomaterials that carry biologically relevant functions. Methods are introduced for modifying biomaterial surface to minimize nonspecific cell adhesion and enhance specific cell adhesion and spreading by incorporating biomolecules. Preparation and processing of biomaterials that form 3-D scaffolds for supporting cell and tissue growth and differentiation are described. Biodegradable (synthetic and natural) polymers, hydrogels, and responsive biomaterials play pivotal roles in performing these biological functions. Finally, the development of functional biomaterials to facilitate gene delivery is discussed in the context of overcoming various biological barriers inside and outside cells.

Gas Explosion Hazard: Prevention and Protection

Dehong Kong
Chilworth Technology, Inc., Monmouth Junction, New Jersey, U.S.A.

INTRODUCTION

Controlling gas/vapor explosion hazards is often a necessity of chemical process safety. To control gas explosion hazards, one has to

- Determine the conditions for forming flammable gas–oxidant mixtures.
- Identify the ignition sources.
- Design plants to eliminate or minimize the likelihood of gas explosions, or provide safety devices to protect people and plant from the harms of gas explosions.

This entry introduces readers to the fundamentals of gas explosions, and basic information on how to identify, assess, and eliminate or control gas explosion hazards in their facilities. Any further detailed information regarding the subjects that are covered in this entry may be obtained from the references.

FUNDAMENTALS OF GAS EXPLOSIONS

Basic Concepts

The term ''explosion'' is best defined as a process that involves a sudden release of energy resulting in a rapid and significant buildup of overpressure. Explosions can be categorized into physical/mechanical and chemical explosions. For example, an explosion caused by a sudden release of compressed gas is a physical explosion. A chemical explosion is caused by a chemical reaction(s), which could be combustion, exothermic decomposition or exothermic reaction. Chemical explosions can occur in gas, liquid or solid phase. Chemical explosions that occur in liquid and solid phases are sometimes called condensed phase explosions. Explosive explosions fall in this category.

Gas/vapor explosions are caused by chemical processes, such as combustions or exothermic decompositions of unstable chemicals like acetylene. Because the mechanisms of gas and vapor explosions are same, ''gas explosion'' means both gas explosion and vapor explosion throughout this entry. Combustion is an oxidation accompanied by a production of heat and light. Three elements must be present to support combustion—a combustible chemical called fuel, an oxidant—usually oxygen in air, and a sufficiently energetic stimulus called ignition source. These three elements are conventionally referred to as the fire triangle.

Fire is referred to as a combustion process in which the fuel and oxidant are transported separately to the reaction zone during the combustion. Because the rate of combustion in fires is limited by the rate of transportation of fuel and oxidant molecules, which are usually slower than the rate of oxidation, fires do not cause rapid pressure buildup. Gas explosions are combustions of premixed fuel–oxidant mixtures in confined spaces.

Flash fire is referred to as combustion of gas–oxidant mixture in which the flame propagates through the mixture, in a manner such that negligible or no damaging overpressures are generated. Although gas explosions and flash fires are different in the magnitude of overpressures and the mechanical damages, they are all combustions of premixed fuel–oxidant mixtures. Therefore, the basic mechanisms, prevention and protection methods for gas explosions are also applicable to flash fires.

Two velocities are used to express the speed of flame propagation. The first is the velocity of the flame front relative to the unburned gas mixture, which is called burning velocity (u). The second is the velocity of a flame front with respect to a stationary observer, which is called flame speed (S). The relationship between these two velocities is:

$$S = u \pm U \tag{1}$$

where U is the velocity of the unburned gas mixture relative to a stationary observer. The sign in front of U will be ''+'' when flame propagates in the same direction of the unburned gas flow velocity; and ''−'' when the flame propagates in the direction against the flow velocity.

When a premixed gas–oxidant cloud is ignited, the flame can propagate in two different modes through the gas mixture—deflagration and detonation. Deflagrations propagate at subsonic speeds relative to the unburned mixture and the heat and mass are transported by conduction, diffusion, and convection. Gas mixture detonations propagate at speeds faster than the local sound speed of the unburned gas. In a gas mixture detonation, a shock wave is sustained

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120024364

by the combustion of the flammable gas. The gas mixture at the shock front is compressed, such that the gas temperature exceeds its auto-ignition temperature causing auto-ignition just behind the shock wave. Therefore, the combustion wave and the shock wave propagate at the same speed.

Flammability Limits

Flammability limits and influential factors

A premixed fuel–oxidant mixture can burn only if the mixture composition falls into a certain range, which is referred to as the flammable range. A useful way to express the mixture composition is the triangle coordinates of fuel gas, oxidant and inert diluent, known as the flammability diagram (Fig. 1). If a gas mixture contains multiple fuel gases, all the combustibles can be considered as one fuel gas. For example, if a gas mixture includes methane, propane, and hydrogen with a given composition, the three gases can be considered as a single fuel gas as long as the composition of the mixture of these gases remains constant. The same applies to oxidants and diluents.

The envelope line, which separates the flammable and nonflammable gas compositions, is called the flammability limit. The area enclosed by this line contains all the flammable mixture compositions and the area outside the line contains all nonflammable mixture compositions. The lower section of the line toward the oxidant axis is called the lower flammability/explosible limit (LFL/LEL). The upper section of the line is called the upper flammability/explosible limit (UFL/UEL). Most flammability limits reported in the literature are for fuel–air mixtures, which are the two intersections of the flammability limits line and the constant oxidant/inert (=0.21/0.79) line. The two intersection points of the zero-inert-gas line and the fuel axis are the LFL and UFL in 100% oxidant.

There exists an oxidant concentration below which the fuel–oxidant mixture is not capable of propagating flame. This oxidant concentration is called the limiting/minimum oxidant concentration (LOC/MOC). LOC is dependent on the type of inert gas used.

LOC in air/nitrogen mixture can be estimated using:

$$\mathrm{LOC} = n_{\mathrm{oxygen}} \times \mathrm{LFL} \tag{2}$$

where n_{oxygen} is the moles of oxygen required to burn completely 1 mole of the combustible gas. LFL is

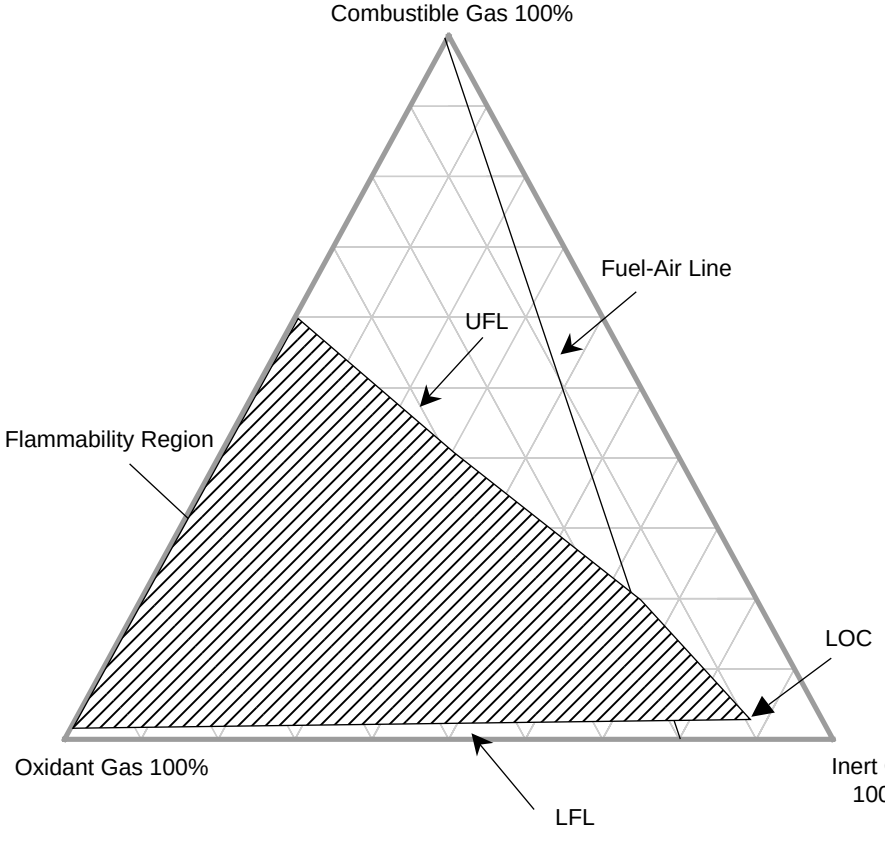

Fig. 1 Flammability diagram. *(View this art in color at www.dekker.com.)*

affected slightly by oxygen concentration. This equation can be used to calculate LOCs with good accuracy provided the LFL measurements are accurate.

To form a flammable vapor–air mixture above the surface of a liquid, the temperature of the liquid must be sufficiently high, and the lowest temperature at which a flammable gas–air mixture is formed at one atmosphere is defined as the flashpoint.[1]

The flammability limits for a vapor–liquid equilibrium system is depicted in Fig. 2.[2] The vapor concentration at the point at which the LFL line intersects the vapor concentration curve is the LFL and the corresponding temperature is referred to as the lower temperature limit of flammability (LTL),[2,3] which is identical to flashpoint. However, the reported LTL and flashpoint can be slightly different because of the different methods used in the tests.

The temperature at which the vapor concentration is equal to the UFL is referred to as the upper temperature limit of flammability (UTL).[2] Above the UTL, the saturated vapor concentration is greater than the UFL, i.e., the gas mixture becomes nonflammable.

Flammability limits are influenced by factors such as pressure, temperature, and oxidant concentration. As pressure increases, the LFL is decreased slightly while the UFL is increased significantly. The effect of higher pressure on LOC is comparable to that on the LFL. For several saturated hydrocarbons at a pressure within 0.1–20.7 MPa (1–204 atm), the effect of elevated pressure on UFL can be estimated using:

$$\mathrm{UFL}_P = \mathrm{UFL}_{P_0} + 20.6 \times (\log P + 1) \quad (3)$$

where UFL_{P_0} and UFL_P (%v/v) are the UFLs at 1 atm (0.1 MPa) and pressure P (MPa), respectively.[4]

Gases such as acetylene that have positive heat of formation can decompose explosively at high ressures in the absence of air when exposed to a sufficiently strong ignition source and, thus, have no UFLs.

A decrease in pressure below one atmosphere has little effect on the LFL as long as the pressure is higher than a limiting level (approximately 5 kPa), below which the mixture becomes nonflammable.[4]

Flashpoint/LTL is related to LFL as:

$$\mathrm{LFL} = \frac{P_{\mathrm{FP}}}{P_{\mathrm{total}}} \quad (4)$$

where P_{FP} and P_{total} are the vapor pressure at the flashpoint/LTL and total gas pressure in the vessel, respectively. As the total gas pressure is decreased, a lower vapor pressure and, thus, a lower temperature (flashpoint) will be required to form a vapor concentration equal to the LFL. Notably, the published flashpoint/LTL data, which are obtained at one atmosphere, do not apply to pressures above or below one atmosphere. Therefore, it is useful to broaden the definition of flashpoint/LTL such as this—the flash point/LTL is the lowest temperature at which the vapor–oxidant mixture at equilibrium with the liquid at a given pressure can be ignited by an incendive ignition source.

As the temperature increases, LFL is decreased and UFL is increased. The effect of temperature T(°C) on LFL can be estimated using the flammability

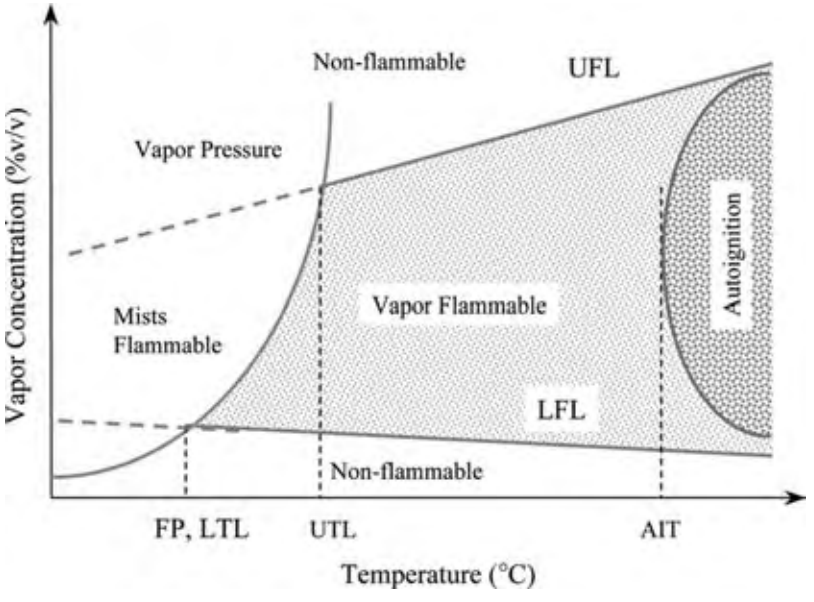

Fig. 2 Effect of temperature on flammability limits of a combustible vapor in air at constant initial pressure. (From Ref.[2].) *(View this art in color at www.dekker.com.)*

limits for 25°C:[2]

$$\mathrm{LFL}_T = \mathrm{LFL}_{25} \times \left[1 - \left(\frac{0.75}{H_c}\right) \times (T - 25)\right] \quad (5)$$

$$\mathrm{UFL}_T = \mathrm{UFL}_{25} \times \left[1 + \left(\frac{0.75}{H_c}\right) \times (T - 25)\right] \quad (6)$$

where H_c is the net heat of combustion (kcal/mol), and 0.75 is essentially a molar heat capacity (kcal/mol) times 100. For many flammable gases and vapors, LFL decreases and UFL increases by approximately 8% as temperature increases by 100°C.[4]

The presence of oxidants such as chlorine, nitrous oxide, and nitric oxide can affect the limits of flammability. As the oxidant concentration is increased, UFL is markedly increased, while LFL is changed little.

The effect of oxygen concentration on flashpoint is similar to that on LFL. Experimental results of Kong et al.[5] using an equilibrium closed bomb (ECB) showed that flashpoint of the flammable liquids in air and in oxygen are essentially the same. The flashpoint of halogenated chemicals such as dichloromethane is dependent on oxygen concentration and the strength of the ignition source. Using the ECB apparatus, the flashpoint of dichloromethane in oxygen was measured to be −7.1°C, however, its flashpoint in air was found to be higher and a more energetic ignition source was required for ignition.[5]

When two or more flammable materials are present, the flammability limits of the mixture can be estimated using the LeChatelier's rule, which is expressed as follows:

$$\mathrm{LFL}_{\mathrm{mix}} = \frac{100}{\sum_{i=1}^{N} \frac{y_i}{\mathrm{LFL}_i}} \quad (7)$$

where subscripts "i" and "mix" refer to the ith fuel component and the fuel mixture; y_i (%v/v) is the concentration of the ith fuel component in the fuel mixture, excluding oxygen and inert-gas components like nitrogen; N is the number of fuel components. This equation works well for some flammable mixtures, but not particularly well for others. It may not work well for chemically dissimilar materials and should, therefore, be applied with discretion. However, this relationship reveals one important nature of mixtures of combustible gases/vapors—a mixture of more than one combustible gas can form flammable mixtures, even when the concentrations of individual combustibles are lower than their respective LFLs.

There are no reliable theoretical equations for the combined effects of pressure, temperature, oxidant type and concentration, and fuel mixture composition on the limits of flammability. However, chemical processes are often operated at elevated temperatures and pressures and at times in oxidant enriched atmospheres. Flammability limits should be measured at actual process conditions with adequate test methods.

Measurements of flammability limits

ASTM E681[6] is a widely used standard for measuring LFLs and UFLs of gases and vapors at one atmosphere or lower. A 5-L and 12-L glass flasks are recommended for testing ordinary and difficult-to-ignite materials, respectively. Ignition is defined as an upward and outward development of the flame front from the ignition source to a certain distance to the vessel wall. Electric spark or fuse wire with sufficient energy can be used as the ignition source.

According to ASTM E918,[7] high-pressure vessels with a minimum volume of 1-L and a minimum diameter of 76-mm should be used for flammability tests at high pressures. A prescribed fuse wire is recommended as the ignition source. A 7% pressure rise is defined as an ignition.

For measuring LOCs for gases/vapors, ASTM E2079[8] recommends that an almost spherical closed vessel, with internal volume not less than 4 L, be used. Several ignition sources are recommended. A 7% pressure rise is defined as an ignition.

Usually, flashpoint is measured in air. Open cup methods may overestimate the flashpoint for liquids containing multiple components because of the loss of more volatile components during testing. Nevertheless, open cup testers can provide flashpoint for situations of open vessels and spills. In contrasts, closed cup techniques prevent the loss of volatile components by keeping the sample enclosed until the ignition source is introduced, and therefore, closed cup data are more conservative than and generally preferred to open cup data.

For LTL tests, ASTM E1232 recommends that a 5-L glass flask equipped with a magnetic stirrer bar be used, which should be placed in a thermally insulated chamber. An electrical arc or fuse wire is used as the ignition source. The equilibrium closed bomb test method[5] has been successfully used to measure flashpoint in air and in oxygen under atmospheric, vacuum, and high pressures.

Ignition of Gases

When a flammable gas–oxidant mixture is heated to a sufficiently high temperature, the mixture ignites

without the presence of external energy sources such as electric sparks and this ignition process is called auto-ignition or spontaneous ignition. The lowest temperature at which a material auto-ignites is called the minimum auto-ignition temperature (AIT).

AIT is affected by the heat loss rate among other factors. The lower the heat loss rate, the lower will be the AIT. The surface (S) to volume (V) ratio affects heat loss rate and, thus, the AIT as shown by Ref.[9]:

$$\ln\left(\frac{V}{S}\right) = \frac{A}{T_{ig}} + B \tag{8}$$

where A and B are constant, and T_{ig} is the AIT. Therefore, a material may autoignite at different temperatures in different test apparatus and the larger the volume the lower the AIT.

Raising the gas mixture pressure causes the mixture to ignite at lower temperatures as shown by Ref.[9]:

$$\ln\left(\frac{P}{T_{ig}^2}\right) = \frac{E}{2RT_{ig}} + \text{constant} \tag{9}$$

For example, as the pressure increases from 1 to 10 atm, the AIT of a mineral oil is lowered from 350°C to 236°C.[2]

Chlorine affects AIT significantly, e.g., the ignition temperature of 18%(v/v) hydrogen in chlorine is 227°C, while the AIT of hydrogen in air is 400°C.[4] The surface material affects AIT by acting as a catalyst or by changing the heat transfer rate at the surface.

The AIT of combustible liquid materials can be measured using the ASTM E659 method,[10] which employs a uniformly heated 500 ml glass flask as the test vessel. A small, metered sample is introduced. The contents of the flask are observed for 10 min following the introduction of the sample, or until auto-ignition occurs. Auto-ignition is evidenced by a sudden appearance of a flame inside the flask.

Flammable gas–oxidant mixtures can be ignited by various ignition sources. Electrical devices can produce heat, which raises the surface temperature. They can also produce sparks or arcs, which concentrate the energy in small volumes lasts as short as a fraction of a microsecond. Electric sparks can be divided into two types—high voltage electrostatic sparks, and low voltage break sparks. The energy of electrostatic spark can be calculated using:

$$E = \frac{1}{2}CU^2 \tag{10}$$

where E, C, and U are the stored energy (J), capacitance (F), and voltage (V) of the conductor, respectively.

Break sparks are formed when current-carrying electrical circuits are abruptly interrupted or interrupted circuits are closed, which results in collapsing or establishing an electric field. These events result in losses of electric energy in the form of sparks. The spark energy is given by:

$$E = \frac{1}{2}LI^2 \tag{11}$$

where E is the stored energy (J), L is the inductance of the circuit (H), and I is the current before the circuit is interrupted or after a broken circuit is closed (A).

The spark energy for igniting a gas–oxidant mixture is a strong function of fuel-gas concentration (Fig. 3).[11] There exists an optimal fuel-gas concentration at which the energy for ignition is minimal and this energy is called minimum ignition energy (MIE). While the MIE may be only a few tenths of a millijoule, the energy for ignition tends to be infinitely large as the fuel-gas concentration approaches LFL and UFL.

The MIE occurs at an optimal spark gap width and varies with temperature, pressure, and oxidant concentration. The MIEs of flammable gases are usually 0.01–1.0 mJ in air and 0.002–0.1 mJ in oxygen. The MIE of gases and vapors can be determined using the method of ASTM E582.[12]

Explosion Consequences

Because of the large amount of heat release from combustion, gas explosions always involve high temperature rise. For example, the maximum flame temperatures for hydrogen and methane are 2045°C and 1875°C, respectively.[13] Even for weak deflagrations in fuel-lean mixtures near the LFL, the flame temperatures of hydrocarbons are in the range of 1300–1350°C (p. 330 in Ref.[13].). This is why even ''weak'' deflagrations such as flash fires can cause severe burn injuries.

The temperature rise and the possible increase in gas molecules as a result of combustion causes the pressure in a closed vessel to rise. The violence of a gas explosion can be expressed by the maximum explosion pressure, P_{max}, and the maximum rate of pressure rise, $(dP/dt)_{max}$, measured in a closed test vessel.[14] The product of the maximum rate of pressure rise and the cubic root of vessel volume:

$$K_G = \left(\frac{dP}{dt}\right)_{max} \times V^{\frac{1}{3}} \tag{12}$$

is called the deflagration index. Potential structural damages by explosions are determined not only by the explosion violence, but also by the strength of the structure. While P_{max} is affected little by the vessel

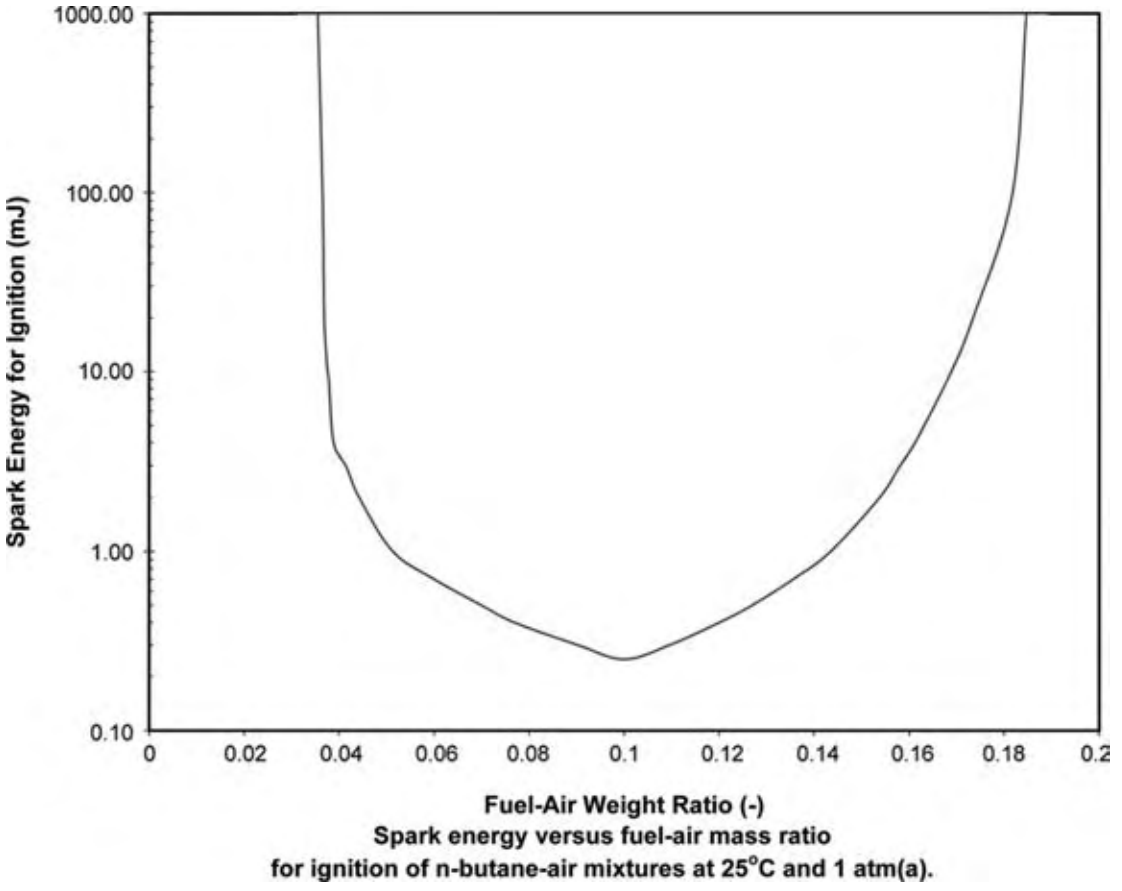

Fig. 3 Influence of fuel-gas concentration on MIE. (From Ref.[11].) *(View this art in color at www.dekker.com.)*

volume, $(dP/dt)_{max}$ and K_G are dependent on many factors, such as gas turbulence, geometry, and size of the vessel. So far, there is no standard test method for K_G measurements. K_G values have been measured using different test apparatus and the results have been used in the development of deflagration venting and suppression techniques. In order to use these guidelines, the measured K_G should be adjusted to be consistent with those data used for developing these guidelines.[15]

PREVENTION AND PROTECTION

Preventive Measures

Elimination/control of flammable gas concentration

Gas explosions can be prevented by keeping the concentration of combustibles below the LFL. For liquid combustibles, this can be achieved by controlling the process temperature below the flashpoint, provided no mists are present. For combustible gases and liquids at temperatures above their flashpoint, ventilation has to be used to control the gas concentration, usually, below 25% of the LFL.[16] Although gas explosions can be prevented by keeping the fuel-gas concentration above the UFL, there exists a risk of gas explosion as the fuel-gas concentration can be diluted to the flammable range when the process conditions are changed.

The release of flammable gases should be minimized with local exhaust ventilation, and the overall gas concentration in process buildings should be controlled with room ventilation. In addition to the common engineering guidelines for ventilation system designs, the following safety precautions should be considered:

- Ensure effective capture of combustibles at the sources.
- Minimize accumulations of condensed liquids.
- Balance airflow without dampers to prevent unwanted change of airflow rates, and eliminate accumulations of condensed liquids and solids.
- Provide air-cleaning devices (air filters, scrubbers, etc.) with protection measures against the consequences of gas explosions (refer to the section titled ''Protective Measures'').
- All ventilation components should be made from conductive and/or static dissipative materials and electrically grounded.

Elimination/control of oxidant concentration

Gas explosions can be prevented by keeping the oxidant concentration below the LOC by adding an inert gas such as nitrogen, carbon dioxide, argon, helium, steam, and flue gas. This method is called inerting.

There are three purging methods. One is called pressure purging, in which a vessel is repeatedly pressurized with an inert gas, and then exhausted to one atmosphere until the desired oxygen concentration is reached. Another method is vacuum purging, in which a vessel is repeatedly evacuated and then pressurized to 1 atm using an inert gas until the desired oxygen concentration is reached. The other type is called flow-through purging, in which a vessel is purged with a continuous flow of an inert gas for a sufficient time, with a given flow rate of the inert gas, until the desired oxygen concentration is reached. The necessary number of purges for pressure and vacuum purging, and the time for flow-through purging can be calculated using the equations given in NFPA 69.[16]

The following precautions should be exercised:

- The inert gas should be allowed to pass through the whole volume of the vessel.
- The design and operation of the protected process vessels should not compromise the inerting system.
- Oxygen sensors should be provided to monitor the oxygen concentration in the protected vessels.
- Flow meters should be provided to measure the inert-gas flow continuously, and equipped with an alarm to signal a low inert-gas flow.

Elimination/control of ignition sources

It suffices to say that all ignition sources should be excluded from areas where flammable gases or vapors may be evolved. Ignition sources that can ignite gas mixtures include but are not limited to:

- Flames and burning materials.
- Welding and cutting.
- Hot-surfaces and sparks generated by frictions.
- Heating by compression.
- Self-heating.
- Electrical sparks.
- Electrostatic discharges.
- Lightning.

Many of these ignition sources can be controlled through effective housekeeping, equipment maintenance, hot work permit, and general safety programs. Only some of the ignition sources are discussed in greater detail in this entry.

Electrical Equipment and Instruments. The ignition hazards of electrical equipment can be eliminated by:

- "Explosion-proof"—internal explosion is stopped by strong enough structures, and narrow enough openings.
- "Intrinsically safe"—the maximum energy of sparks is less than the MIE of gases.
- Placing sparking-equipment in gas-purged enclosures.

In either case, the surface temperature must not exceed the ignition temperature of the gases or vapors. To minimize the cost of using special electrical equipment, the electrical equipment is selected in such a way that the higher the likelihood of forming a flammable mixture in an area, the lower should be the risk of causing ignition by the electrical equipment.

The process of evaluating the likelihood of forming flammable atmospheres in plant areas is commonly referred to hazardous area classifications (HAC). HAC is usually conducted in accordance with regulations, codes, and standards such as the NEC/NFPA 70[17] and NFPA 497.[18] NEC/NFPA 70 classifies hazardous areas into three categories—Class I, II, and III, in which the combustible materials are gas, dust, and fibers, respectively. The degree of hazard is divided into two levels: Division 1 and Division 2.

Static Electricity. When two solid surfaces, one of which or both are electrically insulating, are brought in contact and separated, there is a rearrangement of electrons at the surfaces. One surface is left with a surplus of electrons and is said to be negatively charged, while the other is left in electron deficit and is said to be positively charged. This process of charge separation is called frictional charging or triboelectrification.

Ionic charge-carrying species in liquids are adsorbed nonuniformly at the interfaces with solids, such that charge of one polarity predominates in a tightly held "fixed thin layer," while the ions of opposite polarity within the liquid are attracted loosely by the charge on the "fixed thin layer" forming a layer near the interface. This layer is thin for conductive liquids and more diffused for less conductive liquids because of reduced ion mobility. As the liquid flows relative to the interface, the charge in the loose layer are convected away, which increases the electric potential within the liquid.

Electrification of gases flowing along solid surfaces is negligible at normal temperatures. However, liquid or solid aerosols contained in a flowing gas stream can be charged to a significant level.

As an ungrounded conductor is exposed to an electric field, some electrons travel to direction of the positive pole of the external field, leaving excessive

positive charge on the opposite side of the conductor. This process of charge separation is called induction charging. A spark will occur if the conductor is brought into contact with a grounded object, which leaves a net charge on the conductor. If the conductor is removed from the electric field, the net charge existing in the ungrounded conductor results in an elevated potential relative to ground, and a second spark may occur upon a contact with a grounded object.

Upon separation of static charges, unlike charges start immediately to neutralize each other. The actual charge buildup on the material is the balance between the separated charge and the neutralized charge. As the charges have to physically reach each other, the rate of charge relaxation is determined mainly by the electrical resistivity of the material. Obviously, the more insulating a material is, the more prone will be the material to retain electrostatic charge. Solid and liquid materials are classified into conductive, antistatic (semi-conductive), or insulating based on the electrical resistivity (ρ) and conductivity (γ) (reciprocal of resistivity), respectively as follows:[19]

Solids	
$\rho < 10^8\ \Omega$m	Conductive
$10^8 < \rho < 10^{10}\,\Omega$m	Antistatic
$\rho > 10^{10}\,\Omega$m	Insulating
Liquids	
$\gamma > 10^4$ pS/m	Conductive
10^2 pS/m $< \gamma < 10^4$ pS/m	Antistatic
$\gamma < 10^2$ pS/m	Insulating

The propensity of charge accumulation can also be expressed by the charge relaxation time, which is defined as the time required for a charge on a material to decay to a certain percentage (typically 37% ($=e^{-1}$)) of its initial value. For conductive and semiconductive materials the charge relaxation time is typically less than 1 sec.

The discharges of static electricity that occur in common industrial processes can be classified as spark, corona, brush discharges, propagating brush discharges, and cone discharges.[19]

The assessment and control of electrostatic hazards associated with process or operation requires a systematic analysis. General precautions include:

- Ground all conductive and antistatic parts.
- Avoid or minimize using insulating materials.
- Add antistatic agents to insulating liquids.
- Keep high relative humidity (usually >65%).
- Use electrostatic deionization/neutralization devices. However, these devices are not without problems, and should only be used after consulting expert advice.

Frictions and Impacts. Friction produces hot surfaces and emits small luminous objects called mechanical sparks, both of which can ignite flammable gases. Impact can cause friction between the two surfaces. Impact without friction can cause ignition of shock sensitive materials.

Friction and impact are complex mechanical processes at the surfaces where a portion of the kinetic energy is converted to heat. Whether a mechanical spark will be incendive toward a flammable gas is determined on a number of factors, which include:[9]

- Type of gas.
- Anvil material.
- Striker material.
- Geometry and roughness of the impacting surfaces.
- Angle of contact between the striker and anvil.
- Frequency of striking.
- Length of strike contacting time.
- Pressure applied at the interface.
- Energy expended at the point of striking.
- Direction of travel of sparks.
- Nature of the sparks—size, temperature, and possibility of exothermic.

In general, the higher the pressure or rubbing speed, the more incendive will be the sparks. However, quantitative predictions can be done only within narrowly defined experiments.

The temperature rise at the surface and sparks is limited by the melting point of the lower-melting-point solid. This limit does not apply if one of the materials can be easily oxidized and the oxidation is highly exothermic. Apart from direct heating because of friction, substances that can undergo a local oxidation sustain additional heating, and can build up much higher temperatures. Thermite reactions are special oxidations of metals by metal oxides. The most common thermite reaction is between aluminum and rust:[4]

$$2Al + Fe_2O_3 = 2Fe + Al_2O_3 - 15.56\text{MJ/kgAl} \quad (13)$$

This reaction releases a large amount of heat, which elevates the temperature to the order of 2200°C. Other metals, such as magnesium and titanium, can also undergo thermite reactions.

The following precautions are recommended:

- Use spark-resistant materials for moving/rotating parts.
- Avoid using aluminum tools, paints, and ladders at carbon steel surfaces.

- Avoid using aluminum paints on rusty steel surfaces.
- Avoid striking surfaces containing flint, rock, or grit with a hard object.

Protective Measures

If gas explosion hazards cannot be eliminated with preventive measures, the plants and personnel should be protected against the damaging effects of gas explosions by using protective measures as introduced below.

Explosion containment

Containment means to construct a vessel or equipment to withstand the maximum explosion pressure resulting from gas explosions. The following points should be considered:

- All interconnected pipes, flanges, covers, etc., should withstand the maximum explosion pressure.
- If an explosion resistant vessel fails, the pressure effects will be more severe than if an extremely weak vessel fails in a gas explosion.
- Explosion containment is normally considered for small-size equipment because of its relatively high cost.

Explosion venting

The principle of explosion venting is that a gas explosion in an enclosure causes the vent(s) of sufficient area to open rapidly at a pressure well below the enclosure's strength, releasing hot gases to a safe location. In other words, the vessel ''fails'' in a predictable way such that people and plant are protected from the pressure effects of the explosion.

In the USA, NFPA 68[15] provides comprehensive guidelines on deflagration venting. The required vent area is dependent on:

- K_G of the gas.
- Shape, volume, pressure rating, and available vent area of the vessel.
- Location of the vessel in relation to outside walls.
- Vent activation pressures.

Explosion venting is not suitable for materials whose combustion products are toxic, or having other adverse effects on human health or environment. It is not acceptable to vent combustion products to the inside of a building without quenching the flame. No venting recommendations are currently available for fast-burning gases with fundamental burning velocities greater than 1.3 times that of propane, such as hydrogen.[15]

Explosion suppression

Explosion suppression systems restrict and confine the fuel combustion in an early stage of an explosion by rapidly supplying flame suppressant into the fuel–air mixture. An explosion suppression system consists of the following elements:

- Explosion sensor.
- Control unit.
- High rate discharge (HRD) explosion suppressors.
- Suppressant.

The sensing and control system detects an incipient explosion and send an electrical signal to activate the valves of the pressurized HRD suppressors. Typically, the membranes of the valves are blown by explosive charges. Before the explosion suppression is achieved, combustion can develop producing modest overpressures.

Optical flame sensors can be used for detecting the initial explosion, provided interference of environmental conditions can be reliably prevented. Pressure transducers are often used because the pressure wave travels at the speed of sound and can be detected at various angles. Vibrations and other mechanical movements can interfere pressure sensors. Therefore, efforts have to be made to minimize the influence of these interferences. The suppressant must be effective in flame quenching and compatible with product and the material of the plant. The suppressors must be designed and arranged adequately, so that the suppressant is rapidly and uniformly injected to the gas mixture in the protected enclosure.

Flame/explosion isolation

Openings in and pipe connections between process plants provide paths for flame propagations. If a path for flame propagation is sufficiently long, deflagration can develop to detonation. Such a flame path should be fitted with explosion isolation devices.[16] Fast-acting shut-off valves can be closed quickly to stop flame propagation of gas explosions. Such valves are typically equipped with pneumatic actuators, which are activated upon receiving a signal of explosions that are sent from an explosion detection and control unit. The distance between a detector and the fast-acing valve should be based on the maximum flame speed expected in the duct, and the response time of the detector, valve, and the actuator circuitry.

Chemical barriers are similar to deflagration suppression systems. Typically, optical sensors are installed in upstream locations of the pipeline in which the flame is to be stopped. Upon a detection of flame, the sensor sends a signal to the control unit, which amplifies the signal and triggers the detonator-controlled valve in a suppressant bottle. The extinguishing agent is injected into the pipeline through a suitable nozzle. Pressure

sensors are not suitable for chemical barriers, as there is no clear correlation between the pressure wave front and the flame front. The distance between the sensor and the suppressant discharge point should be based on the maximum flame speed expected in the pipe, and the response time of the sensor and the discharge rate.

A liquid seal prevents the passage of flame by forcing the hot gas through a liquid. The liquid absorbs the pressure wave and quenches the flame. The liquid seal should be designed for the gases being handled at the flow velocity range in the system and to withstand the maximum anticipated deflagration pressure. Liquid seals may fail to stop flame propagation through the liquid seal for high velocity gas mixtures under certain conditions.[14,20]

Solid flame arresters are built based on the principle of flame quenching by narrow passages. If the spacing of a passage formed by solid surfaces is sufficiently small, flame can be quenched. The minimum characteristic spacing of such a passage is referred to as quenching distance. Solid flame arresters are made in a variety of forms depending on material and geometry of the passages in the flame arresters.[20]

CONCLUSIONS

A substantial amount of information on gas/vapor explosion hazards and prevention and protection techniques has been made available. However, a successful use of the available prevention and protection techniques to control gas/vapor explosion hazards can be achieved, only if the explosion hazard characteristics of the gases/vapors are determined adequately.

Most of the published explosion hazard data were obtained under standard conditions. If the actual process conditions are different from the standard conditions, the published data may not represent the actual gas explosion hazards, and the ignition sensitivity, flammability, and explosion severity/violence of the combustible gases should be measured under the actual process conditions with adequate test methods.

INTRODUCTION

Gas–liquid contacting operations, which transfer one or more components between a gas phase and a liquid phase, are important to numerous industrial chemical processes. Their significance is reflected in the abundance of different contactor designs and review articles.[1,2] The importance of these operations to the chemical industry is affirmed by their global prevalence and involvement in annually producing hundreds of millions of tons of basic chemicals. The various gas–liquid contactor designs attempt to optimize controlling parameters or such specific domains as the gas–liquid interface or continuous-phase residence time.

BACKGROUND INFORMATION

To illustrate the various gas–liquid contactor designs, consider worldwide phenol production which totaled 6.1 million tonnes in 2001.[3] Bubble columns are the gas–liquid contactor typically used in a common phenol process that oxidizes cumene (at ~7 bar and ~110°C) to produce intermediate cumenehydroperoxide. The compressed air introduced into the base of the oxidizer provides oxygen for chemical reaction, as well as the agitation needed to keep the alkali and organic phases intimately mixed.

Another process example, that of fiber grade terephthalic acid (TPA), had a worldwide production of 22.7 million tonnes in 2001.[4] Stirred tank reactors (STRs) operating at 14 bar and 200°C are a preferred gas–liquid contactor in at least one continuous, multistep TPA process. This particular liquid-phase air blown process oxidizes *p*-xylene to crude terephthalic acid (CTA) in the presence of acetic acid, a bromine promoter, and a cobalt catalyst. Heat from the highly exothermic oxidation is removed by condensing and refluxing solvent, *p*-xylene, and water vapor. Another gas–liquid contactor located downstream, a packed bed hydrogenation reactor, uses hydrogen to remove color impurities (4-CBA) from aqueous CTA. Hydrogen in the reactor headspace is absorbed into a thin film of liquid pooled atop the catalyst packing. As this liquid film moves down through the packing, the absorbed hydrogen reacts with the trace liquid impurities.

More fundamentally, gas–liquid systems promote reaction in the liquid phase by utilizing the following three possible modes of gas–liquid contact: 1) gas bubbling through a liquid (as in bubble columns and stirred tanks); 2) gas contacting a thin film of flowing liquid (as with packed beds or columns); and 3) liquid droplets dispersed in gas (as in spray columns and venturi scrubbers).

The best possible mode of gas–liquid contact for a given process depends upon a combination of effects, including hydrodynamics, mass transfer, and chemical kinetics. In treating this combination, a dimensionless parameter "β" has been defined as the ratio of "total volume of the liquid phase" to "volume of the liquid diffusion layer." Krishna and Sie[5] reported general values of β to be 10–40 for thin liquid films and liquid sprays, and 10^3–10^4 for gas bubbles within a continuous liquid. The relative rates of mass transfer and chemical reaction show whether high values or low values of β best utilize available reactor volume.

For example, when mass transfer limits the overall reaction rate, reaction occurs near the gas–liquid interface to make significant liquid volume unnecessary. To minimize the value of β, bulk liquid volume is minimized, while interfacial area is maximized. As intense mixing and turbulence throughout a large liquid volume would be of limited benefit, the gas–liquid contactor of choice is a packed bed or a spray column as in the earlier TPA hydrogenation reactor example.

Conversely, if chemical reaction in the liquid phase limits the overall reaction rate, a large value of β suggests minimizing the gas–liquid interface and maximizing both liquid volume and turbulent mixing. The best contactor would disperse discrete bubbles in a continuous liquid phase. Both the bubble column

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120016177

mentioned in the phenol example and the stirred reactor in the CTA example utilize this gas–liquid contacting mode.

SCOPE

After introducing the theoretical basis of gas–liquid contacting, the remainder of this entry focuses on gas–liquid contact through gas bubbles dispersed within a continuous liquid, i.e., the most common mode of gas–liquid contact within the chemical industry. Finally, the gas–liquid contactor design procedure is presented, followed by an example involving an industrial-scale STR. Further discussion of bubble columns, packed beds, thin films, and venturi scrubbers is found in related entries in this encyclopedia.

GAS–LIQUID CONTACTING IN STR

STRs create the intimate gas–liquid contact needed for mass transfer in aerobic fermentation, hydrogenation, phosgenation, neutralization, chlorination, organic oxidation, and numerous other chemical processes. Extensive experimental and computational (e.g., computational fluid dynamics) effort has been expended to develop and apply gas–liquid contacting competencies to manufacturing practices. STR design significantly affects bubble dispersion, bubble size distribution, bubble surface transients, and consequently the coefficient of mass transfer. In gas dispersion applications, an ideal agitation system performs the following tasks:

- Increases the interfacial area for mass transfer by dispersing the gas as small bubbles.
- Decreases mass transfer resistance by providing shear and turbulence to thin films and constantly renews the liquid film around the bubbles.
- Distributes the gas bubbles throughout the liquid by creating synergistic axial flow.
- Achieves homogeneous temperature and concentrations by blending the liquid.

GAS–LIQUID CONTACTOR THEORY

Film theory says that the gas–liquid interface is separated from the bulk gas and liquid phases by a gas film on one side and a liquid film on the other. While Fig. 1 shows this specifically for bubble or droplet systems, it is easily extended to liquid film contactors as well. Resistance in both films decreases the concentration of species diffusing across the gas–liquid interface irrespective of whether that diffusion is from gas to liquid (as depicted in Fig. 1) or from liquid to gas.

Because diffusion in the liquid phase is much slower than in the gas phase, the liquid film presents most of the resistance to mass transfer. Gas–liquid film theory defines the mass transfer rate (MTR) in terms of the liquid film, as follows

$$\begin{aligned} \text{MTR} &= k_{\text{L}}a(C^* - C_{\text{L}}) \\ &= k_{\text{L}}a(C_{\text{g}}H_{\text{e}} - C_{\text{L}}) \ (\text{mol/m}^3\,\text{s}) \end{aligned} \tag{1}$$

where k_{L} is the liquid film mass transfer coefficient (m/s), a is the interfacial area per unit volume (m^{-1}), C^* is the saturation concentration at the gas–liquid interface (mol/m^3), C_{L} is the bulk concentration in the liquid phase (mol/m^3), C_{g} is the transfer gas concentration in the bubble (mol/m^3), H_{e} is Henry's law constant [$H_{\text{e}} = C^*RT/p_{\text{g}}$], R is the universal gas constant [$\equiv$ 8.314] (J/mol K), T is the temperature at the gas–liquid interface (K), and p_{g} is the transfer gas pressure in the bubble (Pa).

Values of k_{L} typically average $0.02\,\text{cm/s} \pm 0.02$[5] depending on diffusivity of the dissolved gas and relative velocities of the gas and liquid phases. The value of "a" can vary by several orders of magnitude especially in bubble systems where it is inversely proportional to bubble size. Because of difficulties in measuring k_{L} and "a" individually, the lumped parameter or volumetric mass transfer coefficient $k_{\text{L}}a$ (i.e., k_{L} times "a") is typically used to determine MTR. The value of $k_{\text{L}}a$ can be raised by increasing superficial gas velocity and power input. A higher $k_{\text{L}}a$ can cut capital costs by producing a comparable MTR with a smaller vessel, a shorter batch process time, or a higher continuous process throughput.

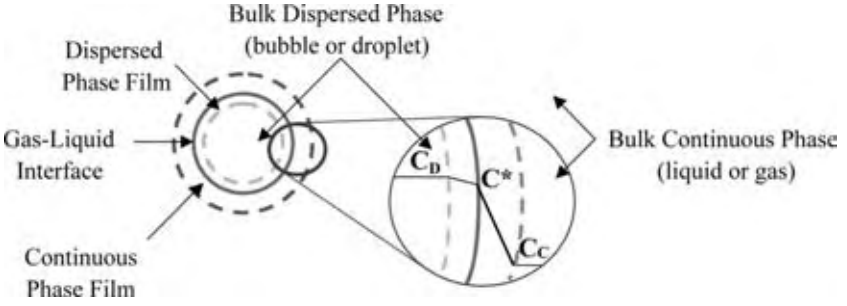

Fig. 1 Gas–liquid film theory for diffusion from the dispersed phase to the continuous phase (with maximum diffusion resistance in the continuous phase film). *(View this art in color at www.dekker.com.)*

EXPERIMENTAL DETERMINATION OF k_La

Values of k_La can be evaluated for a diffusing gas (e.g., O_2) as a function of operating conditions by using an appropriate dissolved gas probe, and either a transient or a steady-state experimental measurement method. While these methods apply to all diffusing gas species, they will be confined to oxygen for the sake of this discussion. The transient method of determining k_La for oxygen at a given set of operating conditions begins by sparging an inert gas (e.g., N_2) into the liquid to purge it of dissolved oxygen (DO). After the DO probe reading indicates essentially zero concentration, the flowing N_2 is turned off and replaced with air. The increasing concentration of DO in the liquid phase "$C(t)$" is recorded as a function of time. As the gas dissolution process can be described by Eq. (2), the corresponding value of k_La is obtained by regressing the experimental data as suggested in Eq. (3)

$$\ln\left[\frac{C^* - C_L}{C^* - C(t)}\right] = k_La \cdot t \tag{2}$$

$$C(t) = C^* + (C_L - C^*)\exp(-k_La \cdot t)\ (\text{mol/m}^3) \tag{3}$$

While these equations include interfacial concentration of the DO (C^*), its value need not be known to determine k_La from the "$C(t)$ vs. t" data regression shown in Eq. (3). Accurate determination of k_La requires a DO probe with adequate response time.

The steady-state k_La method uses chemical reaction in the liquid phase to generate oxygen at a "steady-state" rate. Oxygen is transferred from the bulk liquid into the gas bubbles, an exact reversal of the transfer direction employed in the transient k_La measurement method. For example, the NEL/Hickman[6] steady-state method for measuring oxygen mass transfer continuously feeds hydrogen peroxide solution (H_2O_2) and dry air into the liquid at known rates. Bovine catalase in the liquid decomposes H_2O_2 into H_2O and O_2.

The DO concentration in the liquid is monitored with a DO probe and recorded after it reaches a steady-state (i.e., constant) value. The oxygen generation rate (OGR) in the liquid equals the oxygen transfer rate (OTR), and is related to the hydrogen peroxide mass feed rate ($Q_{H_2O_2}$) as shown in Eq. (4)

$$\text{OGR} = \left[\frac{Q_{H_2O_2}}{2 \cdot \text{MW}_{H_2O_2}} \cdot \frac{1}{V_L}\right] = \text{OTR} = k_La \cdot (C_L - C^*)\ (\text{mol/m}^3\text{/s}) \tag{4}$$

where $\text{MW}_{H_2O_2}$ is the H_2O_2 molecular weight (34 g/mol), V_L is the volume of liquid phase (corrected for H_2O_2 addition) (m^3), and C^* is the average saturation concentration at the gas–liquid interface (mol/m^3).

The H_2O_2 feed rate is divided by 2 because of the stoichiometry of oxygen formation. As liquid temperature and salinity change during a measurement, oxygen concentrations in the liquid must be corrected accordingly. In addition, use of this method requires the following assumptions:

- Gas phase is ideal gas.
- Liquid phase is well mixed.
- Oxygen concentration at the gas–liquid interface is in equilibrium with that in the bulk gas.
- Oxygen partial pressure in air is fixed at 0.2095 atm.

The presence of H_2O_2 and salt in the liquid phase generally elevates the associated k_La values above those obtained by the transient method.[7] A slight modification of this steady-state method allows the authors to use ferric chloride instead of bovine catalase in large-scale experiments.

MASS TRANSFER COEFFICIENT

The mass transfer coefficient, k_La, is correlated with power per mass, superficial gas velocity, and media viscosity as follows

$$k_La_{20} = \alpha(\varepsilon)^{\beta}(V_{sg})^{\gamma}(\eta_r)^{\kappa}\ (\text{s}^{-1}) \tag{5}$$

$$k_La_{20} = k_La(1.024)^{(20-t)}\ (\text{s}^{-1}) \tag{6}$$

where ε is the specific energy (shaft power per unit mass) under gassed conditions (W/kg), V_{sg} is the superficial gas velocity [vol. gas flow rate (m^3/s)/tank cross-sectional area (m^2)] (m/s), η_r is the relative viscosity, i.e., viscosity of working media/viscosity of water, and k_La_{20} is the mass transfer coefficient at 20°C.[8]

Example values of the coefficient α and exponents β, γ, κ are shown in Table 1[9] for an air–water system that was extended to higher viscosities as noted. The value of α can change significantly for different working media. For example, $k_La_{\text{saltwater}} = 1.5\text{–}2 \times k_La_{\text{purewater}}$. Furthermore, k_La is less dependent on specific power at higher levels of power input, such as $\varepsilon > 3$ W/kg (see Table 2). In practice, appropriate values for each variable in the k_La correlation should be determined for specific process or simulation fluids of interest.

Effect of Surface Active Agents

The presence of low molecular weight surfactants in the working media reduces interfacial tension and

Table 1 Fitting parameters for a coalescing gas–liquid system ($\varepsilon < 3\,W/kg$)

Source	Working media	Interfacial characteristics	Viscosity ratio	α	β	γ	κ
van't Riet/Dow	Air–water	72 dynes/cm	1	0.412	0.4	0.5	−0.46[a]

[a]Extended correlation using k_La data from noncoalescing 5 cP glucose broth, 10–300 cP penicillin cultures, and 2000 cP polyglycol.

resulting bubble sizes. Consequently, k_La increases significantly. In one instance, the presence of 1 wt% formic acid (free surface ions) in an agricultural intermediate surprisingly yielded the 34% increase in k_La seen in Table 2.[10] High concentrations of high molecular weight surfactants, however, tend to decrease k_La by increasing the viscosity of liquid film surrounding the bubble.

Effect of Solids on the Mass Transfer Coefficient

In gas–liquid mixing applications, solids are often present as a catalyst or a product. Inherently having small solids present on the bubble surface can diminish the effective intrinsic bubble surface area and significantly decrease the mass transfer coefficient. Though others report just the opposite effect, an illustrative example from Dow is shown in Table 3.[10]

GAS HOLDUP

Besides the mass transfer coefficient, k_La, other parameters help quantify gas–liquid contactor performance in bubble systems. One such parameter is gas holdup (ε_g), which is the ratio of gas volume within the media to the mixture volume as shown in Eq. (7)

$$\varepsilon_g = (V_g)/(V_g + V_L) \tag{7}$$

where V_g is the gas-phase volume (m^3) and V_L is the liquid-phase volume (m^3).

Sometimes gas holdup information is expressed as the fluid volume expansion factor, or $1/(1 - \varepsilon_g)$. Gas holdup is correlated with power per mass (ε) and superficial gas velocity (V_{sg}) as follows

$$\varepsilon_g = \alpha_1(\varepsilon)^{\beta_1}(V_{sg})^{\gamma_1} \tag{8}$$

Table 2 Effect of surface active agents (free surface ions) on k_La ($\varepsilon > 3\,W/kg$, at 40 °C)

Working medium	α	β	γ
Dilute slurry + SARAN particles	0.945	0.05	0.47
Dilute slurry + SARAN particles + formic acid	1.265	0.05	0.47

For the air–water (coalescing) system at specified conditions (8), $\alpha = 0.65$, $\beta = 0.20$, and $\gamma = 0.55$.

Gas holdup is an important parameter for fill volume calculations and reactor sizing. In the case of aqueous coalescing systems, gas holdup normally ranges between 10% and 20%. This is also typical of most aerobic bioreactors. In aqueous noncoalescing systems or viscous systems, gas holdup can be appreciably higher (e.g., 50%). For example, gas holdup in a ~12% acetic acid solution is in the range of 45–50% depending on power level and superficial gas velocity. Significantly, a typical coalescing medium such as water may often be converted into a noncoalescing medium with the addition of salt or other electrolytes.

Higher gas holdup generally produces significant increases in the volumetric mass transfer coefficient, k_La. An exception, however, is high viscosity media where initially many tiny (<2 mm) noncoalescing bubbles and a few relatively large (50–300 mm) coalescing bubbles form. As viscous forces dominate over local turbulence (inertial forces), the tiny bubbles are trapped in the liquid phase and have little-to-no relative velocity with respect to the bulk liquid motion (i.e., the two-phase media behave as a single liquid phase). This phenomenon limits bubble surface transience and gas disengagement, and consequently, the volumetric MTR. Simultaneously, the large bubbles quickly disengage (burp) from the media with little contribution to the mass transfer.

AGITATION SYSTEM

A modern high efficiency gas–liquid STR commonly consists of a radial gas dispersing impeller in combination with one or more axial down-pumping impellers, as seen in Fig. 2. The type and number of open impellers used in the tank depend on the gassed liquid height and the media viscosity (see Table 4). Recommended axial impellers are 45° four-bladed pitch blade turbines

Table 3 Effect of solid SARAN particles on k_La ($0.4 < \varepsilon < 3\,W/kg$, at 22 °C)

Working medium	α	β	γ
Slurry	0.476	0.52	0.46
Slurry + SARAN	0.378	0.53	0.44

Fig. 2 A typical high efficiency gas–liquid mixing system. *(View this art in color at www.dekker.com.)*

(PBTs) for lower viscosity (<200 cP) working media. High efficiency low solidity three-bladed hydrofoils such as Lightnin A-320s and Chemineer Maxflow are suggested for higher (≥200 cP) viscosity working media. Possible radial impellers include the Rushton turbine and such concave-blade turbines as the Smith turbine (see Fig. 3). The authors recommend six-bladed Smith turbines over Rushtons. Normally the impeller diameter to tank diameter ratio ranges between 0.4 and 0.54.

Table 4 shows the recommended numbers of impellers used in low viscosity working media. In the case of high viscosity media, the impeller spacing, S, normally needs to be decreased, i.e., $S = 0.75$–$1.0\,D$. Multiple axial impellers are desirable for a synergistic flow pattern.

Down-Pumping vs. Up-Pumping

In recent years, some mixer manufacturers have promoted agitation systems that are up-pumping as opposed to down-pumping.[11] To verify their claims, the authors conducted several experiments in both low viscosity medium (water) and high viscosity medium (polyglycol) using the up-pumping configuration shown in Fig. 4A and the corresponding down-pumping configuration. Results from these experiments (Fig. 4B) show the down-pumping k_La to be 20% higher than the corresponding up-pumping value.

Power Draw

The power draw characteristics of open impellers are expressed in terms of power number (N_P) vs. Reynolds number (N_{Re}). By definition,

Table 4 Multiple impeller arrangement

Gassed height/ tank diameter (Z_g/T)	<0.9	0.9–1.7	1.7–2.5	2.5–3.3
Number of impellers	1	2	3	4

$$N_p = P/(\rho \cdot N^3 \cdot D^5) \tag{9}$$

$$N_{Re} = \rho \cdot N \cdot D^2/\mu \tag{10}$$

where P is the shaft (hydraulic) horse power (W), ρ the density of the working media (kg/m^3), and μ the viscosity of the working media (kg/m s or Pa s).

Impeller power number is fairly constant for the fully turbulent ($N_{Re} > 10^4$) flows encountered in most production-scale vessels working with a low viscosity media. For various reasons including synergy between impellers, the N_P vs. N_{Re} relationship approaches an asymptote more slowly in multiple impeller systems than in single impeller systems. Fig. 5 shows power number vs. Reynolds number characteristics for two different dual impeller systems, i.e., Rushton turbine + PBT and concave disk turbine + PBT. Slopes of Fig. 5 curves flatten as $N_{Re} > 10^6$ (beyond the fully turbulent flow regime), and increase significantly where $N_{Re} < 75{,}000$ (the transition flow regime). The ungassed fully turbulent flow power numbers for the standard Rushton, Smith, and PBTs are 4.6, 3.2, and 1.27, respectively.

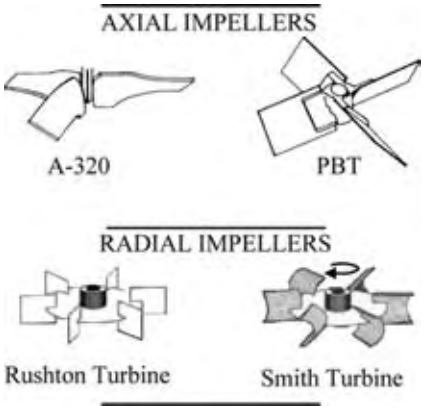

Fig. 3 Examples of common axial and radial impellers. *(View this art in color at www.dekker.com.)*

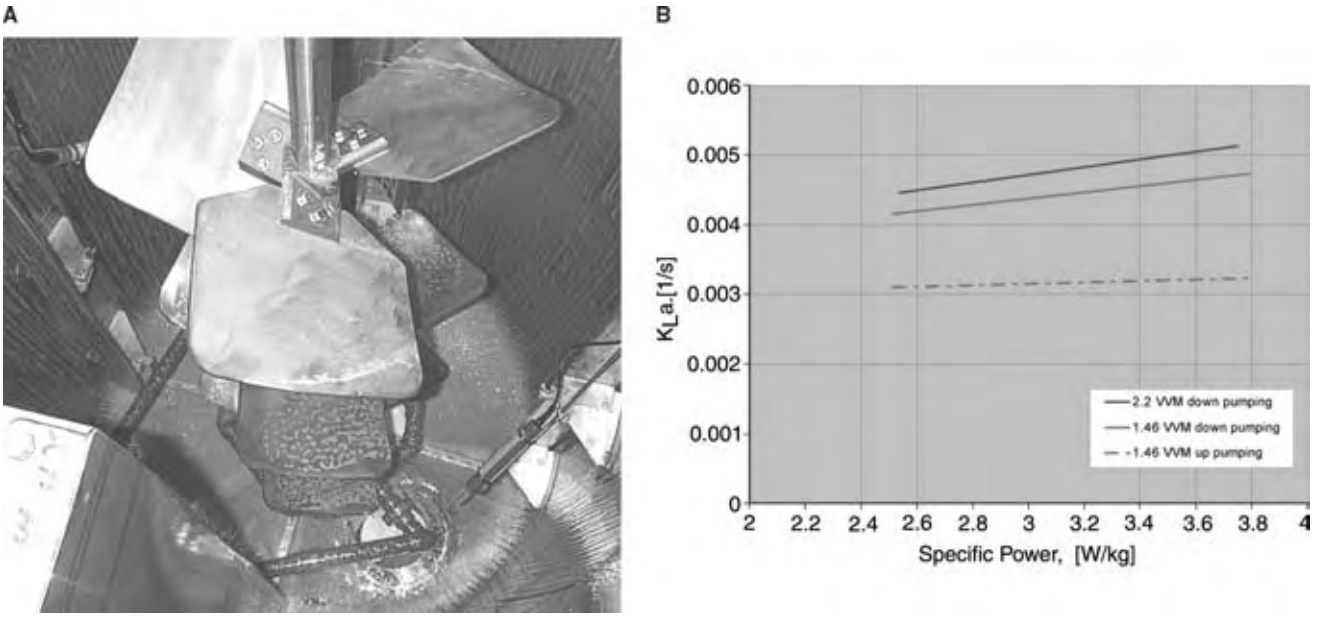

Fig. 4 Up-pumping (A-320) agitation system (A) photograph (counterclockwise rotation), and (B) experimental k_La results in a polyglycol (2000 cP) medium. *(View this art in color at www.dekker.com.)*

The *k*-Factor

The k-factor is the ratio of the power drawn under gassed conditions to that under ungassed conditions, i.e., P_g/P_{ug}. Its value is generally less than unity and varies with changes in such operating conditions as gas flow rate, impeller type, and impeller speed. The k-factor decreases with increasing aeration number N_a as shown in Fig. 6. While lower power draw under gassed conditions is generally not considered a problem, it becomes one if the system motor power is sufficient under gassed conditions but insufficient during system startup under ungassed conditions. In the limit of fully turbulent gassed conditions, the power draw of all the gas dispersing impellers approaches a similar value.

Fig. 6 shows k-factor vs. aeration number curves for the two dual agitator combinations discussed previously. As the power draw (and the power number) is higher under ungassed conditions, agitators typically operate at lower speeds when ungassed. The change in power draw with increasing gas flow is managed by a two-speed motor or a variable frequency drive (VFD) in the drive system.

For design purposes, one could use the k-factors listed in Table 5 for open impellers operating at $N_{Re} \geq 100{,}000$ and $N_a \geq 0.03$.

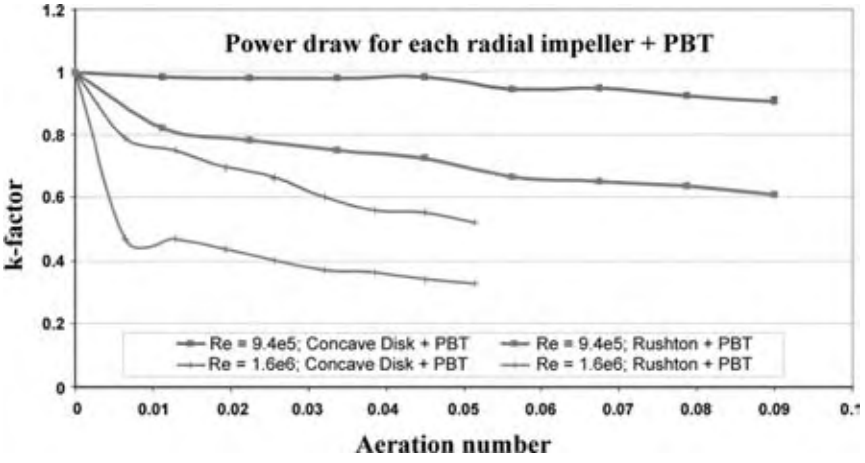

Fig. 6 *k*-Factor vs. aeration number for the two dual agitation systems. *(View this art in color at www.dekker.com.)*

Criteria for Impeller Flooding

The Froude number (N_{Fr}) characterizes gas flow regimes using the following ratio of inertial forces to gravitational forces

$$N_{Fr} = N^2 D/g \tag{11}$$

where g is the acceleration due to gravity (9.81 m/s^2).

The aeration number (N_a) is the ratio of gas flow rate to impeller discharge flow and is written as

$$N_a = Q_g/ND^3 \tag{12}$$

where Q_g is the actual gas flow rate (m^3/s), N is the agitator speed (s^{-1}), and D is the gas dispersing impeller diameter (m).

For a given gas flow rate, the dispersion pattern of gas bubbles in the working media depends on the interplay between the isothermal expansion energy of the gas and the hydraulic power of the impeller. One of three bubble dispersion scenarios is typically expected, i.e., flooding, dispersion in the upper region only, or complete dispersion. Fig. 7[12] illustrates each of these flow regimes.

In water, the maximum aeration number at which flooding occurs ($N_{a,FL}$) with one of several different impellers is correlated[12] as:

$$N_{a,FL} = C_{FL} N_{Fr} (D/T)^{3.5} \tag{13}$$

Table 5 *k*-Factors for different impellers

Impellers	*k*-Factors
Rushton	0.35
CD-6	0.7
PBT	0.9
A-320	0.9

where Rushton $C_{FL} = 30$ and Smith turbine $C_{FL} = 70$.

In the same water system, gas is completely dispersed at transition aeration numbers ($N_{a,CD}$) given by the following correlation:

$$N_{a,CD} = C_{CD}\, N_{FR}^{0.5} (D/T)^{0.5} \tag{14}$$

where Rushton $C_{CD} = 0.2$ and Smith turbine $C_{CD} = 0.4$.

A rule of thumb is that one can expect complete dispersion when the desirable gassed shaft power is greater than three times (minimum two times) the isothermal gas expansion power [defined in Eq. (15)]. A design check for adequate shaft power is absolutely necessary to avoid an undesirable flooding situation

$$P_{gas} = p_1 Q_1 \ln(p_1/p_2) \tag{15}$$

where P_{gas} is the power delivered by the isothermally expanding gas (W), p_1 is the gas pressure (hydrostatic + back pressure) at the sparger (Pa), p_2 is the back pressure (Pa), and Q_1 is the actual volumetric gas flow rate at the sparger (m^3/s).

Gas Sparger

The gas sparger is a critical internal component of STRs used in gas–liquid applications. The type of sparger used depends on the ratio of volumetric gas flow to liquid volume (VVM), and the sizes of any particles present.

Fig. 8 shows the different types of spargers used in STRs. For systems containing large (>50 microns) settling particles, tangential sparger nozzles are more appropriate than common ring spargers. Open pipe spargers provide adequate gas delivery under low (<0.2 min^{-1}) VVM conditions. For high gas flow

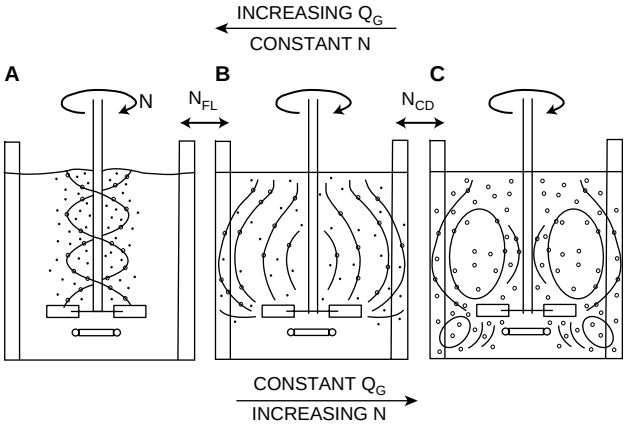

Fig. 7 Gas bubble dispersion in an STR.

rates (high VVM, i.e., $>2.0\,\text{min}^{-1}$), plate spargers are typical, though an alternative approach uses a draft-tube impeller agitation system. Sometimes, gas is self-induced through the rotation of hollow shafts and blades.[13] Disadvantages of self-induction include susceptibility to plugging in sticky polymers and variation of gas flow with hydrostatic head pressure.

Tickler (Kicker)

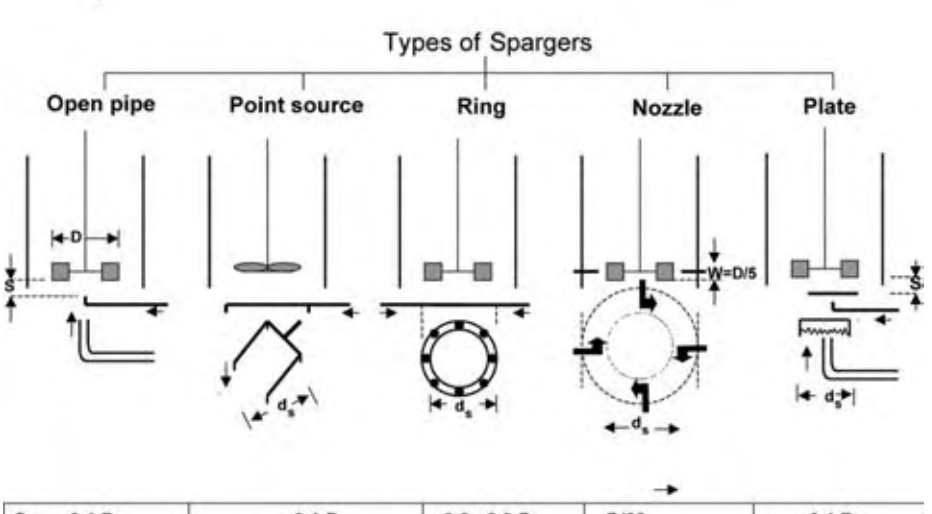
A tickler is a relatively smaller impeller placed at close proximity to the vessel bottom. Often in gas–liquid mixing systems that contain some solids, an axial- (up- or down-pumping) or a radial tickler is used to overcome the solid suspension deficiency of radial gas dispersing impellers. Pitched blade or flat blade turbines are normally used as ticklers. In the case of gas–liquid–solid systems where the slurry needs to be drained through a central nozzle, the authors recommend the Dow-designed KT-3 tickler. Use this tickler prevents pump starvation and facilitates solid removal.

Steady Bearing

Gas–liquid mixing systems typically operate at high power levels, i.e., 1–4 W/kg, and often involve tall vessels ($H/T > 2$) with long mixing shafts. Most tall vessels incorporate a steady bearing or a limit ring to prevent the shaft deflection caused by severe transient loading of the agitation system. Unfortunately, steady bearings wear out (requiring regular maintenance), are susceptible to fouling in sticky polymers, and are often recognized as a contamination source in bioreactors. Thus, caution must be exercised and vendors should be consulted during the consideration and mechanical design of steady bearings.

Baffles

In stirred tanks for gas–liquid mixing, baffles are essential to create axial flow and maintain overall



S = 0.1 D	0.1 D	0.2 - 0.3 D	- D/20	0.1 D
d_s = -	1.3 - 1.4 D	0.7 - 0.8 D	1.1 D	0.7 D

V_p = Gas velocity in the pipe, m/s

Fig. 8 Sparger types and design rules. *(View this art in color at www.dekker.com.)*

uniformity in the mixture. Normally, four simple flat baffles are recommended. The baffle width and baffle clearance from the wall are usually in the range of $^1/_{12}$ – $^1/_8$ and $^1/_{64}$ – $^1/_{48}$ times the tank diameter, respectively. Profiled baffles are preferred for sticky high viscosity or shear-sensitive materials.

STIRRED TANK DESIGN METHODOLOGY

As discussed earlier, stirred tanks are desirable when the overall reaction rate is limited by liquid-phase reaction. Bubbling gas through well-mixed liquid in a stirred tank should minimize the thickness of the gas–liquid interface while maximizing the availability of the liquid volume ($\beta = 10^3$–10^4). Consequently, process conditions that achieve this objective are the first consideration in designing stirred tank gas–liquid contactors.

The optimal configuration depends on numerous factors, including the required gas transfer and mixing rates, and an acceptable range of shear rates. Some factors may be mutually contradictory as in a crystallizer where the required gas–liquid transfer rate is best achieved by increasing turbulence and shear; yet the crystals are shear sensitive. In these cases, successful design carefully balances the contradictory factors.

This section describes the design of a stirred tank contactor for a given range of operating variables and includes the selection of geometric parameters. Important correlations and formulae are presented and followed by an example design case. The design process actually requires multiple iterations to simultaneously satisfy both geometric and mass transfer requirements, but such iteration has become almost trivial when using tools such as spreadsheet-based ''goal-seek'' computations.

Process conditions that must be considered early in the design process include:

- Desired batch size (required tank dimensions) based on required yield.
- Physical and thermal properties of the working media.
- Volumetric gas demand based on reaction kinetics.

Gas demand influences mass flow meter selection, as indicated in the following calculations:

- Actual cubic meters per minute (ACMM) of the reacting gas.
- ACMM of (reacting + carrier) gas based on percentage of reacting gas consumed.
- VVM (gas volumetric flow rate per minute/volume of liquid).
- Standard cubic meters per minute (SCMM) in selecting a mass flow meter.

Design of the gas sparger and agitation system can proceed at this point:

1. Sparger:
   a. Choose the sparger type.
   b. Determine superficial gas velocity from the required ACMM at the sparger.
2. Agitation system (radial + axial impellers):
   a. Calculate C^* and required bulk mean gas concentration in the liquid phase.
   b. Determine k_La from the gas transfer rate.
   c. Calculate the overall transfer rate $\text{OTR} = k_La(C^* - C_L)$ or $k_La\ (\Delta C_{lm})$.
   d. Predict gassed power per mass using k_La correlation (α, β, γ, and κ).
   e. Determine gassed power, P_g.
   f. Determine ungassed power per mass using k-factor.
   g. Calculate gas isothermal expansion energy.
   h. Check the P_g/P_{gas} ratio (>2 as a minimum; >3 to ensure full dispersion).
   i. Check the flooding conditions for the gas dispersing impeller.
   j. Check for gas holdup and recheck tank dimensions.

Table 6 Specification of reactor dimensions, sparger type, and mass flow meter

Tank diameter (m)	3.80
Tank height: tangent–tangent (m)	4.66
Nominal tank volume (m^3)	60
Working media volume (m^3)	45
Unaerated liquid height (m)	4.3
Liquid height/tank diameter	1.13
Volumetric gas flow rate (m^3s^{-1})	0.21
Midpoint pressure (Pa)	1.57×10^5
Pressure at the sparger (Pa)	1.78×10^5
Required ACMM of oxygen (m^3min^{-1})	3.0
Required ACMM of air (m^3min^{-1})	14.4
VVM (min^{-1})	0.37
Required SCMM (m^3min^{-1})	23.6, specify mass flow meter
Superficial gas velocity at the sparger (m^3s^{-1})	0.031
Type of sparger	Ring

Table 7 Design of agitation system

C^* ($mol\,m^{-3}$)	1.72	
C_L ($mol\,m^{-3}$)	1.0	
Henry's law constant ($mol\,m^{-3}\,Pa^{-1}$)	1.26×10^{-5}	
Volumetric mass transfer coefficient (s^{-1})	0.12	Eq. (4)
Power per mass (W/kg)	1.82	Eqs. (5) and (6)
Gassed power (kW)	82	Eq. (9)
k-Factor	0.7	Table 5
Ungassed power (kW)	117	
Gas isothermal expansion power (kW)	14.4	Eq. (15)
Gassed agitation power/gas expansion power	5.7	>3 Check
Aeration number for flooding conditions	2.10	Eqs. (11)–(14) Check
Gas holdup	0.11	Eq. (8)
Aerated liquid height (m)	5.0	Recheck tank dimensions

k. Specify agitation system:
   i. Motor power.
   ii. Gearbox.
   iii. VFD or two-speed motor.
   iv. Operating conditions.

The optimal stirred tank design is identified through iterating until both geometric and mass transfer requirements are simultaneously satisfied.

Design Example

The design of an STR for a fast reacting oxidation process is illustrated in the following section. Operational parameters include a process oxygen demand of $250\,mmol\,l^{-1}\,hr^{-1}$ and a required batch size of $45\,m^3$. Reactor absolute pressure and temperature are 1.32 bar and 30°C, respectively. Minimum required oxygen concentration in the liquid is $1.0\,mol\,m^{-3}$. Physical properties of this Newtonian working media are: viscosity, 1×10^{-3} Pas; density, $1000\,kg\,m^{-3}$; and interfacial tension (gas–liquid), $7.1 \times 10^{-2}\,N\,m^{-1}$.

Design Worksheet

Based upon product batch requirements, preliminary vessel dimensions are listed in Table 6. Gas flow rate (ACMM) is determined to obtain the mass transfer required by reaction kinetics. A ring sparger is selected as discussed in conjunction with Fig. 8. Table 7 summarizes the calculation of the required specific power and gas holdup based on mass transfer and the desired oxygen concentration in the liquid. It must be confirmed that vessel dimensions accommodate the aerated liquid height. An appropriate agitation drive system is recommended in Table 8. Fig. 9 is a schematic of the reactor in this design example.

CONCLUSIONS

This entry briefly presents the mass transfer fundamentals of gas–liquid contacting followed by a series of experimental correlations for the design of STRs. Discussions are intended to familiarize practicing engineers with how to design, optimize, and troubleshoot

stirred tank gas–liquid contactors. To illustrate the design methodology, the design of a typical industrial-scale stirred tank oxidation reactor is presented in a worksheet. Gas–liquid contact in bubble columns, packed beds, thin films, and venturi scrubbers is also discussed in related chapters.

ACKNOWLEDGMENTS

The authors would like to thank the Dow Chemical Company for permitting external release of the information in this chapter, Erik Gasiewski for CAD drawings the figures, and Jan Tuinstra for her final review. Gratitude is also expressed to Tim Geiger of Mattoon & Lee Equipment, Inc. for valuable feedback on this topic.

NOMENCLATURE

a	Gas–liquid interfacial area per unit volume (m^{-1})
c	Impeller off-bottom clearance (m)
C	Concentration of diffusing gas ($mol\,m^{-3}$)
C^*	Saturation concentration at the gas–liquid interface ($mol\,m^{-3}$)
C_L	Bulk concentration in the liquid phase ($mol\,m^{-3}$)

C_g	Transfer gas concentration in the bubble ($mol\,m^{-3}$)
k_L	Liquid film mass transfer coefficient (m/s)
D	Impeller diameter (m)
g	Acceleration due to gravity ($m\,s^{-2}$)
H	Tank height (m)
H_e	Henry's law constant ($H_e = C^*RT/p_g$)
MW	Molecular weight ($g\,mol^{-1}$)
N	Impeller speed (rpm)
p	Pressure (Pa)
P	Power (W)
Q	Volumetric gas flow rate ($m^3\,s^{-1}$)
R	Universal gas constant (= 8.314) ($m^3\,Pa\,mol^{-1}\,K^{-1}$)
S	Impeller spacing (m)
t	Time (s)
T	Temperature at the gas–liquid interface (K)
T	Tank diameter (m)
V	Volume (m^3)
V_{sg}	Superficial gas velocity ($m\,s^{-1}$)

Greek Letters

ε	Power per mass ($W\,kg^{-1}$)
ε_g	Gas holdup
ρ	Density ($kg\,m^{-3}$)
μ	Dynamic viscosity (Pa s)
ν	Kinematic viscosity ($m^2\,s^{-1}$)
η_r	Viscosity ratio of the liquid phase to that of water

Subscripts

g	Gassed or gas phase
gas	Gas expansion
ug	Ungassed
L	Liquid phase

INTRODUCTION

Gas–liquid contacting is important in many reactive processes. In gas–liquid operations, a gas must be effectively and efficiently contacted with the liquid to provide mass transfer. Different contexts bring different challenges. Fermentations and effluent treatment can be at a very large scale, but the product value and workup tend to be comparatively low, so mixer capital and energy are important, whereas mass transfer requirements can be modest (which is fortunate, if the microorganisms are shear-sensitive). Gas–liquid reactions in low-viscosity liquids are often conducted at large scale, have reaction selectivity issues involving the dissolved gas concentration, and have rapid reactions with large exotherms. So for these, scale-up, liquid mixedness, and mass and heat transfer are important while impeller capital and energy cost are not.

Absorption of a gas into a liquid to produce a chemical reaction is often a particularly critical duty. Chlorinations and sulfonations tend to be fast reactions with soluble gases, so high mass transfer intensity with short contact time is efficient. With oxidations, the gas is less soluble, but selectivity is often critical. Hydrogenations involve longer contact times, often with gas recycling (where compression safety can become an issue) and solid particles to be kept in suspension. [1]

Many equipment possibilities exist for gas–liquid operations. They are outlined in Table 1 with their main operational characteristics (at least in air–water systems) presented in Table 2. However, the remainder of this section will deal exclusively with agitated vessels containing low-viscosity liquids in which turbulent flow is achieved ($Re = \rho_L N D^2/\mu > \sim 10^4$).

SELECTION AND CONFIGURATION OF GAS–LIQUID EQUIPMENT

In stirred vessels, the gas should preferably be fed beneath the impeller such that the impeller will "capture" the rising gas plume. [Note that in some cases the gas is drawn in from the headspace using a special self-inducing impeller system (see Ref.[1])]. With radial or upward flow impellers it is sufficient to use a sparger ring with a diameter smaller than the impeller itself ($D_{sparger} = \sim 0.75D$ is recommended). This ensures that the gas can be dispersed into fine bubbles by the impeller, thus providing a high gas–liquid contact area (Figs. 1 and 2). To provide maximum gas contact time the impeller should be near the base of the vessel, but not so near as to inhibit its liquid pumping action: a clearance of $T/4$ is recommended. The bubble breakup mechanism relies upon a high relative velocity between the impeller blades and the liquid, so wall baffles are necessary to restrict the circumferential motion of the liquid. Baffles also enhance the vertical motion of the liquid and hence the mixing of the liquid bulk and the recirculation of liquid and gas back to the impeller, increasing the gas holdup. For any single impeller this recirculation is favored by an aspect ratio (liquid height/vessel diameter $= H/T$) of about one. A vessel of larger aspect ratio (with multiple impellers) may be required to provide a longer contact time for the gas.

An impeller that produces power dissipation under gassed conditions as close as possible to the ungassed power level will provide maximum stability and minimal scale-up difficulties. In the past, flat-blade disk turbines (Rushton turbines) (Fig. 3) have been extensively used in gas–liquid operations. However, their power dissipation is drastically affected by the gas, and they are no longer considered optimal for gas–liquid applications. Recommended impeller types (Fig. 3) include, for radial flow, "hollow-blade" (or "concave-blade") disk turbine designs such as the Scaba SRGT, Chemineer CD6 or BT6, and Lightnin R-130, and, for axial flow, upward-pumping wide-blade hydrofoils such as the Lightnin A345 or A340, and the Prochem-Chemineer Maxflo. Down-pumping hydrofoils or pitched-blade turbines may be unstable during gas–liquid operation because the liquid flow induced by such impellers is opposed to the natural tendency of buoyant gas to rise.[2–4]

(From Ref.[1].)

In vessels where $H > 1.2T$ multiple impellers may be required. These improve liquid mixing, and help redisperse and redistribute the gas. Generally, spacing between impellers should be larger than their diameter D. Multiple radial impellers tend to generate zoned or compartmentalized flow fields in contrast with the better top to bottom circulation generated by multiple axial flow configurations. A combination of a lower radial flow impeller to produce dispersion together with one or more axial flow impellers placed above the radial impeller is often recommended (Fig. 2). Many operators use upward-pumping wide-blade hydrofoils ($D/T = \sim 0.6$) even though there is a tendency for these to develop regions of very high gas fraction in the upper part of the vessel.[5]

TURBULENT MECHANISMS OF GAS DISPERSION

The processes of liquid mixing, generation of interfacial area, and gas–liquid mass transfer in turbulent systems are primarily controlled by the power dissipated in the fluids and the retained gas volume fraction (or gas holdup), ϕ. The power and the fluid properties influence the bubble size. The gas is broken up into a dispersion of bubbles in a so-called ''high-shear'' zone, such as at the impeller-blade tips in an agitated vessel. The power dissipated in this zone controls the bubble breakup process. However, with agitated vessels the design correlations are commonly based on the average energy dissipation per unit mass in the vessel, ε_{avg}. The power in this term is the sum of the shaft power and the, mainly potential, energy introduced as a result of injecting the gas at depth.[6] The ratio of local to average energy dissipation rates can be large and will differ between impeller types.

The bubbles may or may not subsequently recoalesce to some extent, depending on the local fluid dynamics and the interfacial behavior. The unpredictability of this phenomenon rules out a priori prediction of bubble size and interfacial area in general, so design via scale-up from experiments is preferred.

GAS FLOW PATTERNS AND OPERATING REGIMES

The gas flow pattern depends on the regime of gas–impeller interaction. For 6-blade disk turbines and similar impellers, three regimes of flow in the vessel can be defined, as shown in Fig. 4.

- *Flooding*, in which the impeller is overwhelmed by the gas. Gas–liquid contact, mixing and mixing-controlled phenomena (e.g., mass transfer) are very poor.
- *Loading*, in which the impeller disperses the gas throughout the upper portion of the vessel, and the bubbles reach the tank walls but do not recirculate below the impeller.
- *Complete gas dispersion*, in which gas bubbles are distributed throughout the vessel, and a significant amount of gas can be recirculated back to the impeller.

Which regime exists will depend primarily on the impeller agitation speed and the magnitude of the gas flow rate (Fig. 4). These regimes are closely related to the type of gas–impeller interaction: as more gas is fed to the impeller (or the impeller speed is decreased), the impeller becomes increasingly unable to disperse the gas effectively, and there is a greater tendency for the gas to accumulate in the low-pressure regions behind the blades, forming ventilated ''cavities'' (Fig. 5). When such cavities are large they cause a significant reduction in the power number of the impeller (related to their obstruction of the liquid discharge from the impeller; Fig. 6), and hence in its performance for mixing, mass, and heat transfer. This is particularly important for flat-blade disk turbines with four, six, or eight blades.

The transitions between the various regimes generated by a gassed disk turbine can be quantified using dimensionless numbers such as the gas flow number, $Fl_G(=Q_G/ND^3)$, the impeller Froude number, Fr $(=N^2D/g)$, and system geometry ratios, such as the impeller diameter to tank diameter ratio (D/T).[7] For 6-blade disk turbines the cavity regime as well as other regimes are best obtained from the flow

Table 2 Characteristics of gas–liquid contacting equipment

Type of absorber	Typical gas velocity ($\times 10^2$ m/sec)	Residence time distribution		Residence time of liquid	Fractional liquid holdup	$k_L \times 10^4$ m/sec	a_v (m^2/m^3)	$k_L a_v \times 10^2$ sec^{-1}

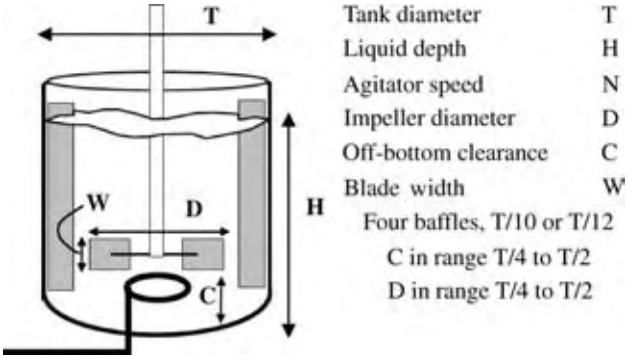

Fig. 1 Standard vessel geometry (single impeller, $H \approx T$). (From Ref.[1].)

regime maps of Warmoeskerken and Smith (Fig. 7) (also summarized by Middleton) valid only for a disk turbine with $D = 0.4T$.[8,9] For other D/T ratios, the regime boundaries should be adjusted using the appropriate correlations given here for flat-blade disk turbines and concave-blade disk turbines:

- Below a certain minimum agitation speed, the impeller has no discernible action on gas dispersion, irrespective of any other factor, including blade type. This occurs approximately when:

$$Fr < 0.04 \tag{1}$$

  which is represented by a horizontal line in the Fr vs. Fl_G. flow map.
- As the impeller speed is increased the impeller starts interacting with the gas. However, when the impeller speed is too low (at a given gas flow rate) the impeller is not capable of dispersing the gas effectively, and flooding will result. For a flat-blade disk turbine flooding will occur when:

$$Fl_G > 30Fr\left(\frac{D}{T}\right)^{3.5} \tag{2}$$

  For a concave-blade disk turbine, the multiplying constant in this equation is 70 instead of 30.[10] The values of this constant clearly show that the concave-blade disk turbine can handle more than twice as much gas flow rate as the flat-blade disk turbine before becoming flooded. Eq. (2) also shows that, for a given D/T ratio, a linear dependence exists between the Froude number and the gas flow number at flooding. Eq. (2) creates two regions separated by a straight line with a slope of 1 in the logarithmic Fr vs. Fl_G flow map. From Eq. (2), it also must be that $Q_G \propto N^3$ at flooding, for a given system.
- Bakker, Smith, and Myers combined the results of Nienow and those of Warmoeskerken and Smith to establish an equation for the determination of the transition point at which the gas becomes completely dispersed in the liquid (in the regions both below and above the impeller). For flat-blade disk turbines, the expression that they found is:[10–12]

$$Fl_G = 0.2Fr^{0.5}\left(\frac{D}{T}\right)^{0.5} \tag{3}$$

  The multiplying constant for concave-blade disk turbines is 0.4 instead of 0.2. Again, these numbers show that concave-blade turbines completely disperse twice as much a gas flow rate at the same agitation speed. This equation delimits two regions separated by a straight line with a slope of 2 in the logarithmic Fr vs. Fl_G flow map.
- Large cavities are developed by a flat-blade disk turbine when:

$$Fl_G > \sim 0.025\left(\frac{D}{T}\right)^{-0.5} \tag{4}$$

  The multiplying constant for concave-blade disk turbines is 0.058 instead of 0.025. This constant has a weak dependence (to the power of about 0.2) on the scale of the equipment. This inequality defines two regions delimited by a vertical line in the Fr vs. Fl_G flow map, for a given value of the D/T ratio.
- Nienow, Wisdom, and Middleton developed a relationship to predict the agitation speed of a flat-blade disk turbine at which gas recirculation occurs for a given gas rate.[13] This expression

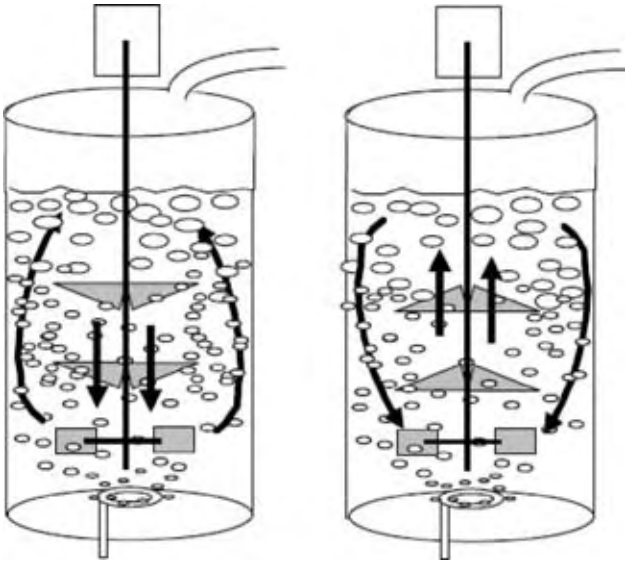

Fig. 2 Multiple impeller agitators: down- and up-pumping hydrofoils above a radial dispersing impeller. (From Ref.[1].)

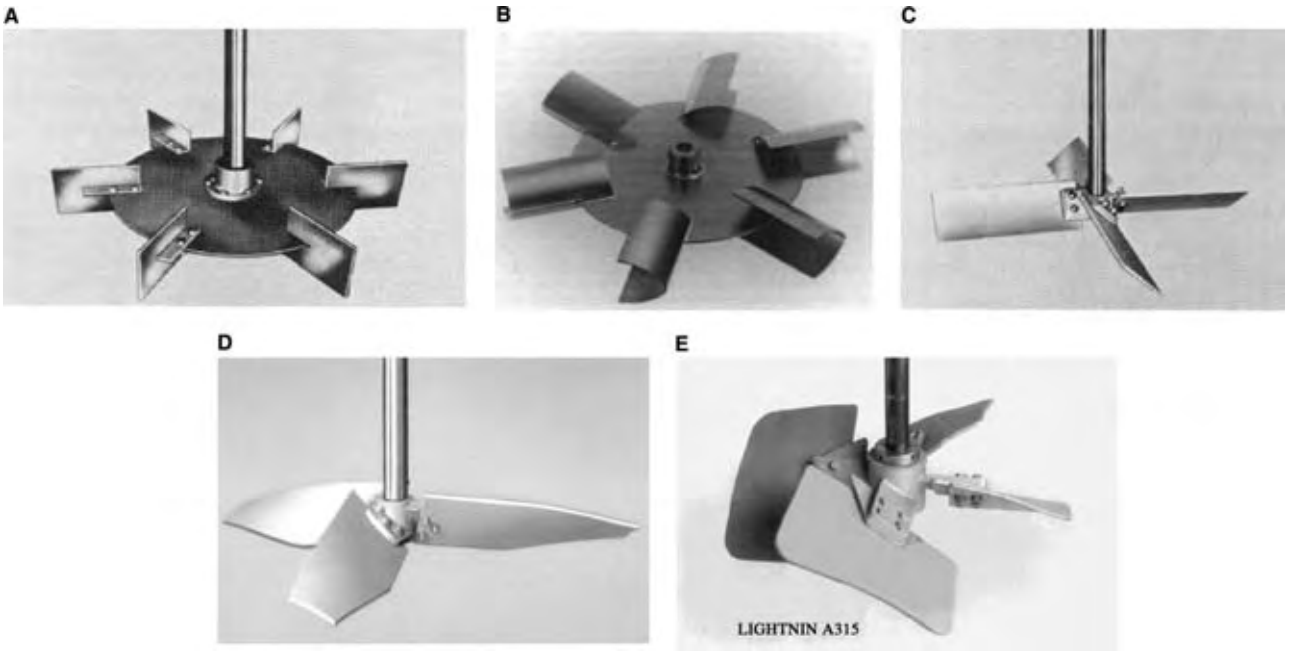

Fig. 3 Various impellers: (A) Rushton disk turbine, (B) hollow-blade turbine, (C) pitched-blade turbine, (D) narrow-blade hydrofoil (Lightnin A310), and (E) wide-blade hydrofoil (Lightnin A315). (From Ref.[1].)

can be reformulated and expressed as:

$$Fl_G < 13Fr^2\left(\frac{D}{T}\right)^{5.0} \quad (5)$$

which defines two regions delimited by a straight line of slope 0.5 in the logarithmic Fr vs. Fl_G flow map.

The equations above allow one to predict the operating conditions in any coalescing gas–liquid system equipped with a flat-blade disk turbine. A similar analysis and flow map have been produced for a concave-blade impeller such as the CD6.[12]

With axial-flow impellers in down-pumping mode, two important regimes are identified: ''direct'' and ''indirect'' loading (Fig. 8).[14] At lower gas flow rates and higher impeller speeds, the downflow from the impeller dominates and gas enters the impeller from above; this is known as indirect loading. If the gas buoyancy dominates, the gas loads the impeller ''directly,'' and the impeller now pumps radially with a much diminished power number (Fig. 9). Operation near the transition is to be avoided because the regime can flip unstably, giving rise to serious mechanical and operational problems. It is preferable to avoid this possibility altogether by operating in an upward-pumping

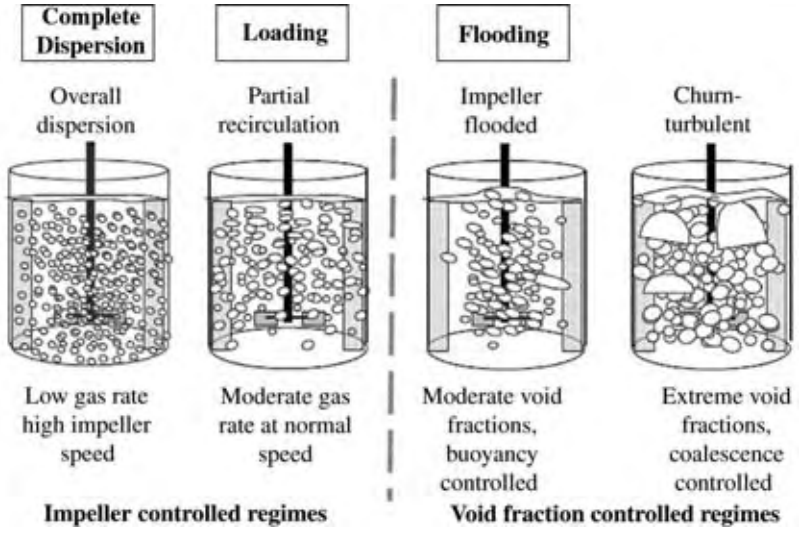

Fig. 4 Typical void distributions in vessels with a single impeller. (From Ref.[1].) *(View this art in color at www.dekker.com.)*

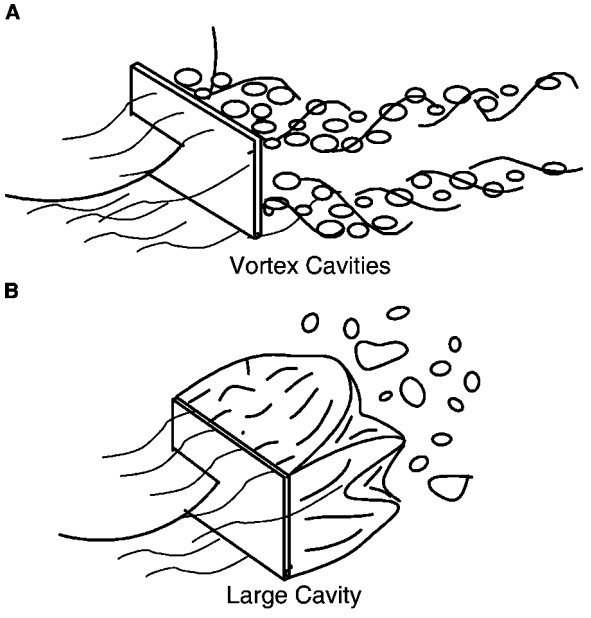

Fig. 5 Ventilated gas cavity forms on turbine blades. (From Ref.[1].)

mode. Here, the gas and liquid flows are not in conflict, and the power curve with gassing is stable.

POWER DISSIPATION IN GAS–LIQUID STIRRED REACTORS

Under turbulent flow conditions, power dissipation is the controlling factor for mass transfer and phase dispersion. The power drawn by a single impeller in a liquid–gas system is typically lower than that drawn by the same impeller in liquid alone. The presence of the gas reduces the average density of the mixture, and the gas flow regime (e.g., flooding) may cause the impeller blades to be locally surrounded by a higher fraction of low-density gas than other locations in the vessel. The power dissipated by an impeller under gassed conditions can be calculated from:

$$P_G = K_{G/U}P_U = K_{G/U}N_p\rho_L N^3 D^5 \quad (6)$$

where P_U (equal to P in the liquid alone) is the power drawn at the same impeller speed under ungassed conditions, which is given by:

$$P_U = N_p\rho_L N^3 D^5 \quad (7)$$

In Eq. (6) $K_{G/U}$ ($=P_G/P_U$) is the "gassing factor" or relative power demand (RPD) between (otherwise identical) gassed and ungassed systems. $K_{G/U}$ depends on the impeller type, Q_G, N, and D, and generally decreases with increasing gas flow number, Fl_G. A summary of typical $K_{G/U}$ values for popular impellers at high gas flow rates ($Fl_G = \sim 0.1$) is given in Table 3.

The value of $K_{G/U}$ in Eq. (6) can easily fall as low as 0.4 for 6-blade flat-blade disk turbines (Fig. 6) and downflow pitched-blade turbines and hydrofoils (Table 3). However, for modern impellers with parabolic concave blades (e.g., Scaba SRGT, Chemineer BT6, Lightnin R-130), $K_{G/U}$ typically falls to only about 0.9 (and then only at high Fl_G values). The ability to deliver high power makes these impellers highly suitable for gas–liquid operations.

If higher power numbers are required, flat-blade turbines with more than six blades (preferably 12 or 16) can be used, for which $K_{G/U}$ eventually drops to about 0.4, but not until much higher flow numbers than for six flat blades. $K_{G/U}$ for up-pumping wide-blade hydrofoils remains close to 1.0. Axial-flow impellers (e.g., Lightnin A345, Prochem Maxflo W, APV B6), if used for gas–liquid duty, should be preferentially operated in the upflow direction, when they are stable and maintain more than 70% of their ungassed power draw

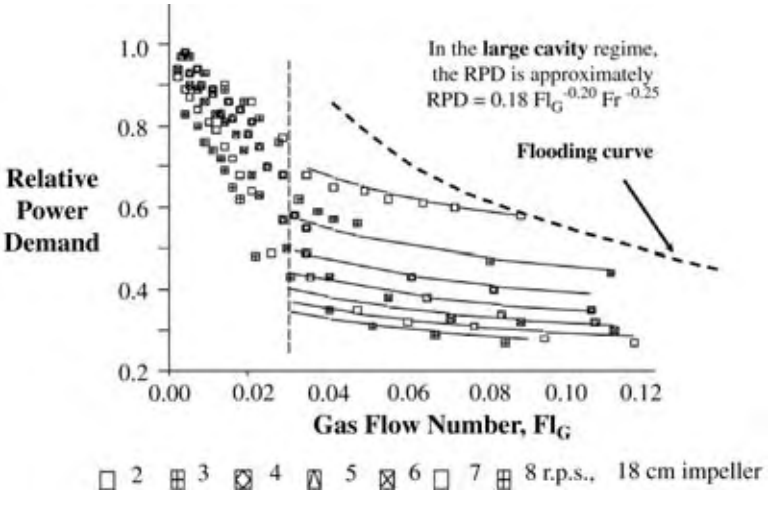

Fig. 6 Relative power demand for a gassed Rushton turbine ($D/T = 0.4$). (Data from Refs.[1,20].)

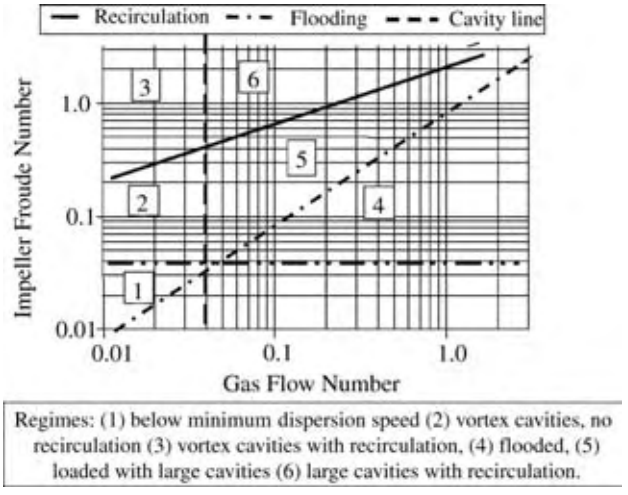

Fig. 7 Flow map for single Rushton turbine (T/D = 2.5). (From Ref.[1].)

on gassing. Down-pumping axial impellers, especially pitched-blade turbines and narrow-blade hydrofoils, have a seriously unstable operating regime in gassed systems, and suffer a drastically sharp fall in $K_{G/U}$ under particular conditions (the direct–indirect loading transition) with dire consequences such as fluctuating process performance, rapid seal and bearing wear, and high risk of shaft failure. However, wide-blade hydrofoils can be quite effective, especially as the upper impellers in multiple impeller agitators. High gas–liquid mass transfer requires high P_G values. Hence, impellers with a combination of high N_p and $K_{G/U}$ are best suited for gas–liquid duties.

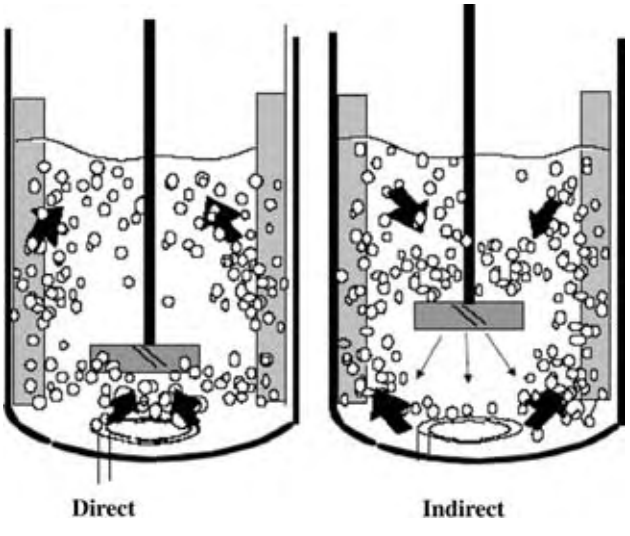

Fig. 8 Direct and indirect loading of a downward pumping axial flow impeller. (From Ref.[1].)

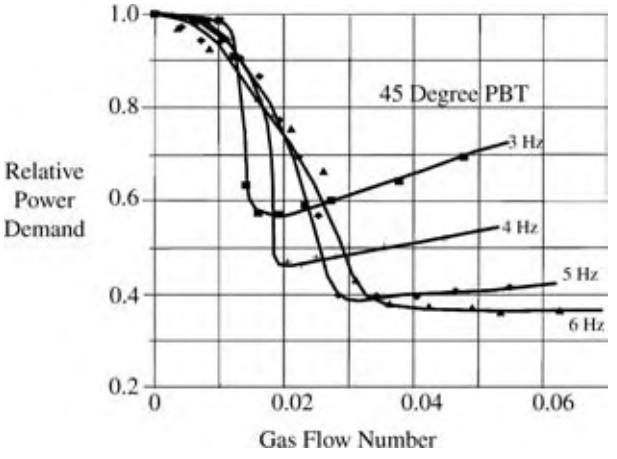

Fig. 9 Relative power demand for a down-pumping 45° pitched-blade turbine. (From Refs.[1,14].)

Correlations have also been developed for P_G. Bakker, Smith, and Myers report the following equation for a single gassed impeller:[10]

$$\frac{P_G}{P_U} = [1 - (b - a\mu)Fr^d]\tanh(cFl_G) \quad (8)$$

where the values of the constants a, b, c, and d are given in Table 4 for two different types of impellers, i.e., flat-blade disk turbine and concave-blade disk turbine. The use of this equation clearly shows that for the same Fl_G value the P_G/P_U ratio is much higher for the concave-blade disk turbine than for the flat-blade disk turbine. This confirms that the concave-blade design is superior to the flat-blade disk turbine in being able to deliver high power at high gas flow. However, it should also be remarked that the power number under ungassed conditions is quite different for the two impellers (5.0 for the flat-blade disk turbine vs. 3.2 for the concave-blade design). Nevertheless, the concave-blade turbine typically delivers more power under most gassed conditions than a straight-blade impeller such as the flat-blade disk turbine.

In the large-cavity regime of gassed aqueous systems, a good approximation for the gassed power of a single flat-blade disk turbine ($D/T = 0.4$) is given by the following expression:[1]

$$\frac{P_G}{P_U} = 0.18Fl_G^{-0.20}Fr^{-0.25} \quad (9)$$

Multiple impellers are often used in gas–liquid operations. Assuming that the lowest impeller is used for the primary gas dispersion, the upper ones are not loaded by all the gas entering through the sparger.[7,10] For the purpose of power demand estimation, it can be assumed that upper impellers experience about half the total gas rate. Correlations to estimate

Table 3 $K_{G/U}$ value for various impellers

Impeller type	N_p	$K_{G/U}$ ($Fl_G = 0.1$)
Radial flow		
6-Blade disk turbine[a] $D = T/3$	5	0.4
12-Blade disk turbine $D = T/3$	10	0.6
18-Blade disk turbine $D = T/3$	12	0.7

[a]This is actually a function of scale.[15]
(From Ref.[1].)

the power dissipated in multiple impeller systems are also available.[1,10,16,17]

GAS HOLDUP

Gas holdup (or retained gas volume fraction), ϕ, is the volumetric fraction of gas in the vessel with respect to the total volume of the gas–liquid mixture, i.e.,

$$\phi = \frac{V_G}{V_L + V_G} \tag{10}$$

In this expression, V_G is the gas volume in the tank under (dynamic) gassed conditions. Experimentally, the gas holdup can be obtained by taking the ratio of the observed incremental height of the gas–liquid mixture (with respect to the height of the liquid when no gas is present) to the total height of the gas–liquid mixture under gassed conditions.

Gas holdup in agitated vessel is difficult to predict a priori, but scale-up can be made reasonably accurately using empirical correlations of the form:

$$\phi = \alpha' \left(\frac{P_G}{\rho V_L}\right)^{\beta'} (v_s)^{\gamma'} \tag{11}$$

where the superficial gas velocity, v_s, is defined as the velocity of the gas in the empty vessel:

$$v_s = \frac{Q_G}{(\pi/4)T^2} \tag{12}$$

The constants α', β', and γ' are independent of scale. The value of α' depends on the physical properties of the liquid in a way that is in general difficult to predict (hence, the recommendation to obtain at least one measurement at the pilot plant scale during process development and use the above correlation for scale-up only). Published data are for aqueous systems, in which the addition of any solute exhibiting surface activity (including electrolytes, alcohols, and surfactants) has a large impact on the gas fraction. For example, in a given system the value of ϕ may be, say, 0.1 if water is used, whereas ϕ may be 0.25 with a solution of a simple electrolyte. For engineering purposes, the situation has been simplified to cover two ''extreme'' classes of liquid system, the so-called ''coalescing'' and ''noncoalescing'' systems, with separate correlations for each for gas fraction and mass transfer.

Values of β' and γ' vary in the literature between 0.2 and 0.7. Generally, $\beta' = 0.48$ and $\gamma' = 0.4$ are quite reliable.[18] More recent work has led to the equation

Table 4 Values of the constants a, b, c, and d in Eq. (8)

Impeller type	a	b	c	d
Rushton turbine	0.72	0.72	24	0.25
Concave-blade turbine (CD6)	0.12	0.44	12	0.37

(From Ref.[10].)

(expressed in W, m, sec units):[19]

$$\phi = 0.9\left(\frac{P_G}{\rho_L V_L}\right)^{0.20}(v_s)^{0.55} \quad (13)$$

for holdup in vessels with multiimpeller agitators dispersing air in water. This equation is for operation at ambient temperature. In the fully turbulent regime, there is a dependence of void fraction on temperature, which results in $\phi \propto \mu^{0.55}$.

INTERFACIAL AREA AND MASS TRANSFER COEFFICIENT IN GAS–LIQUID DISPERSIONS

Because of the difficulty of evaluating independently the specific gas–liquid interfacial area and the mass transfer coefficient, the group $k_L a_v$ is often determined experimentally and correlated to other variables, such as power dissipation under gassed conditions and superficial gas velocity. Correlations for $k_L a_v$ under turbulent conditions are typically expressed in the form:

$$k_L a_v = \alpha''\left(\frac{P}{\rho_L V_L}\right)^{\beta''}(v_s)^{\gamma''} \quad (14)$$

where P includes both the shaft power and the gas buoyancy power ($= QHg[\rho_L - \rho_G]$), but not the gas kinetic energy.[6] Typical values for the air–water system at 20°C are $\alpha'' = 1.2$, $\beta'' = 0.7$, and $\gamma'' = 0.6$, with P (W), V_L (m^3), v_s (m/sec), $k_L a_v$ (sec^{-1}) and α'' dimensioned appropriately.[9] However, it has been found (for example, by Smith, Middleton, and van't Riet) that whereas the indices β'' and γ'' do not change with liquid type, impeller type, or scale, α'' is a strong function of liquid type and properties, with the noncoalescing value of α'' being about twice that for coalescing systems.[18] Thus, such correlations can be used for scale-up purposes, but not for general prediction.

Although it is commonly assumed that when agitation conditions are sufficiently intense for effective gas–liquid dispersion, the liquid mixedness will be good, it is worth checking this, particularly for large vessels. If the mixing time is longer than mass transfer time (90% mass transfer time $= 2.3/k_L a_v$), then the liquid mixing should be improved, or otherwise a more complex design calculation with interlinked zones of different driving force (and even perhaps local values for $k_L a_v$) will be necessary.

The gas–liquid mass transfer rate can be calculated from:

$$\dot{m} = k_L a_v V_L \Delta C \quad (15)$$

where ΔC is the concentration driving force across the phases. This equation shows that knowledge of $k_L a_v$ [through Eq. (14)] is needed to calculate the mass transfer rate. In general, V_L can be taken as the entire volume of the gas–liquid system, provided that the agitation speed is high enough to ensure that the complete dispersed regime has been achieved.

CONCLUSIONS

Mixing is a critical component in the analysis of any gas–liquid reactor system. Mixing significantly affects mass transfer, which, in turn, can have a profound effect on the final yield and selectivity of gas–liquid reactions, especially if the reaction step is faster than the mass transfer step. The complexity of a typical gas–liquid system is such that experimentation should always be incorporated in any development and scale-up work. As in many other multiphase mixing systems, the designer should be aware that the selection of the mixing system and the determination of the operating conditions will have a significant effect on the attainment of adequate gas dispersion and the generation of high interfacial area and a large mass transfer coefficient. The material presented here contains some fundamental knowledge, which, when integrated with practical insight and engineering judgment, can help solve problems associated with industrial gas–liquid applications.

NOMENCLATURE

A	Interfacial area between phases (m^2)
a_v	Interfacial area per unit volume of liquid (m^2/m^3)
B	Baffle width (m)
C	Impeller clearance measured from the impeller centerline to the vessel bottom off the vessel bottom (m)
ΔC	Concentration driving force for mass transfer (mol/m^3)
D	Impeller diameter (m)
$D_{sparger}$	Diameter of sparger ring (m)
g	Gravitational acceleration (m/sec^2)
H	Height of liquid in vessel (m)
$K_{G/U}$ ($=P_G/P_U$)	Gassing factor, i.e., ratio of gassed to ungassed power dissipations
k_L	Mass transfer coefficient (m/sec)
m_L	Mass of liquid (kg)

N	Impeller speed (rotations/sec)
P	Power dissipation (W)
P_G	Power dissipation under gassed conditions (W)
P_U	Power dissipation under ungassed conditions (W)
Q_G	Mean gas volumetric flow rate (m^3/sec)
RPD	Ratio of gassed to ungassed power for impeller (–)
t	Time (sec)
T	Vessel diameter (m)
v_s	Superficial gas velocity, i.e., volumetric gas flow rate/cross-sectional area of vessel (m/sec)
V_G	Volume of gas in vessel (m^3)
V_L	Volume of liquid in vessel (m^3)
W	Width of an impeller blade (m)

Greek Symbols

α', β', γ'	Empirical constants in holdup correlations (–)
α'', β'', γ''	Empirical constants in gas–liquid mass transfer correlations (dimensioned appropriately)
ε	Energy dissipation rate (or power draw) per mass of mixture (W/kg)
ε_{avg}	Average energy dissipation rate (or power draw) per mass of mixture per mass (W/kg)
ϕ	Gas holdup (retained volume fraction of gas phase), i.e., ratio of volume of gas phase to total volume of the gas–liquid mixture (–)
μ	Viscosity (Pa sec)
ν	Kinematic viscosity (m^2/sec)
ρ_L	Density of liquid (kg/m^3)
ρ_G	Density of gas (kg/m^3)
$\bar{\rho}$	Average density of mixture (kg/m^3)
σ	Interfacial tension (N/m)

Dimensionless Groups

Fr	Impeller Froude number, $=N^2D/g$
Fl_G	Gas flow number, $=Q_G/ND^3$
N_p	Power number, $=P/(\rho_L N^3 D^5)$
P_G/P_U	Ratio of gassed to ungassed power for impeller
Re	Impeller Reynolds number, $=\rho_L ND^2/\mu$

INTRODUCTION

The gas adsorption isotherm can be used as an effective way of continuously delivering and replenishing lubricant molecules on solid surfaces when lubrication boundary layers approach molecular length scales. As the gas has essentially negligible viscosity, this approach is favorably applicable to micromechanical systems where power dissipation by the lubricant media is a serious problem. Gas adsorption is fully conformal to all regions of the device when the mean free path of the adsorbate is less than the distance between lubrication faces. This approach is suitable for the lubrication of both buried and exposed surfaces that exist in micro-electromechanical system (MEMS) devices. This entry describes the lubrication effects of alcohol adsorption for native silicon oxide surfaces. The need and advantage of gas-phase lubrication and the molecular basis for alcohols being a good gas-phase lubricant are explained in the background section. The use of atomic force microscopy (AFM) and quartz crystal microbalance (QCM) for gas-phase lubrication measurements are described in the experimental section. The adhesion and the friction of silicon oxide surfaces measured in ambient air and alcohol vapor containing environments are then compared. The alcohol molecules such as ethanol, *n*-propanol, *n*-butanol, and *n*-pentanol adsorb on the substrate surface from the gas phase and form a lubricating film. The resulting film decreases both the adhesion and friction forces between two silicon oxide surfaces. The possible lubrication mechanism and its implication to micromechanical devices are discussed.

BACKGROUND

One of the issues in the design of micromachines is the lubrication of device surfaces and the elimination of wear and stiction between moving parts.[1] As critical dimensions decrease, adhesion and friction become larger problems relating to the reliable operation of these devices.[2] Current approaches to solve the friction and wear problems in MEMS utilize mainly solid-phase lubrication films, which can be deposited on the device surface during the device fabrication.[1,2] Although these approaches have made significant improvements in yielding conformal coating and reducing friction as well as wear in laboratory tests, they have technical limitations relating to the durability of what is essentially a one-time loaded coating. Solid lubricant coatings and organic self-assembled monolayers have been shown to wear off during MEMS operation.[3,4] What is absent in these thin film lubrication systems is the capability for continuous replenishment of the lubricating layer. In fact, the continuous replenishment of lubricating layers has been the key feature of the conventional lubrication approaches typically using viscous liquids. Unfortunately, the viscous nature of the liquid lubricant causes power dissipation, making their usage in MEMS devices undesirable and impractical.

The surface of all inorganic materials exposed to ambient (humid) air is always covered with a thin layer of water adsorbed from the gas phase.[5] The thickness of the adsorbed water layer varies with the humidity and surface chemistry.[6] This water layer has been shown to reduce wear in MEMS operation.[7] However, the high surface tension of the water film can cause an in-use stiction problem. The gas-phase lubrication concept discussed here employs the same equilibrium adsorption principle as the water adsorption in humid environments. The difference is that our approach utilizes a ''surfactant-like'' molecule that can provide low adhesion and good lubrication. The entry summarizes the advantages of gas-phase lubrication for MEMS devices and discusses the effect of alcohol adsorption on the adhesion and lubrication of silicon oxide surfaces.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120041047

ALCOHOL AS A GAS-PHASE LUBRICANT FOR MEMS DEVICES

Alcohols are chosen as a gas-phase lubricant candidate because they have high enough vapor pressure for gas-phase mass transport to the buried surfaces at room temperatures, are environment friendly, and can readily dissolve into the water film present on inorganic solid surfaces in ambient conditions. The vapor pressures of different *n*-alcohols are shown in Fig. 1. The solubility of alcohols in water is shown in Fig. 2. The diffusivity of alcohols in the air is quite high, and their mean free path at room temperature and ambient pressure is much less than device part dimensions. This ensures the lubrication of sidewalls and buried surfaces. Simple alcohols can be used for lubrication of MEMS devices that operate at as low as –100°C and as high as 150°C depending on the number of carbons in the alkyl group (Table 1). The thickness of the adsorbed alcohol layer can be varied by adjusting the alcohol vapor pressure and the substrate temperature.[8,9] In bulk liquid lubrication studies, alcohols have shown good lubrication and antiwear properties for silicon oxide and silicon nitride surfaces in the liquid phase.[10] As in the case of water molecules in the humid air, the presence of the gas-phase alcohol molecules and a few layers of alcohol molecules at the surface will not interfere with optical reflection or electrical contact of devices.

One of the significant problems in MEMS operation under humid conditions is the high stiction forces owing to adsorbed water molecules on the device surfaces. The thickness of the condensed water layer varies with the relative humidity and the surface chemistry (hydrophilicity, hydrophobility, organic contamination, etc.). As water has a very high surface tension (γ_{water} = 72 dyn/cm), the water meniscus formed between two

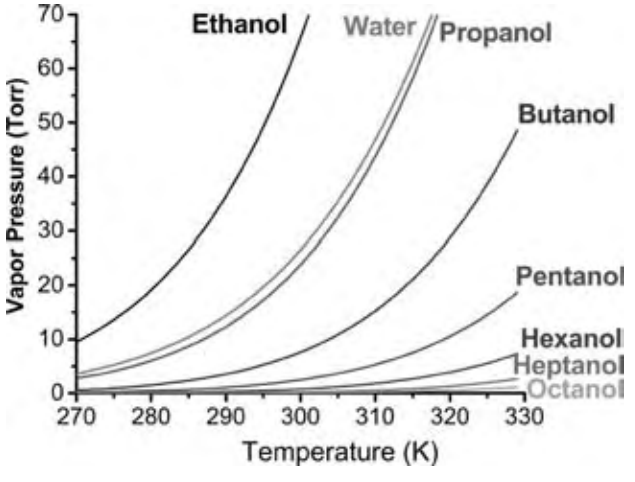

Fig. 1 Vapor pressure of water and 1-alcohols calculated from Antoine equation. *(View this art in color at www.dekker.com.)*

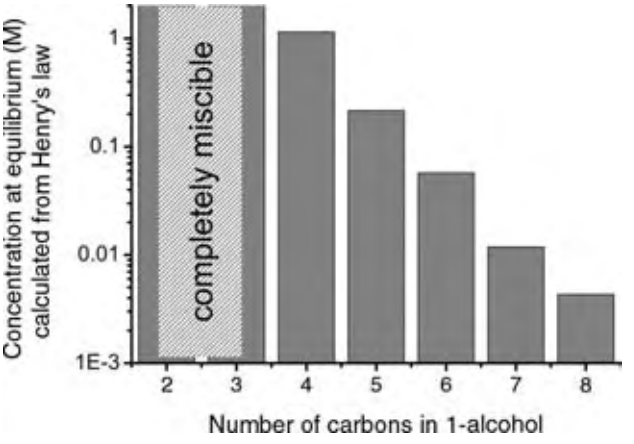

Fig. 2 Solubility of alcohols in water calculated from Henry's law. *(View this art in color at www.dekker.com.)*

surfaces separated by a distance d and having a contact angle θ generates a large Laplace pressure, P_L:

$$P_L = (2\gamma_{water}\cos\theta)/d$$

On a high surface energy substrate, the water contact angle is small and the capillary forces thus generated are sufficiently strong to collapse a typical suspended microstructure to the substrate.[11]

This problem can be mitigated by adding alcohol molecules at the interface. The mass accommodation coefficient for alcohol adsorption at the vapor/water interface varies in the range of 0.1–0.98, depending on the types of alcohols, temperature, and partial pressure.[12,13] Taking into account the high collision frequency of vapor-phase molecules at ambient pressure (in the order of 10^7–10^9collisions/site/sec), the measured accommodation coefficients of alcohol molecules indicate that the dissolution of gas-phase alcohol into water takes place very fast.

The surface tension of aqueous organic solution is lower than that of water.[14] The Gibbs isotherm predicts surface excess of organic molecules at the gas/liquid interface, leading to a nonlinear decrease of the surface tension with respect to the bulk mole fraction of organic molecules in the solution.[15,16] The same effect is expected to occur in the condensed liquid layer of water and alcohol on the substrate surface. The saturated surface concentration of small alcohols reaches $\sim 10^{14}$ molecules/cm^2, resulting in an almost complete coverage of the gas/liquid interface with organic molecules.[17,18] The amphiphilic nature of the molecular structure induces orientational ordering at the gas/liquid interface such that hydrophobic hydrocarbon groups are pointing toward the gas phase and the hydroxyl groups being fully immersed in water.[19,20] This surface ordering is driven by an

Table 1 Melting and boiling points of linear *n*-alcohols

Alcohols	Melting point (°C)	Boiling point (°C)
1-Octanol	−15	196
1-Heptanol	−36	176
1-Hexanol	−52	156
1-Pentanol	−78	137
1-Butanol	−90	118
1-Propanol	−127	97
Ethanol	−117	78

excellent match between water and alcohol OH groups. This reduces the large stiction forces, achieving a film with a lower surface tension because of the hydrocarbon groups of the alcohol molecules, which results in a significant reduction of the free energy.[21,22]

EXPERIMENTAL

Fig. 3 is a basic schematic of the apparatus used for adhesion and friction measurements as a function of the alcohol vapor pressure. Linear *n*-alcohols were used as received, including absolute ethanol (C_2H_5OH, 99.5%), 1-propanol (C_3H_7OH, 99.95%), 1-butanol (C_4H_9OH, 99.9%), and 1-pentanol ($C_5H_{11}OH$, 99+%). The gas composition is controlled by adjusting the ratio of dry argon flowrate to the saturated alcohol/argon flowrate. The mixture of argon and saturated alcohol vapor is produced by flowing dry argon gas through a heated bubbler containing alcohol and a condenser held at the experimental temperature. The purpose of the condenser is to remove any supersaturated alcohol vapor from the argon gas flow, leaving only argon with saturated alcohol vapor at the experimental temperature. The fully saturated vapor experiment was done in a small environment chamber (not shown in Fig. 3) that contained a source of liquid alcohol and concealed the sample compartment of the AFM. The AFM experiments were performed using a Molecular Imaging PicoSPM head and an RHK Technology controller. All measurements were made at room temperature. The substrate was cleaned with a piranha solution followed by UV-ozone cleaning and heating to 300°C. Silicon tips (force constant = 2.2 and 4.5 N/m) covered with a native oxide layer were cleaned with the UV-ozone treatment. The nominal tip diameter characterized by the manufacturer was 20 nm; however, the tip sharpness was readily reduced in our experiment conditions (applied normal force up to 10–100 nN). Adhesion force was determined from the difference between the pull-off point and the free standing location on the force–distance (*f*–*d*) curve. Friction force was determined from the lateral force hysteresis in the left and right scans in contact-mode operation. To minimize experimental artifacts because of the uncertainty in tip diameter and AFM tip aligning, the measured adhesion and friction forces were normalized to the initial adhesion and friction force values measured with dry argon flowing previous to each experiment. A QCM was used to measure the approximate thickness of the alcohol on a gold substrate.

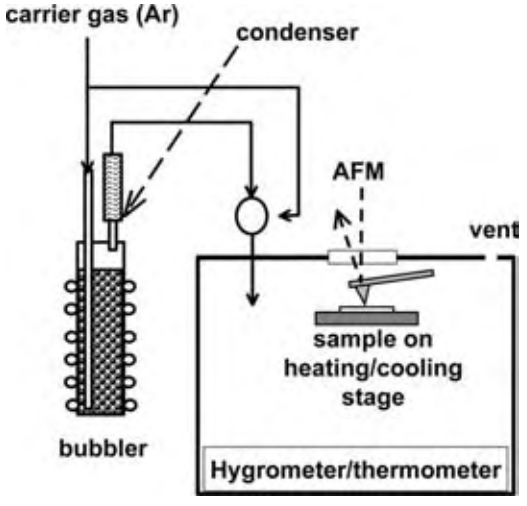

Fig. 3 Schematic diagram of the gas-handling system and the environment-controlled AFM chamber. The alcohol partial pressure is controlled by varying the ratio of dry Ar and alcohol saturated Ar gas flowrates. The alcohol saturated Ar gas stream is generated by flowing Ar through a heated bubbler followed by a condensor held at room temperature.

RESULTS AND DISCUSSION

Adsorption Isotherm of *n*-Propanol on QCM Electrode

Fig. 4 shows the adsorption isotherm of *n*-propanol on the QCM sensor at room temperature. The observed trend of the *n*-propanol film thickness as a function of partial pressure is consistent with the general characteristic of the alcohol adsorption isotherm observed for other systems.[8,9] The inset in Fig. 4 gives the approximate thickness of the adsorbed alcohol layer on the QCM sensor measured at a partial pressure of 90 ± 10% to the saturation pressure of each alcohol. The actual alcohol thickness on the clean, hydrophilic silicon oxide surface would be slightly larger than that on gold.

Formation of the Condensed Liquid Layer at the Saturation Vapor Pressure

At fully saturated vapor pressure, condensation occurs forming a thick liquid layer. The condensed alcohol

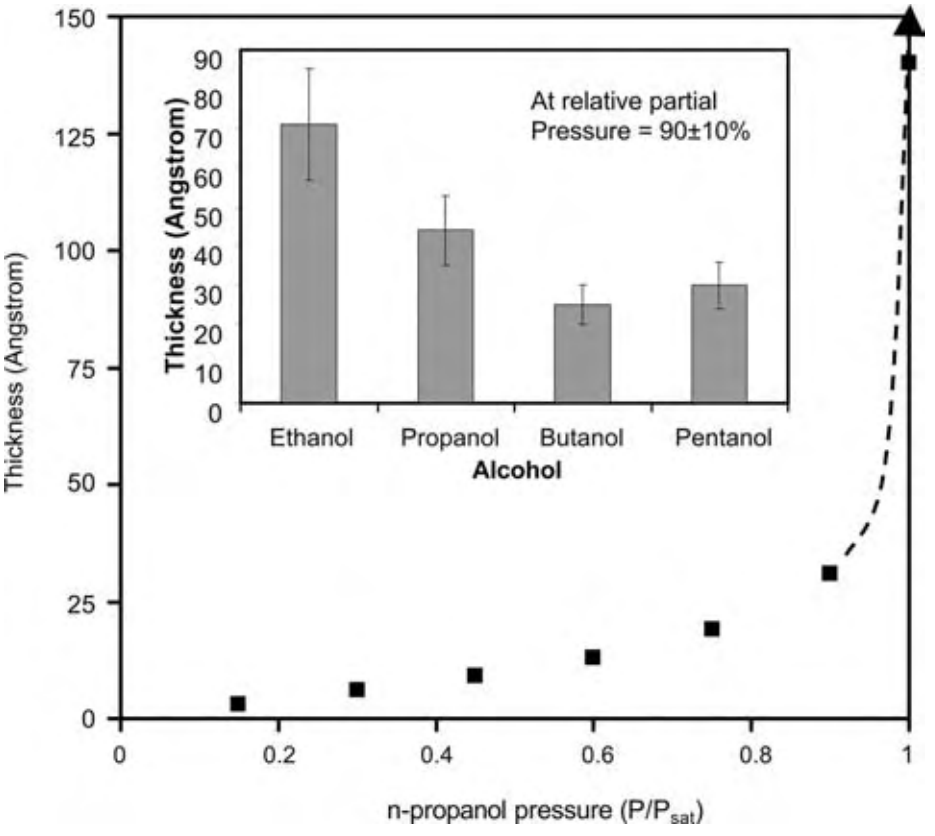

Fig. 4 Thickness of the adsorbed *n*-propanol layer measured with QCM as a function of *n*-propanol partial pressure. It should be noted that the QCM measures the thickness on a gold surface. The 100% saturation data point contains large error because a slight fluctuation in the substrate temperature causes a large change in the condensed layer thickness. The saturation vapor pressure on *n*-propanol is 21.2 Torr at room temperature. The inset shows the adsorbed layer thickness of different alcohols at partial pressures 90 ± 10% to the saturation. *(View this art in color at www.dekker.com.)*

layers are detected in the AFM *f–d* measurements. Fig. 5 shows the approach curve of the *f–d* measurement in the saturated butanol vapor as a function of time. At time zero, the environment suddenly changes by moving the AFM from the ambient air to the *n*-butanol saturated chamber. In ambient air, the AFM tip is snapped into the substrate surface at ~9 nm from the surface. When the environment is changed to saturated butanol vapor, the tip snaps in at a larger distance from the substrate surface. As the condensed butanol layer forms at both substrate and tip surfaces, capillary necking is formed between these condensed layers and pulls the cantilever downward (negative force in Fig. 5). The cantilever remains bent downward because of the capillary action of the condensed butanol layer until the tip finally touches the substrate surface at which the cantilever bends upward upon further movement toward the substrate. As the condensed layer forms on both the tip and the substrate surfaces, half of the distance between the initial snap-in and the substrate contact roughly corresponds to the thickness of the condensed butanol layer (~13 nm in Fig. 5). The calculation of the exact thickness will require detailed knowledge of the curvature dependence of the liquid layer thickness and the capillary neck formation dynamics, which are beyond the scope of this entry.

The snap-in behavior because of the capillary necking of the condensed layer is observed for all alcohols tested. The rate of the condensed layer formation and the equilibrium thickness of the condensed layer are very sensitive to small differences between the initial substrate temperature and gas temperature in the environment chamber. When the substrate

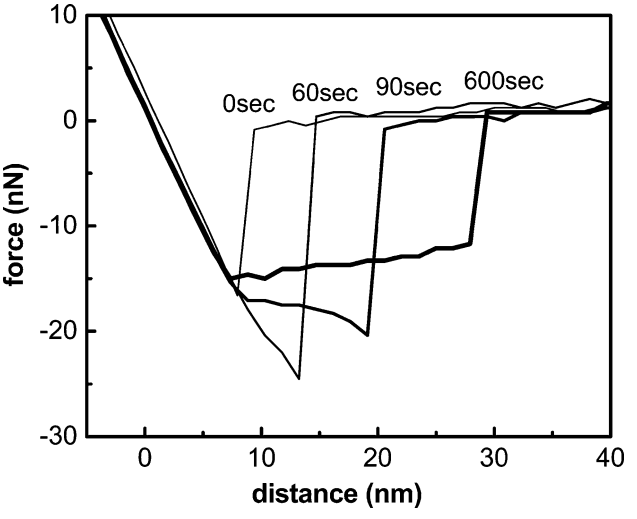

Fig. 5 Approach curve of *f–d* measurement as a function of time upon environment change from ambient air to saturated butanol vapor. The force constant of the cantilever is 2.4 N/m. A blunt tip is used for this measurement.

temperature is lower than the environment chamber temperature, a thick condensed layer (up to ~100 nm) is formed.

The presence of the condensed alcohol layer affects tip–substrate separation processes in *f–d* measurements. Fig. 6 shows the change in adhesion force over time as the environment changes from ambient air to saturated propanol vapor. The pull-off force shown in this figure was measured using a blunt (used) tip to minimize the tip damage/wear effect in subsequent measurements. Although it makes quantitative calculation difficult, the use of a blunt tip is advantageous when taking a series of measurements under high load conditions. The relative change of the contact area occurring at each contact with the substrate surface is assumed to be negligible for a blunt tip. The data obtained with a single blunt tip can then be directly compared without a contact area calibration. In ambient humid air, there is only one pull-off from the substrate. The adhesion force is very large because of the large contact area and the presence of water molecules at the interface. Upon introduction of saturated *n*-propanol vapor, the force required to pull the tip off the surface decreases by ~70% within the first 30 sec. At equilibrium, the adhesive force is reduced to ~90% of the original value. It should also be noted that there is a second snap-off in the retraction curves taking place in saturated alcohol environments. This second snap-off is because of the presence of condensed alcohol formed on the tip and the substrate surfaces. In the first snap-off, the tip is separated from the substrate, but it is still immersed in the condensed layer. As the tip is pulled further away from the surface, it eventually detaches from the condensed layer. As the thickness of the condensed alcohol layer increases, the second pull-off occurs further from the substrate surface.

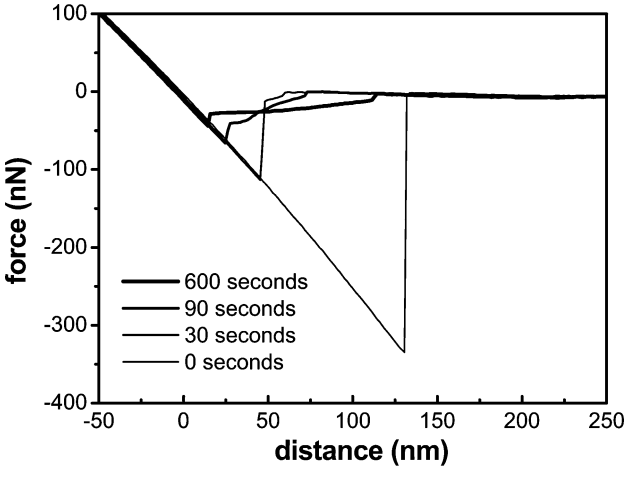

Fig. 6 Retraction part of the *f–d* measurement shown in Fig. 5.

Reduction of Adhesion Force by Alcohol Adsorption

The *n*-propanol adsorption from the gas phase significantly decreases the adhesion force between the silicon oxide surfaces measured with AFM. Fig. 7 illustrates the adhesion force measured with a single tip (2.2 N/m) at various partial pressures of *n*-propanol. The adhesion force decreases 40% compared with the dry Ar case upon initial introduction of *n*-propanol partial pressure. This reduction is not as drastic upon further increase of the *n*-propanol partial pressure. A sudden change in adhesion with only 10% partial pressure indicates that a few monolayer thick *n*-propanol film, as shown in Fig. 4, is sufficient to reduce the adhesion between the silicon oxide surfaces. This behavior is in sharp contrast to the relationship between the adhesion force and the water adsorption isotherm. In the case of water, the adhesion force increases several fold when the relative humidity increases from zero to 50%.[23,24]

This difference could be attributed to the amphiphilic nature of the alcohol. In the case of water, the free OH groups at the surface of the adsorbed water layer on the substrate can form hydrogen bonding with their counterparts on the AFM tip causing high adhesion force. In the case of *n*-propanol, the OH groups have strong interaction with the substrate surface,[25] and the hydrophobic propyl groups are likely to be exposed at the air interface of the adsorbed layer. In this structure, the hydrogen bonding interaction between the two *n*-propanol layers adsorbed on the substrate and the tip will be very small, leading to much smaller adhesion force.

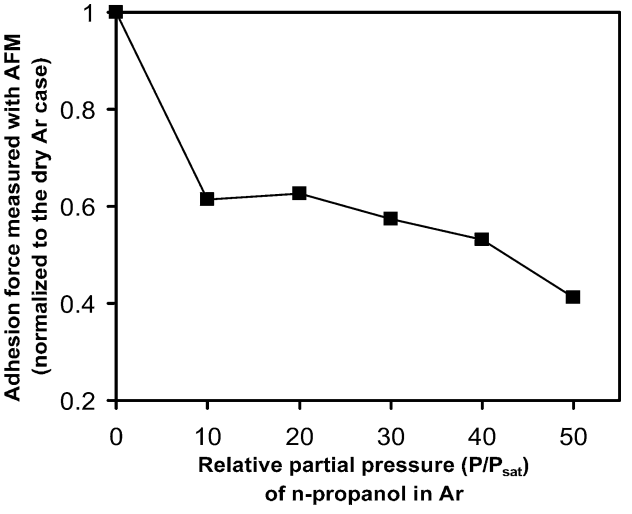

Fig. 7 Adhesion force measured with AFM as a function of *n*-propanol partial pressure. The data are normalized to the dry Ar case, which is measured before the *n*-propanol exposure. Data are acquired with a single tip (2.2 N/m).

Fig. 8 shows the variation of the force required to pull off the tip from the substrate surface with time as the environment is changed from ambient air to the saturated *n*-propanol environment and back to ambient air. Once an equilibrium was reached, the tip was scanned over a $2\,\mu m \times 2\,\mu m$ region of the substrate for further data analysis. The pull-off force decreases immediately upon the exposure of the substrate and tip to the saturated *n*-propanol vapor and increases upon the return of the substrate to ambient humid air. When the substrate is returned to ambient humid air, the pull-off force is initially higher than the equilibrium value and then gradually decreases to the equilibrium with some scatter. The transient behavior is somewhat different from run to run, but the overall trend is quite reproducible. Similar behavior is observed for all four alcohols studied. The origin of this transient overshoot is not clear at this moment. It might be related to the fast evaporation of alcohol from the condensed layer. As the alcohol evaporates, the substrate is cooled locally, prompting large adsorption of water at the cold surface. As the substrate temperature recovers to the temperature equilibrated with the surroundings, the excess water will desorb and the surface reaches equilibrium.

Lubrication by Adsorbed Alcohol Molecules

The change in friction force upon introduction of alcohol vapors is monitored with the lateral force signal during contact-mode scanning. The lateral force signal was measured for several seconds in ambient air to find the initial equilibration value. The substrate and AFM tip were then enclosed in the saturated alcohol vapor environment while scanning, and the lateral force signal was monitored. Fig. 9 shows the magnitude of friction force decrease for each alcohol vapor at saturation environments. To make qualitative comparisons between different alcohols without experimental artifacts caused by the tip curvature difference in each run, all of the data in Fig. 9 are normalized to the initial lateral force signal measured on native silicon oxide in ambient air. The inset in the figure illustrates the change in lateral force signal vs. time. At $t = 0$ sec, the AFM is moved from ambient air to propanol saturated environments and at $t = \sim 1000$ sec, it is returned back to ambient air. The spike in friction force measured upon return to the air might be related to the transient cooling because of evaporation of condensed alcohol. These results illustrate that the lateral force decreases significantly in all the cases studied.

Fig. 10 displays the friction coefficient as a function of the *n*-propanol partial pressure. The friction coefficient is determined from the slope of the lateral force vs. normal load plot. It illustrates that the formation of the *n*-propanol layer on the silicon oxide surface significantly reduces the friction coefficient. It should be noted that the decreasing friction coefficient trend

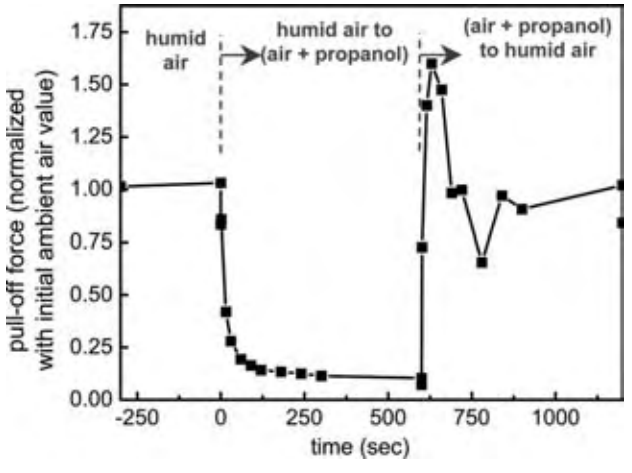

Fig. 8 Pull-off force changes upon environment change from ambient humid air to saturated *n*-propanol vapor and back to ambient air. The $1\,\mu m \times 1\,\mu m$ surface was scanned between –300 and 0, 300 and 600, and 900 and 1200 sec with a normal force of 50 nN. The tip is blunt because of wear in contact-mode scanning made before each *f–d* measurement. The force constant of the cantilever is 2.2 N/m. *(View this art in color at www.dekker.com.)*

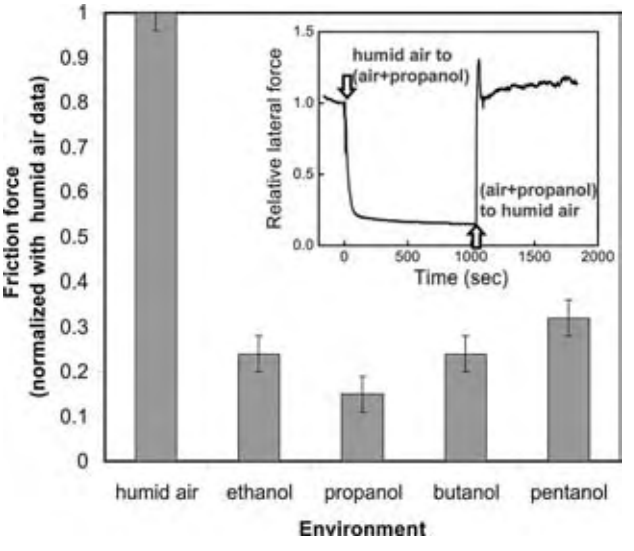

Fig. 9 Decrease of friction force upon environment change from ambient humid air to saturated alcohol vapor. The friction signals are normalized to the initial friction signals measured in ambient air for each experiment to minimize errors because of tip diameter variance in each measurement and emphasize the relative change because of condensed alcohol layer formation. The inset shows temporal changes of friction force upon sudden environment changes. The applied normal signal is kept constant at 75 nN. *(View this art in color at www.dekker.com.)*

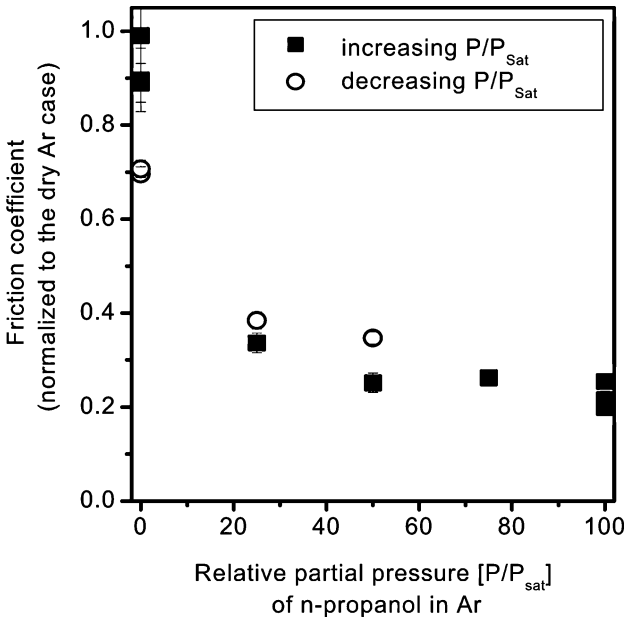

Fig. 10 Friction coefficient measured in contact-mode AFM scan as a function of *n*-propanol partial pressure. Filled squares are data taken at increasingly larger constant partial pressures, and open circles are those taken at decreasingly smaller constant partial pressures.

is very close to that of the adhesion force (Fig. 7). Both the friction coefficient and the adhesion force show large initial decreases upon introduction of *n*-propanol vapor followed by a small decrease with further increase of *n*-propanol vapor. The friction coefficient was also measured while the *n*-propanol partial pressure was decreased from the saturated vapor condition to the dry argon condition. Upon decrease of the *n*-propanol partial pressure from the saturation vapor pressure to zero, the friction coefficient increases close to its initial values.

Lubrication Mechanisms

A qualitative model for lubrication of the condensed alcohol layer is not fully developed yet. We present here the best qualitative model based on the literature. As the applied pressure is very large and the scanning speed is very low in AFM, one can rule out the hydrodynamic lubrication even in the presence of condensed alcohol layer on the substrate. The AFM tip and substrate interface must be in the boundary lubrication regime. Figs. 7–10 show that the adhesion force reduction upon alcohol adsorption is accompanied by reduction of the friction force. Part of the adhesion force reduction is because of the surface tension decrease of the water layer on the substrate. When alcohol is dissolved in water, the surface tension decreases significantly because of segregation of alcohol molecules to the liquid–air interface.[15] Considering purely mechanical components, one can relate this to the JKR theory, which predicts a smaller contact area at a lower adhesion force ($A \propto F_{ad}^{1/3}$). In asperity contact, the friction force is proportional to the contact area as well as the friction coefficient ($F = sA + \mu F_{normal}$ where s is the critical shear modulus and μ is the friction coefficient).

The main question from a chemical aspect is the identification of the species that are responsible for reduction of adhesion and friction at the interface. It is speculated that the alkoxide groups are formed at the substrate. In the self-assembled monolayer study, it is well known that alkyl groups at the interface reduce the adhesion and friction forces.[26] Gates and Hsu pointed out the alkoxide formation at the alcohol and silicon oxide interface and demonstrated their lubrication and antiwear properties.[10] These alkoxide groups can effectively prevent the chemical wear process associated with water. In the presence of water molecules and surface Si–OH groups, the Si–O–Si bonds can be easily formed and dissociated at the interface.[27] This bond formation and dissociation would cause large adhesion and friction. If the reaction proceeds to the formation of $Si(OH)_4$ or other easily removable species, these reaction products would be released from the substrate surface, producing wear. In the presence of alkoxide at the surface, the water-mediated chemical reactions will not take place, which will result in lower adhesion and friction and prevention of wear. The alkoxide group is of course susceptible to wear under extreme pressure. In our approach, the surface sites exposed by the loss of alkoxide groups will be replenished immediately with alcohol layers. It is this continuous replenishment that makes the adsorption of gas-phase alcohol molecules work as an effective lubrication process. Without continuous replenishment, the alcohol layer lubrication will eventually fail as do other self-assembled monolayer approaches.

CONCLUSIONS

The adhesion and friction forces between silicon oxide surfaces decrease drastically and immediately upon exposure of native silicon oxide surface to vapors of short-chain linear alcohols. The adhesion and friction force changes appear to have reversibility. Re-exposure of the substrate to ambient (humid) air causes the adhesion and friction force to increase back to the original values. The large decrease in friction force in an alcohol environment is in agreement with the decrease in adhesion force. These results indicate the potential of the gas-phase lubrication for MEMS applications. The gas-phase process can be used as an in-use lubrication in which lubricant molecules are supplied to the working

interface while the device is in operation. Furthermore, it can be used in combination with other solid lubricants to enhance their performance.

Gas–Solid Reactions

Douglas P. Harrison
Gordon A. and Mary Cain Department of Chemical Engineering, Louisiana State University, Baton Rouge, Louisiana, U.S.A.

INTRODUCTION

Noncatalytic gas–solid reactions are discussed from the perspectives of single-pellet kinetics and integral reactor design. The single-pellet kinetics section includes a description of the traditional unreacted core and grain models followed by a brief discussion of the importance of solid structural property changes resulting from reaction and/or sintering. The basic equations used to describe noncatalytic gas–solid reactions in fixed-bed, fluidized-bed, and moving-bed reactors are then developed. The mathematical analysis is limited to isothermal reactions. This entry concludes with brief descriptions of selected commercial processes in which noncatalytic gas–solid reactions play a major role. Traditional processes such as the production of iron from its ore in the blast furnace and new processes such as the production of silicon for semiconductor applications are included. The processes selected represent each of the integral reactor types.

BACKGROUND

Gas–solid noncatalytic reactions are encountered in a broad range of industrial processes, including coal combustion and gasification, mineral processing, the capture of contaminants from gas streams, and the regeneration of coked catalysts. In applications such as combustion and gasification, the solid phase disappears as the reaction proceeds, while in others such as the capture of sulfur from gas streams, the solid reactant is converted into a solid product.

Although many similarities exist between gas–solid catalytic and gas–solid noncatalytic reactions, the noncatalytic systems, particularly when a porous reactant is converted to a porous product, are more complex. Both occur as the result of a number of series–parallel steps. Mass transfer of reacting gas from the bulk gas to the exterior of the solid and that of gas product from the solid to the bulk gas are involved in each. Diffusion of the reacting gas from the exterior surface into a porous catalyst or porous solid reactant and that of gas product from the pores to the exterior surface are also common to the two types of reactions. Adsorption of reacting gas, surface reaction, and desorption of product gas on catalyst active sites and on solid reactant are similar. However, the noncatalytic gas–solid system is inherently unsteady state as the solid is a stoichiometric participant in the reaction. Catalytic reactions, except when catalyst deactivation is rapid, are generally considered to be steady state. While catalysis is limited to surface active sites, the noncatalytic reaction may occur throughout the solid volume, which adds a product layer diffusion step. In addition, structural properties such as surface area and pore size distribution of catalysts are generally constant and they may vary in a noncatalytic reaction because of differences in the molar volumes of solid reactant and product. While sintering can cause structural properties to change in both a catalyst and solid reactant, catalytic reaction conditions are chosen so that sintering is, at worst, a slow process. In contrast, noncatalytic reactions may occur at such high temperatures that sintering cannot be avoided.

The desired product from gas–solid reactions may be a gas, such as in the production of synthesis gas during coal gasification, a solid, as encountered in the roasting (oxidation) of sulfide ores, "heat" from the combustion of a solid fuel, or some combination. The solid product may be used directly or may require further processing. When the solid is used to capture contaminants from the gas stream, it may constitute a waste material such as occurs during the formation of $CaSO_3$ and $CaSO_4$ in flue gas desulfurization processes, or the solid reactant may be regenerated for multicycle use as in the fluidized-bed catalytic cracking process.

The types of reactors used for catalytic and noncatalytic gas–solid reactions are also often similar. Moving-bed reactors are used in blast furnaces and cement kilns. Fluidized-bed reactors are used for the roasting of sulfide ores and regeneration of catalytic cracking catalyst, and fixed-bed reactors are used to remove sulfur compounds from ammonia synthesis feed gas. When regeneration of the solid reactant is desired, two or more reactors operating in parallel are required if continuous, steady-state operation is to be achieved.

This entry examines noncatalytic gas–solid reactions beginning with the behavior of single pellets, moving to the performance of integral reactors, and ending with a description of selected noncatalytic gas–solid reaction processes.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007786

SINGLE-PELLET REACTIONS MODELS

Numerous mathematical models describing the reactions of single solid pellets were proposed in the period ranging roughly from 1960 to 1980. While more sophisticated variations have been presented subsequently, the early models established the basic mathematical framework. The appropriate kinetic model depends on whether the solid reactant is porous or nonporous and whether a solid product is formed by the reaction. With no solid product, the pellet gradually disappears as the reaction proceeds, while if a solid product is formed it is normally assumed that the pellet is of constant diameter. These cases are represented by the generic equations:

$$\mathrm{A}(g) + b\mathrm{B}(s) \leftrightarrow c\mathrm{C}(g) \tag{1}$$

$$\mathrm{A}(g) + b\mathrm{B}(s) \leftrightarrow c\mathrm{C}(g) + d\mathrm{D}(s) \tag{2}$$

The following discussion is limited to pellets of constant diameter. The so-called unreacted core and grain models, which are developed in the following sections, provide a clear picture of the overall processes that occur in the reactions of nonporous and porous particles of constant diameter. Mathematical analysis is limited to isothermal reactions. Models that include the effects of property variations are then described briefly.

The mathematics is based on a single spherical pellet. Szekely et al.[1] present a similar approach for other geometries (cylinders and flat plates).

THE UNREACTED CORE MODEL

This model is applicable to the reactions of nonporous pellets and to porous pellets when the global rate is controlled by pore diffusion. Reaction is limited to a surface separating the solid reactant at the core of the pellet surrounded by a porous layer of solid product. It occurs initially on the external surface of the pellet, and the thickness of the product layer increases as the reaction proceeds, as illustrated in Fig. 1. The global reaction rate is determined by three resistances—mass transfer from bulk gas to particle surface, diffusion through the product layer, and the intrinsic chemistry at the reaction surface.

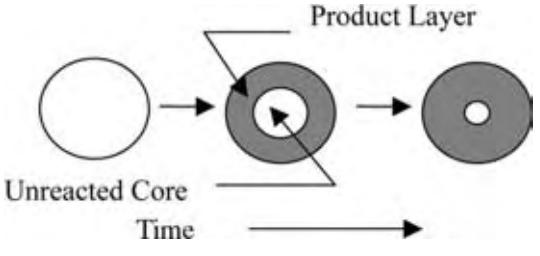

Fig. 1 The unreacted core model.

The mass balance equation and boundary conditions for gas reactant A are:

$$\frac{1}{r^2}\frac{\mathrm{d}}{\mathrm{d}r}\left(\frac{r^2\mathrm{d}C_\mathrm{A}}{\mathrm{d}r}\right) = 0 \quad \text{for } r_\mathrm{s} > r > r_\mathrm{c} \tag{3}$$

$$D_\mathrm{eA}\left(\frac{\mathrm{d}C_\mathrm{A}}{\mathrm{d}r}\right) = -R_\mathrm{A} \quad \text{at } r = r_\mathrm{c} \tag{4}$$

$$D_\mathrm{eA}\left(\frac{\mathrm{d}C_\mathrm{A}}{\mathrm{d}r}\right) = k_\mathrm{mA}(C_\mathrm{Ao} - C_\mathrm{As}) \quad \text{at } r = r_\mathrm{s} \tag{5}$$

The intrinsic rate equation for first-order kinetics is

$$R_\mathrm{A} = k_\mathrm{s}C_\mathrm{So}C_\mathrm{Ac} \tag{6}$$

The position of the unreacted core as a function of time is given by the solid reactant material balance and initial condition

$$\frac{\mathrm{d}r_\mathrm{c}}{\mathrm{d}t} = bk_\mathrm{s}C_\mathrm{Ac} \tag{7}$$

$$r_\mathrm{c} = r_\mathrm{s} \quad \text{at } t = 0 \tag{8}$$

The fractional solid conversion and the radius of the unreacted core are related by

$$x = 1 - \frac{r_\mathrm{c}^3}{r_\mathrm{s}^3} \tag{9}$$

All terms are defined in the nomenclature section. The above equations can be solved analytically for an isothermal reaction to obtain the following algebraic relationships for C_A as a function of r_c and x as a function of t.

$$\frac{C_\mathrm{A}}{C_\mathrm{Ao}} = \frac{\left[\left(1 - \frac{D_\mathrm{eA}}{K_\mathrm{s}C_\mathrm{So}r_\mathrm{c}}\right)\frac{1}{r_\mathrm{c}} - \frac{1}{r}\right]}{\left[1 - \frac{D_\mathrm{eA}}{k_\mathrm{s}C_\mathrm{So}r_\mathrm{c}}\right]\frac{1}{r_\mathrm{c}} - \left[1 - \frac{D_\mathrm{eA}}{k_\mathrm{mA}r_\mathrm{s}}\right]\frac{1}{r_\mathrm{s}}} \tag{10}$$

$$t = \frac{r_\mathrm{s}C_\mathrm{So}}{(-b)C_\mathrm{Ao}}\left[\frac{x}{3k_\mathrm{mA}} + \frac{r_\mathrm{s}}{6D_\mathrm{eA}}\{1 + 2(1 - x) - 3(1 - x)^{2/3}\} + \frac{1}{k_\mathrm{s}C_\mathrm{so}}\{1 - (1 - x)^{1/3}\}\right] \tag{11}$$

Eq. (11) shows the relationship between the three reaction resistances. The first term represents the external mass transfer resistance, the second the resistance associated with diffusion through the product layer, and the third the chemical reaction resistance at the reactant-product interface.

In spite of the existence of the three resistances, it has been common practice to interpret experimental data on the basis of a single controlling resistance. When external mass transfer resistance controls, $k_{mA} \ll D_{eA}/r_s$ and $k_{mA} \ll k_s C_{So}$, so that Eq. (11) reduces to

$$t = \frac{r_s C_{So} x}{3(-b) C_{Ao} k_{mA}} \tag{12}$$

A linear relationship between t and x is used to conclude that mass transfer is the controlling resistance and to evaluate the mass transfer coefficient. In practice, the relative importance of the mass transfer resistance should decrease with time as the reaction proceeds and the global rate decreases. Hence, it is unlikely that mass transfer resistance would be the rate-controlling step throughout the entire reaction period.

When diffusion through the product layer controls the global rate, $D_{eA}/r_s \ll k_{mA}$ and $D_{eA}/r_s \ll k_s C_{So}$, Eq. (11) becomes

$$t = \frac{r_s^2 C_{So}}{6(-b) C_{Ao} D_{eA}} \left[1 + 2(1 - x) - 3(1 - x)^{2/3}\right] \tag{13}$$

A linear relationship between t and the term in brackets is indicative of product layer diffusion control. However, the product layer diffusion resistance must be zero initially when no product layer exists. Product layer diffusion resistance may increase rapidly as the product layer thickness increases, and, particularly at high temperature, can become rate-controlling during a large portion of the reaction.

Finally, when the surface reaction resistance controls the global rate, $k_s C_{So} \ll k_{mA}$ and $k_s C_{So} \ll D_{eA}/r_s$, Eq. (11) becomes

$$t = \frac{r_s}{(-b) k_s C_{Ao}} \left[1 - (1 - x)^{1/3}\right] \tag{14}$$

The surface reaction resistance is most likely to be important at lower reaction temperatures and is the only resistance that can truly be rate controlling throughout the entire reaction.

A similar treatment may be used to describe the gas–solid reaction rate when there is no solid product formed such as encountered in solid fuel combustion. However, in that case, the product layer diffusion resistance is always zero.

A classic example of the use of the unreacted core model is that of Weisz and Goodwin[2] who studied the regeneration of fluidized-bed cracking catalyst. Although the cracking catalyst was porous, at a reaction temperature of 700°C the global rate was controlled by diffusion through the coke-free layer of catalyst and the relation between fractional regeneration and time agreed with Eq. (13). In addition, an examination of the radial profile of coke concentration in partially regenerated catalyst showed a high coke concentration near the center surrounded by a layer of essentially zero coke.

In another example, Beveridge[3] studied the oxidation of zinc sulfide spheres and reported that the global rate was, in turn, controlled by the surface chemical reaction at low temperatures, diffusion through the zinc oxide product layer at intermediate temperatures, and external mass transfer resistance at higher temperatures.

Costa and Smith[4] studied the hydrofluorination of nonporous uranium dioxide pellets under conditions where external mass transfer resistance was negligible. The global rate was initially controlled by the surface chemical reaction resistance, but switched to product layer diffusion as the reaction progressed and the product layer thickness increased.

For nonisothermal reactions, the energy balance must also be considered. The mass and energy balances are coupled through the reaction rate term and an analytical solution is no longer possible. Temperature increases for exothermic reactions may sometimes be quite large. For example, Themelis and Yannopoulos[5] studied the reduction of cupric oxide with hydrogen and, by imbedding very fine thermocouples in the pellet, found that the temperature increased from about 250 to 900°C in 1 min. Luss and Amundson[6] developed a model to calculate the maximum temperature rise in a spherical pellet by assuming a uniform temperature within the pellet.

THE GRAIN MODEL

The grain model is perhaps the simplest of a number of so-called structural models. The porous spherical pellet is assumed to be composed of a large number of spherical grains, each of which reacts according to the unreacted core model. A diagram of this model is shown in Fig. 2. The magnified section shows completely reacted grains near the outside of the pellet, unreacted grains toward the center, and partially reacted grains between. Grain size may be estimated from measured surface area, while diffusion properties

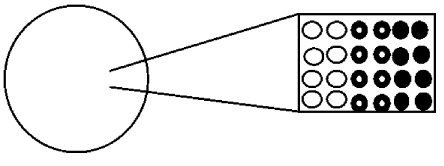

Fig. 2 The grain model.

between the grains may be estimated from porosity and pore size distribution measurements.

The grain model contains four reaction resistances: mass transfer of reactant gas from the bulk gas to the pellet surface, diffusion between the grains, diffusion through a solid product layer surrounding individual grains, and reaction at the interface of each grain. Product layer diffusion may occur by a solid-state mechanism or by diffusion through micropores. When chemical reaction at the grain interface is the controlling resistance, the gas concentration will be constant at all radial positions and the grains will react uniformly. When diffusion between grains is the controlling mechanism, the thickness of the reaction zone approaches zero and the grain model becomes identical to the unreacted core model.

The grain model gas phase material balance and boundary equations for a first-order reaction are

$$\frac{1}{r^2}\frac{\mathrm{d}}{\mathrm{d}r}\left[\frac{D_{\mathrm{eA}}r^2\mathrm{d}C_{\mathrm{A}}}{\mathrm{d}r}\right] + \frac{(-3)r_{\mathrm{c}}'^2k_{\mathrm{s}}'C_{\mathrm{So}}C_A}{r_{\mathrm{s}}'^3\left[1 - \frac{k_{\mathrm{s}}'C_{\mathrm{So}}r_{\mathrm{c}}'}{D_{\mathrm{eA}}'}\left(1 - \frac{r_{\mathrm{c}}'}{r_{\mathrm{s}}'}\right)\right]} = 0 \tag{15}$$

$$D_{\mathrm{eA}}\left(\frac{\mathrm{d}C_{\mathrm{A}}}{\mathrm{d}r}\right) = k_{\mathrm{mA}}(C_{\mathrm{Ao}} - C_{\mathrm{As}}) \quad \text{at } r = r_{\mathrm{s}} \tag{16}$$

$$\frac{\mathrm{d}C_{\mathrm{A}}}{\mathrm{d}r} = 0 \quad \text{at } r = 0 \tag{17}$$

The concentration at the grain surface, C_{As}', is assumed to be the same as that within the pores at the same radial position.

The radius of the unreacted core within each grain as a function of time is given by the solid reactant material balance and initial condition:

$$\frac{\mathrm{d}r_{\mathrm{c}}'}{\mathrm{d}t} = \frac{bk_{\mathrm{s}}'C_{\mathrm{A}}}{\left[1 - \frac{k_{\mathrm{s}}'C_{\mathrm{So}}'r_{\mathrm{c}}'}{D_{\mathrm{eA}}'}\left(1 - \frac{r_{\mathrm{c}}'}{r_{\mathrm{s}}'}\right)\right]} \tag{18}$$

$$r_{\mathrm{c}}' = r_{\mathrm{s}}' \quad \text{at } t = 0 \tag{19}$$

Numerical solution is required even for an isothermal reaction. However, an approximate solution based on adding the times required to reach a given fractional conversion if each separate step in the process is assumed to be rate limiting has been published[7] that agrees quite well with the numerical solution.

A number of studies have used the grain model as the basis for comparison with experimental data. For example, Szekely and Evans[8] studied the reduction of nickel oxide pellets with hydrogen. Their grain model analysis considered the effects of external mass transfer, diffusion between grains, and surface reaction, but assumed that diffusion resistance through the product layer was negligible. Reasonable agreement was obtained between model predictions and experimental results except at reaction temperatures above 650°C, where the product solid experienced significant sintering.

Gibson and Harrison[9] used the grain model to analyze data on the reaction of hydrogen sulfide with zinc oxide. All model parameters with the exception of the grain diffusion coefficient were directly measured or estimated from literature correlations. Good agreement between the model and experimental results was found in the temperature range of 600–700°C when the grain product layer resistance was neglected. However, at lower temperatures, the grain model without product layer resistance was unable to predict the reaction "die-off" that occurred well before complete conversion of oxide to sulfide. Qualitative agreement was obtained when product layer diffusion resistance was included with the grain diffusion coefficient treated as a fit parameter. At higher temperatures, the failure of the model to agree with experimental results was attributed to solid structural property changes associated with sintering.

Other Single-Pellet Kinetic Models

The need to include solid structural property variations in the single-pellet models was illustrated by the high-temperature results from the two examples cited above. In those cases, the structural property variations were attributed to sintering of the solid product and/or reactant. Structural property variations may also occur at lower temperatures where sintering would not be expected because of the differences in molar volumes of solid reactant and product.

One of the early models that considered property variations owing to molar volume differences was the single pore model of Ramachandran and Smith.[10] The solid reactant initially consisted of a number of cylindrical pores of fixed length and diameter. The reaction that occurs along the walls of the pores causes a decrease in pore diameter when the molar volume of the product is larger than that of the reactant and an increase in pore diameter for the reverse case. The global reaction rate is determined by four resistances: external mass transfer, pore diffusion, solid product layer diffusion, and surface chemical reaction. Fig. 3 illustrates a case in which pore diffusion resistance is important and the molar volume of the product is greater than that of the reactant. The reaction tends to occur first near the entrance to the pore, causing the pore radius to be smaller near the pore mouth. Depending on the relative molar volumes of solid

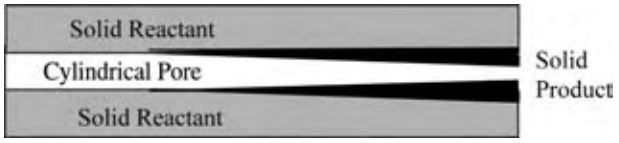

Fig. 3 Single pore model.

reactant and product, complete pore mouth closure may occur, thus preventing reactant gas from entering the pore and causing reaction "die-off" well before complete conversion of the solid. If the pore diffusion resistance is negligible, the gas concentration will be uniform throughout the length of the pore and pore radius change will be independent of pore length.

Ramachandran and Smith obtained satisfactory agreement with experimental results on the reduction of nickel oxide with carbon monoxide (pore opening case) by considering the product layer diffusion coefficient as an adjustable parameter. Similarly, the model predicted pore closure and reaction "die-off" for the reaction of calcium oxide with sulfur dioxide, where the molar volume of calcium sulfate product is about three times that of the calcium oxide reactant.

Hartman and Coughlin[11] modified the grain model to consider structural changes because of the differences in molar volume and also applied the model to the reaction between calcium oxide and sulfur dioxide. Although the grain radius was assumed to remain constant, the pore structure of the solid was allowed to change as the reaction progressed. As a result, the diffusion coefficient between grains was a function of radial position in the pellet. Again the product layer diffusion coefficient was treated as a fit parameter. The predicted fractional solid conversion corresponding to reaction "die-off" closely matched experimental values for a number of pellet sizes.

In a subsequent paper, Ramachandran and Smith[12] again used the grain model as the basis and considered the effects of both reaction and sintering on solid physical properties. As reaction proceeds, the grains expand, contract, or remain the same size due to differences in molar volumes and sintering. Sintering results in a decrease in product layer porosity that causes a reduction in product layer diffusion coefficient. By using best-fit model parameters, there was good agreement with experimental data on the hydrofluorination of uranium dioxide. It is important to note, however, that although the model was capable of including sintering, the effect was ignored in this case as sintering was thought to be negligible at the reaction temperature tested.

Ranade and Harrison[13] also modified the grain model to account for structural changes because of the combined effects of reaction and sintering. As the reaction proceeds, the individual grains expand or contract owing to the different molar volumes of solid reactant and product. Also, because of sintering, adjacent grains combine to give larger grains as shown in Fig. 4. The large number of small grains initially present is replaced by a smaller number of larger grains. For mathematical simplicity, a single unreacted core is assumed to remain at the center of sintered grains. In contrast to the standard grain model in which the grain core radius decreases monotonically as the reaction proceeds, sintering may actually lead to an increase in the unreacted core radius within the larger grains.

Solid structure was correlated with surface area measurements as a function of solid conversion under conditions where no sintering occurred, as a function of sintering time and temperature in the absence of reaction, and at conditions where reaction and sintering occurred simultaneously. The model was then tested using the experimental data of Gibson and Harrison[9] for the reaction between hydrogen sulfide and zinc oxide referred to in the previous section. Although sintering was quite severe at temperatures above 500°C, its inclusion in the model had a relatively small effect on predicted time–solid conversion performance.

INTEGRAL REACTOR MODELS

Gas–solid reactions are carried out on a commercial basis using fixed-bed, moving-bed, and fluidized-bed reactors. The fixed-bed reactor is an unsteady-state system as reactive gas is fed on a continuous basis through the reactor that is packed with a finite quantity of solid reactant. The solid is depleted and breakthrough of the gas reactant occurs after a certain reaction time. In the moving-bed reactor, both solid and gas are fed on a continuous basis and overall operation is steady state. The fluidized-bed reactor, where small solid particles are fluidized by upward flow of gas, also operates in a steady-state manner. Diffusional reaction resistances are reduced because of the small solid particles while solid backmixing reduces solid concentration gradients and promotes isothermal operation.

At least two reactors are needed with each reactor type if the solid is to be regenerated for multicycle operation. In the fixed-bed operation, the primary

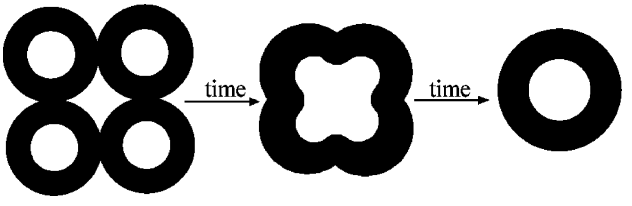

Fig. 4 The changing grain size model.

reaction is carried out in one reactor while regeneration occurs in the second. Gas flows are reversed when breakthrough occurs in the primary reactor and the functions of the two reactors are reversed. In the moving-bed system with solid regeneration, the first reactor is always used for the primary reaction and the second for regeneration. Solids are transported between the two reactors, perhaps by a system that resembles a bucket elevator, but gas flows always remain constant. The functions of the two reactors remain constant in the fluidized-bed scheme as well, where the small solid particles are pneumatically transferred between reactors.

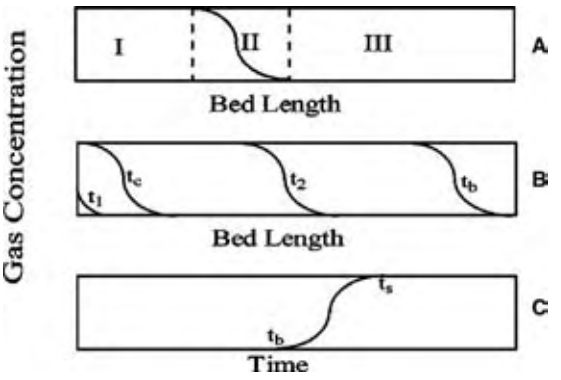

Fig. 6 Fixed-bed reactor performance.

Fixed-Bed Reactor System

A schematic diagram of the two-reactor fixed-bed system is shown in Fig. 5. The primary reaction occurs in the reactor on the left while regeneration occurs on the right. Dashed lines indicate gas flow paths when the functions of the two reactors are reversed. Both gas and solid concentrations and temperatures (for non-isothermal reactors) are functions of time and axial position.

The progress of the reaction is shown in Fig. 6. In Fig. 6A the reactor is divided into three regions. In region I, the solid has been fully reacted and the gas concentration is equal to the inlet gas concentration. Reaction occurs in region II where the gas concentration is reduced from its inlet value to near zero or to near the equilibrium value. Solid reactant in region III has not yet been exposed to reactant gas. Fig. 6B illustrates the movement of the reaction front through the bed with time. To a good approximation, once the reaction front is fully established at time, t_c, it moves through the bed at a constant velocity (known as constant-pattern behavior) until the leading edge of the reaction zone just corresponds to the exit of the packed bed at t_b, the breakthrough time. After the constant-pattern behavior has been established, the solid fraction conversion profile and the gas concentration profile shown in Fig. 6B are identical. Fig. 6C shows the product gas concentration as a function of time. Before breakthrough, the exit gas concentration is near zero. After breakthrough, the reactant gas concentration increases with time until all solid has reacted at t_s. Inlet and outlet gas concentrations are then equal.

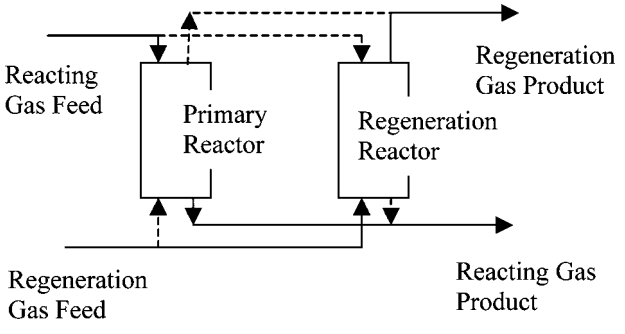

Fig. 5 The fixed-bed reactor system.

The performance of an isothermal fixed-bed reactor may be described by solving appropriate material balances on the gaseous and solid reactants. If plug flow of the gas phase is assumed, the gas reactant material balance and boundary condition are

$$U_o \frac{dC_A}{dz} = -k_{mA} a_v (C_{Ao} - C_{As}) = R_A^v \quad (20)$$

$$C_A = C_{Ai} \quad \text{at } z = 0 \quad (21)$$

Similarly, the solid phase material balance and initial condition are

$$(1 - \varepsilon_v) \frac{dC_s}{dt} = b k_{mA} a_v (C_{Ao} - C_{AS}) = b R_A^v \quad (22)$$

$$C_s = C_{So} \quad \text{at } t = 0 \quad (23)$$

The expression for R_A^v is obtained from the appropriate single-pellet model.

Wang et al.[14] compared the model predictions to experimental data on the desulfurization of simulated coal gas from a laboratory-scale fixed-bed reactor and from a process development reactor operated on actual coal gas. The solid reactant was formed from cylindrical pellets of zinc and titanium oxides. Data from six experiments using different temperatures, pressures, feed gas flow rates, and feed gas H_2S concentrations were available. Product gas concentrations were measured as a function of time, and the axial distribution of sulfur within the reactor was determined at the conclusion of the test.

The unreacted core model, suitably modified for cylindrical geometry, was used to describe the behavior

of a single pellet. All fixed-bed model parameters with the exception of the diffusion coefficient through the product layer, D_{eA}, associated with each pellet were established a priori. D_{eA} was chosen to provide good fit with experimental gas product concentrations during breakthrough. Variations in best-fit values of D_{eA} from run-to-run were qualitatively consistent with those in reactor temperature and pressure. In addition, the model predictions of axial sulfur concentration within the bed at the conclusion of the test using the previously determined value of D_{eA} were in good agreement with the measured sulfur distributions.

Fluidized-Bed Reactor System

A fluidized-bed reactor system may be operated with dual circulating beds as shown in Fig. 7, when the solid is to be regenerated or in a single bed if regeneration is not required. In the dual-bed mode, the solid is pneumatically transferred between reactors to provide for steady-state operation. The roasting of sulfide ores is an important example of the use of a single fluidized bed, while the dual circulation fluidized beds are used in the catalytic cracking of gas oil and regeneration of the coked catalyst.

The three-phase bubble model developed by Kunii and Levenspiel[15] shown in Fig. 8 is used to illustrate fluidized-bed reactor modeling. The bed is composed of bubble, cloud plus wake, and emulsion phases. The gas in the bubble phase is assumed to be in plug flow, and gas flow through the cloud and emulsion phases is neglected. The bubble is assumed to be free of solids so that reaction is restricted to the cloud and emulsion phases. Because of extensive solid backmixing, it is assumed that no solid concentration gradients exist (or temperature gradients in the case of a nonisothermal system). As the particles are much smaller than those used in fixed or moving beds, there is little, if any, mass transfer or intraparticle diffusion limitation on the global reaction rate, which leaves the intrinsic reaction rate as the dominant reaction resistance.

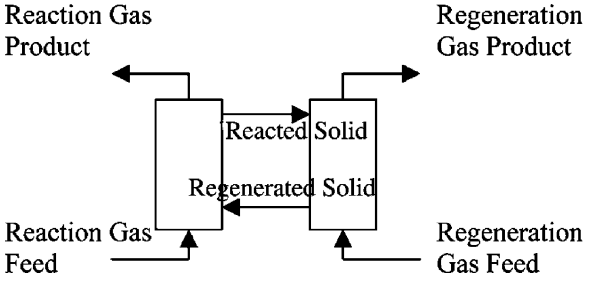

Fig. 7 The fluidized-bed reactor system.

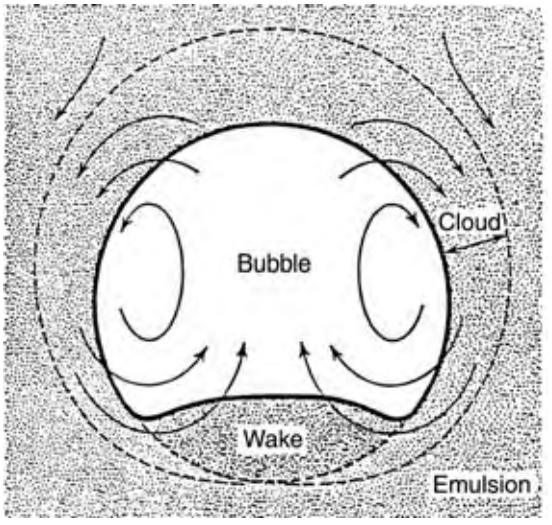

Fig. 8 The three-phase fluidized-bed reactor model.

With these simplifications, the material balance equation for reacting gas is

$$-U_b \frac{dC_{Ab}}{dz} = K_r C_{Ab} \tag{24}$$

K_r is a pseudo first-order rate constant. As the reactor is isothermal and the solid concentration is constant, Eq. (24) can be integrated to give an algebraic relationship between bed height and gas phase concentration in the bubble. Likewise, an overall solid reactant material balance yields an algebraic expression for the concentration of solid reactant in the reactor product.

$$C_{Ab} = C_{Ai} \exp\left(\frac{-K_r z}{U_b}\right) \tag{25}$$

$$C_{sf} = C_{So} + \frac{bV_o}{Q_{So}}(C_{Ao} - C_{Af}) \tag{26}$$

The pseudo first-order rate constant includes the effects of gas phase transfer between the bubble, cloud, and emulsion phases. Correlations for estimating model parameters may be found in the original reference.[15]

$$K_r = k_i C_{Sf} \left\{ \rho_b + \left[\frac{1}{\frac{k_i C_{Sf}}{k_{bc}} + \left(\frac{1}{\frac{\rho_c V_{jz}}{V_b} + \frac{1}{\frac{k_i C_{Sf}}{k_{ce}} + \frac{f}{\rho_c (1-f)}}} \right)} \right] \right\} \tag{27}$$

Matsui et al.[16] compared experimental data on the steam gasification of coal char from a laboratory-scale fluidized-bed reactor with the Kunii and Levenspiel model. Good agreement was reported when the bubble diameter was treated as a fitted constant.

Moving-Bed Reactor System

The moving-bed reactor has features common to both the fixed-bed and fluidized-bed reactors. Like the fluidized bed, the moving-bed reactor operates in a steady-state manner by continuous feed of both the solid and gas phases. Flow directions may be countercurrent, cocurrent, or crossflow as shown in Fig. 9. However, the particle sizes used in moving-bed reactors are similar to those used in fixed-bed reactors so that the resistances associated with mass transfer and intraparticle diffusion must be considered. Solids move slowly through the moving-bed reactor without the vigorous mixing encountered in the fluidized-bed system.

In the following analysis, both the solid and gas phases are assumed to move in countercurrent plug flow so that both concentrations (and temperature in nonisothermal reactors) vary with axial position. The material balance with boundary condition for the gas phase reactant is

$$\frac{U_o dC_A}{dz} = -k_{mA} a_v (C_A - C_{As}) = -R_A^v \tag{28}$$

$$C_A = C_{Ao} \quad \text{at } z = 0 \tag{29}$$

The material balance and boundary condition for the solid reactant are

$$U_S(1 - \varepsilon_v)\frac{dC_S}{dz} = -bk_{mA} a_v (C_A - C_{As}) = -bR_A^v \tag{30}$$

$$C_S = C_{So} \quad \text{at } z = L \tag{31}$$

The unreacted core or other appropriate single-pellet model may be used to describe the reaction rate.

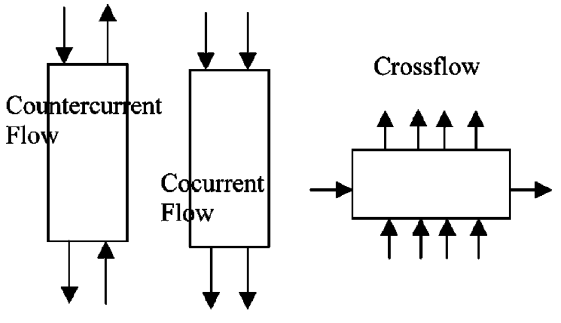

Fig. 9 Flow directions in moving-bed reactors.

PROCESSES INVOLVING NONCATALYTIC GAS–SOLID REACTIONS

This section provides brief descriptions of industrial processes in which noncatalytic gas–solid reactions play a major role. Although by no means complete, the discussion includes both traditional processes, such as the blast furnace for the production of iron from ore and the regeneration of fluidized-bed catalytic cracking catalyst, and newer processes such as the dry capture of SO_2 from flue gas and the production of silicon for semiconductor applications. Each of the three primary reactor types is represented in the processes described.

Blast Furnace

The iron blast furnace, which is the first step in the production of steel, provides an example of a countercurrent flow moving-bed reactor in which numerous gas–solid reactions occur. Iron ore, coke, and limestone are charged to the top, while hot air is fed to the bottom of a refractory-lined reactor vessel. The solids have a residence time of 6–8 hr, whereas the air residence time is only 6–8 sec. The iron ore may contain 50–70% iron, while the molten iron product will typically contain about 95% iron, 4% carbon, and 1% of a number of compounds including silicon, manganese, titanium, phosphorus, and sulfur.

Although large, modern blast furnaces are capable of producing more than 10,000 tons per day of iron, the basic process has not changed since iron was first produced some 700 years ago. Heat is supplied by the oxidation of coke, primarily to carbon monoxide. Both coke and carbon monoxide act as reducing agents for the reduction of iron oxide to metallic iron. The blast furnace temperature is sufficiently high that product iron is a liquid that flows from the bottom of the reactor. Limestone is decomposed to calcium oxide, which reacts with sulfur compounds present in the ore and also combines with other impurities such as alumina and silica to form a low-melting slag that floats on top of the molten iron. Dirty gases emerging from the top of the blast furnace contain a large quantity of carbon monoxide and are burned to preheat the inlet air and/or to generate steam in the plant boiler.

Direct Reduction Iron (DRI)

While the traditional blast furnace is preferred for large-scale operations, processes for the direct reduction of iron ore using carbon monoxide and/or hydrogen are becoming increasingly important. Such processes have the ability to use lower-grade iron ores, particularly fine ore particles, and fuels such as natural gas that are unacceptable for the blast furnace. The iron

product is used as a substitute for scrap steel in the electric arc steelmaking process, and in powder metallurgy and the briquetting industries.

A schematic diagram of the H-iron process[17] is shown in Fig. 10. The primary chemical reaction is

$$Fe_2O_3(s) + 3H_2(g) \rightarrow 2Fe(s) + 3H_2O(g) \quad (32)$$

Iron ore is charged to the top and hydrogen is fed to the bottom of a three-stage fluidized-bed reactor where the ore is reduced to elemental iron at about 500°C. Only about 5% of the hydrogen is utilized in the reaction, so that unreacted hydrogen is recycled after removal of water. The iron product, which is pyrophoric as it emerges from the reactor, is treated with nitrogen at about 850°C for safe storage.

Catalytic Cracking Catalyst Regeneration

Catalytic cracking is widely used in modern petroleum refineries to increase the yield of gasoline by cracking heavy gas oil. Coke, which destroys the catalyst activity, is rapidly deposited on the catalyst during the cracking step. Burning of the coke in the regeneration reactor to restore catalytic activity is an important example of a noncatalytic gas–solid reaction.

Most catalytic cracking units operate in a recirculating fluidized-bed mode as shown in Fig. 7. The coked and regenerated catalyst are continually transferred between the cracking and regeneration reactors to provide steady-state operation. The regenerator can be operated to produce a gas containing both carbon monoxide and carbon dioxide or carbon dioxide alone. Regenerators typically operate in the temperature range of 650–800°C, and careful temperature control is required to prevent destroying the catalyst activity. The primary reactions are

$$C(s) + \frac{1}{2}O_2(g) \leftrightarrow CO(g) \quad (33)$$

$$C(s) + O_2(g) \leftrightarrow CO_2(g) \quad (34)$$

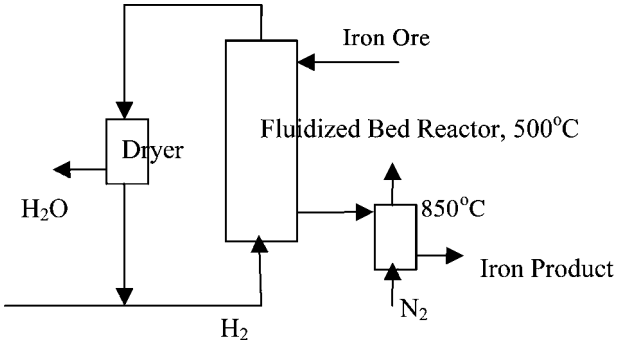

Fig. 10 The H-iron process.

Because the primary cracking reactions are endothermic and the catalyst regeneration reactions are exothermic, the energy associated with the high-temperature regenerated catalyst is used to vaporize gas oil entering the cracking reactor. When flue gas leaving the regenerator contains significant quantities of carbon monoxide, it is burned in a CO boiler to recover the available energy.

Desulfurization of Ammonia Synthesis Feed Gas

Natural gas or light hydrocarbons that serve as feed gas in the synthesis of ammonia contain sulfur compounds that act as poisons for the nickel catalyst used in synthesis gas production. Hydrogen sulfide and mercaptans are the dominant sulfur species in natural gas, while the light hydrocarbons may contain higher boiling sulfur species. A fixed-bed reactor containing zinc oxide is often used to desulfurize the feed gas. The chemical reaction with hydrogen sulfide is

$$ZnO(s) + H_2S(g) \leftrightarrow ZnS(s) + H_2O(g) \quad (35)$$

The reactor operates in the temperature range of 350–400°C and the hydrogen sulfide concentration is reduced from about 50 ppm to less than 1 ppmv in the product gas. Zinc sulfide is not normally regenerated, because regeneration is difficult and the low inlet sulfur concentrations make once-through use economical.

Considerable effort has been expended over the last few years to extend the use of zinc oxide to the desulfurization of coal-derived gases. Harrison[18,19] has described these efforts. The much higher inlet sulfur concentrations in this application require that the sorbent be regenerated so that it can be used for multiple cycles.

Semiconductor-Grade Silicon

High purity silicon is made by the direct decomposition of silane through the reaction

$$SiH_4(g) \leftrightarrow Si(s) + 2H_2(g) \quad (36)$$

Note that this is a special case where the only solid species is a reaction product.

In the process shown in Fig. 11,[20] hydrogen and silane are fed to the bottom of a fluidized-bed reactor, while high purity silicon seed crystals are charged to the top. Hydrogen utilization is quite low so that most of the hydrogen is recycled. The reactor operates at 600–800°C and slightly above atmospheric pressure. The desired decomposition reaction occurs on the surface of the seed crystals and results in particle

size growth. Homogeneous decomposition that occurs in the gas phase produces submicron to 10-μm size particles that tend to be elutriated from the reactor. Product particles in the 700–1000 μm size range are removed from the bottom of the reactor where they are cooled and transferred to a product hopper. Special silicon-lined vessels and piping are required to achieve the high purity required for the semiconductor applications.

Flue Gas Desulfurization

While most commercial flue gas desulfurization processes use wet scrubbing technology, there are economic incentives to develop dry sorption-based processes. The dry processes offer potential for lower capital and operating costs, but are limited primarily by low sorbent utilization.[21]

All dry processes under development use a calcium-based sorbent to react with SO_2 to form $CaSO_3$ and/or $CaSO_4$. All processes are ''once-through'' and the sulfated sorbent is normally land filled along with coal ash. The processes are classified as high-, medium-, and low temperature.

In the high-temperature process, either $CaCO_3$, $Ca(OH)_2$, or CaO is injected directly into the furnace where reaction occurs at 1000–1300°C. Both $CaCO_3$ and $Ca(OH)_2$ decompose to CaO at these temperatures so that the actual desulfurization reaction is

$$CaO(s) + SO_2(g) + \frac{1}{2}O_2(g) \leftrightarrow CaSO_4(s) \qquad (37)$$

The residence time at these temperatures is only about 100 ms so that the reaction must be quite fast if efficient SO_2 capture is to be achieved. Furnace injection is capable of achieving 40–50% SO_2 capture at a molar ratio of Ca/S of 1, and 65–75% capture with Ca/S equal to 2. Sorbent conversion is often limited to about 25% or less because of pore mouth plugging of the particles and sintering at the high temperatures.

In medium-temperature desulfurization, the sorbent is injected into the economizer section of the boiler and reaction occurs at 500–600°C. This temperature is insufficient for $CaCO_3$ calcination to occur so that the feed is limited to $Ca(OH)_2$ or CaO. Finally, the low-temperature process involves sorbent injection at some point in the system where the temperature is below about 350°C. At this low temperature, it is necessary to inject liquid water with the sorbent, either $Ca(OH)_2$ or CaO, to promote the reaction.

In all options, the sorbent is collected along with fly ash in the electrostatic precipitator or bag house, thereby adding to the particulate load on these units.

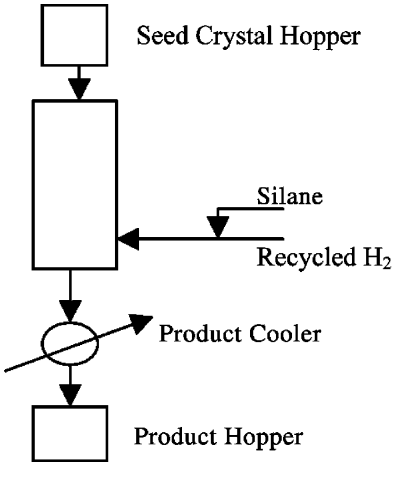

Fig. 11 Fluidized-bed process for silane manufacture.

CONCLUSIONS

The basic framework for modeling noncatalytic gas–solid reactions was established in the 1960–1980 time period. Models include those based on the effects of resistances associated with mass transfer from bulk gas to solid surface, diffusion within the solid pores and through the solid product layer, and the surface chemical reaction. Solid structural property variations associated with reaction and/or solid sintering have been included in the models. The single-pellet models are incorporated into integral models for the design of fixed-bed, fluidized-bed, and moving-bed reactors. Commercial applications of noncatalytic gas–solid reactions include the combustion and gasification of solid fuels, mineral processing, catalytic cracking catalyst regeneration, removal of pollutants from gas streams, and the production of silicon for semiconductor applications.

NOMENCLATURE

a_v	Gas–solid interfacial area per unit bed volume, l^2/l^3
A	Gas reactant
b	Stoichiometric coefficient of the reacting solid, mol B/mol A ($b < 0$)
B	Solid reactant
c	Stoichiometric coefficient of the product gas, mol C/mol A ($c > 0$)
C	Gas product
C_A	Molar concentration of reactant gas A, mol A/l^3; C_{Ab} in the bubble; C_{Ac}, at the interface of the unreacted core; C_{Af}, in reactor gas product; C_{Ai}, in reactor gas feed; C_{Ao}, in the bulk gas; C_{As}, at the external surface of the solid

C_S Molar concentration of reactant solid, mol B/l^3; C_{Sf}, in the fluidized-bed reactor product; C_{So}, initial concentration in the pellet; C'_{So}, initial concentration in the grain
d Stoichiometric coefficient of product solid, mol D/mol A ($d > 0$)
D Solid product
D_{eA} Effective diffusivity of A through the pellet solid product layer, l^2/t
D'_{eA} Effective diffusivity of A through the grain solid product layer, l^2/t
f Volume fraction of bubble phase
k_{bc} Mass transfer coefficient between bubble and cloud, t^{-1}
k_{ce} Mass transfer coefficient between cloud and emulsion, t^{-1}
k_i Reaction rate constant in fluidized-bed reactor, l^6/m mol B t
k_{mA} Mass transfer coefficient of A from bulk gas to pellet surface, l/t
k_s Reaction rate constant based on the surface area of the pellet unreacted core, l^4/mol · t
k'_s Reaction rate constant based on the surface area of the grain unreacted core, l^4/mol · t
K_r Pseudo first-order rate constant in the fluidized-bed reactor, defined by Eq. (27), t^{-1}
L Reactor length, l
Q_{So} Solid volumetric feed rate, l^3/t
r Radial coordinate, l
r_c Radius of the pellet unreacted core, l
r'_c Radius of the grain unreacted core, l
r_s Pellet radius, l
r'_s Grain radius, l
R_A Molar rate of formation of A per unit surface area, mol A/l^2 · t
R^v_A Molar rate of formation of A per unit bed volume, mol A/l^3 · t
t Reaction time, t
U_b Bubble rise velocity in the fluidized bed, l/t
U_o Superficial gas velocity in the fixed-bed and moving-bed reactors, l/t
U_S Superficial solid velocity in the moving-bed reactor, l/t
V_b Bubble volume, l^3
V_{iz} Cloud volume, l^3
V_o Volumetric gas feed rate, l^3/t
x Fractional conversion of solid reactant
z Axial coordinate in the reactor, l
ε_v Bed porosity
ρ_b Mass solid density in bubble, m/l^3
ρ_c Mass solid density in cloud phase, m/l^3
ρ_e Mass solid density in emulsion, m/l^3

Gas-to-Liquid Mass Transfer

Huu D. Doan
Simant R. Upreti
Ali Lohi
Department of Chemical Engineering, Ryerson University, Toronto, Ontario, Canada

INTRODUCTION

Gas-to-liquid mass transfer is a transport phenomenon that involves the transfer of a component (or multiple components) between gas and liquid phases. Gas–liquid contactors, such as gas–liquid absorption/stripping columns, gas–liquid–solid fluidized beds, air-lift reactors, gas bubble reactors, and trickle-bed reactors (TBRs) are frequently encountered in chemical industry. Gas-to-liquid mass transfer is also applied in environmental control systems, e.g., aeration in wastewater treatment where oxygen is transferred from air to water, trickle-bed filters, and scrubbers for the removal of volatile organic compounds. In addition, gas-to-liquid mass transfer is an important factor in gas–liquid emulsion polymerization, and the rate of polymerization could, thus, be enhanced significantly by mechanical agitation.

The objective of this entry is to introduce the readers to the fundamental principles of gas-to-liquid mass transfer, as well as its major applications. Therefore, the first section of the entry is on the three fundamental mechanisms of gas-to-liquid mass transfer: the film theory, the penetration theory, and the surface renewal theory followed by the applications of gas-to-liquid mass transfer in unit operations that are widely used in various chemical processes. There is a vast pool of reported literature on different aspects of gas-to-liquid mass transfer processes, all of which is impossible to be included in this entry. Therefore, only typical gas-to-liquid mass transfer processes are presented here.

PRINCIPLES OF GAS-TO-LIQUID MASS TRANSFER

Gas-to-liquid mass transfer can take place from a gas phase to a liquid phase (and vice versa) with or without chemical reactions. The concentration gradient of a transferred component in the bulk fluid and in the fluid at the interface is the driving force for mass transfer. When the mass transport occurs in a phase that is moving, the transport of the component is known as convective mass transfer. Convective mass transfer is usually expressed in a standard flux equation as:

$$N_A = k_c(C_{Ab} - C_{Ai}) \tag{1}$$

where N_A is the molar flux of component A from gas to liquid, C_{Ab} and C_{Ai} are the concentrations of component A in the bulk gas and in the gas phase at gas–liquid interface, respectively, and k_c is the convective mass transfer coefficient.

Eq. (1) is applicable to both pure diffusion and convective transfer in a laminar or turbulent flow. For a binary system, the total molar flux, which takes into account mass transfer by both molecular diffusion and convection because of bulk flow, can be expressed as:

$$N_A = \frac{k'_c}{\alpha}(C_{Ab} - C_{Ai}) \tag{2}$$

where α is the correction factor for the bulk flow, which can be written as:

$$\alpha = \frac{\left(\frac{N_A}{N_A + N_B} - \frac{C_{Ai}}{C}\right) - \left(\frac{N_A}{N_A + N_B} - \frac{C_{Ab}}{C}\right)}{[N_A/(N_A + N_B)]\ln\{[N_A/(N_A + N_B) - C_{Ai}/C]/[N_A/(N_A + N_B) - C_{Ab}/C]\}} \tag{3}$$

The value of α varies with the system under consideration. For example, in equimolar counter diffusion, N_A and N_B are of the same magnitude, but in opposite direction. As a result, α is equal to 1; and hence, Eq. (2) reduces to Eq. (1), where k'_c is equal to k_c.

Convective mass transfer coefficients are used in the design of mass transfer equipment. However, in most cases, these coefficients are extracted from empirical correlations that are determined from experimental data. The theories, which are often used to describe the mechanism of convective mass transfer, are the film theory, the penetration theory, and the surface renewal theory.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007787

FILM THEORY IN MASS TRANSFER

Proposed by Whitman,[1] the film theory is based on the assumption that for a flowing fluid, there is a fictitious stagnant fluid film at the phase boundary, in which the entire resistance to mass transfer resides and the mass transport is, thus, completely by molecular diffusion. Therefore, the mass transfer coefficient is proportional to the ratio of the diffusivity to the thickness of the fictitious film.

Dependent upon the mode of mass diffusion, i.e., diffusion through a nondiffusing layer, counter-diffusion, or equimolar counter-diffusion, the relationship between the mass transfer coefficient and the diffusivity may take different forms.[2] For example, under the condition of equimolar counter diffusion for a binary system, the molar flux in x-direction can be expressed in terms of the diffusivity as:

$$N_A = D\frac{dC_A}{dx} = \frac{D}{\delta}(C_{Ab} - C_{Ai}) \quad (4)$$

From Eqs. (1) and (4), the relationship of the mass transfer coefficient k_c, with the diffusivity D, and the thickness of the fictitious film δ can be written as:

$$k_c = \frac{D}{\delta} \quad (5)$$

The thickness of the fictitious film can neither be predicted nor measured experimentally. This limits the use of the film theory to directly calculate the mass transfer coefficients from the diffusivity. Nevertheless, the film theory is often applied in a two-resistance model to describe the interphase mass transfer between the two contacting phases (gas and liquid). This model assumes that the resistance to mass transfer only exists in gas and liquid films. The interfacial concentrations in gas and liquid are in equilibrium. The interphase mass transfer involves the transfer of mass from the bulk of one phase to the interfacial surface, the transfer across the interfacial surface into the second phase, and the transfer of mass from the interface to the bulk of the second phase. This process is described graphically in Fig. 1.

The molar flux of a component A can be written for individual phases. For the gas film

$$N_A = k_G(P_{AG} - P_{Ai}) = k_y(y_{AG} - y_{Ai}) \quad (6)$$

where k_G is the mass transfer coefficient in the gas film, P_{AG} the partial pressure of A in the bulk gas, and P_{Ai} the partial pressure of A in gas at the gas–liquid interface. k_y is the mass transfer coefficient defined in terms of the mole fraction of the transferred species, y_{AG} the mole fraction of A in the bulk gas, and y_{Ai} the mole fraction of A in gas at the gas–liquid interface.

For the liquid film

$$N_A = k_L(C_{Ai} - C_{AL}) = k_x(x_{Ai} - x_{AL}) \quad (7)$$

where k_L is the mass transfer coefficient in liquid film, C_{Ai} is the concentration of A in liquid at the gas–liquid interface, and C_{AL} is the concentration of A in the bulk liquid. k_x is the mass transfer coefficient in terms of the mole fraction of A in liquid, x_{Ai} the mole fraction of A in liquid at the gas–liquid interface, and x_{AL} the mole fraction of A in the bulk liquid.

The inability to measure interfacial concentrations limits the use of film molar flux equations to determine film mass transfer coefficients. To overcome this shortcoming, the concept of the overall mass transfer coefficient is used. The molar flux equation can be rewritten for the two phases as below.

For the gas phase:

$$N_A = K_y(y_{AG} - y_A^*) \quad (8)$$

where K_y is the overall gas-phase mass transfer coefficient, and y_A^* is the mole fraction of A in the gas phase in equilibrium with the concentration of A in the bulk liquid.

For the liquid phase:

$$N_A = K_x(x_A^* - x_{AL}) \quad (9)$$

where K_x is the overall liquid-phase mass transfer coefficient, and x_A^* is the mole fraction of A in the liquid phase in equilibrium with the concentration of A in the bulk gas.

By combining and rearranging Eqs. (6)–(9), the relationship between the overall mass transfer coefficients

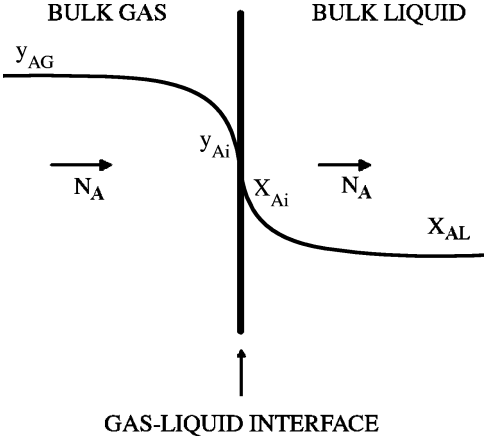

Fig. 1 Solute concentration profile for two-resistance model.

and the film mass transfer coefficients can be written as:

$$\frac{1}{K_y} = \frac{1}{k_y} + \frac{m'}{k_x} \tag{10}$$

$$\frac{1}{K_x} = \frac{1}{k_x} + \frac{1}{m''k_y} \tag{11}$$

where the slopes of the equilibrium curve m' and m'' (see Fig. 2) can be expressed as:

$$m' = \frac{y_{Ai} - y_A^*}{x_{Ai} - x_{AL}} \tag{12}$$

$$m'' = \frac{y_{AG} - y_{Ai}}{x_A^* - x_{Ai}} \tag{13}$$

In a gas–liquid contactor, the film mass transfer coefficient is independent of the solute concentration unless it changes significantly with position in the contactor such that the physical properties of the fluid are changed. On the other hand, as indicated in Eqs. (10) and (11), the overall mass transfer coefficients depend on both the film mass transfer coefficients and the slope of the equilibrium curve over the concentration range of interest. Therefore, experimentally obtained overall mass transfer coefficients should be used for the design of a gas–liquid contactor, only with conditions similar to those under which they were measured. However, when the equilibrium line is straight, m' and m'' are constant, the overall mass transfer coefficients then become independent of the solute concentration.

The film mass transfer coefficient can be extracted from the overall mass transfer coefficient when the experiments are carefully designed, so that the gas–liquid mass transfer is predominantly controlled by either the gas or liquid phase. The gas-phase-controlled mass transfer occurs when the solute is highly soluble in the liquid phase. Almost entire resistance to the mass transfer is within the gas phase and the slope m' is very small. Assuming that the magnitude of the liquid film mass transfer coefficient k_x is comparable to that of the gas film mass transfer coefficient k_y, the overall gas-phase mass transfer coefficient approximates the gas film mass transfer coefficient because the term m'/k_x in Eq. (10) becomes nonsignificant when compared to $1/k_y$. On the other hand, when the solute is only slightly soluble in the liquid phase, almost entire resistance to mass transfer resides in the liquid phase, and the mass transfer process is under the liquid-phase-controlled condition. The slope m'' is large; hence the overall liquid-phase mass transfer coefficient is approximately equal to the liquid film mass transfer coefficient, as shown by Eq. (11). For cases with a significant difference between k_x and k_y, the magnitudes of both the ratio k_x/k_y and m' or m'' must be considered in determination of the controlling phase.

The determination of the controlling phase in a gas–liquid mass transfer operation is of help in identifying the suitable operational parameters that can be manipulated to improve the performance of the operation. For a gas-phase-controlled process, mass transfer can be improved by increasing the gas velocity. A higher velocity causes an increase in the concentration gradient of the solute in the gaseous film; hence a higher mass transfer coefficient is achieved. Similarly, in a liquid-phase-controlled process, increasing liquid flow rate enhances the mass transfer coefficient, thereby improving the mass transfer rate. In addition, for a given solute concentration in the gas phase, when the liquid temperature is decreased, the solubility of solute in liquid increases; hence the equilibrium concentration of the solute in the liquid phase (at the gas–liquid interface) increases. As a result, the concentration gradient of the solute in the liquid film increases and so does the rate of mass transfer.

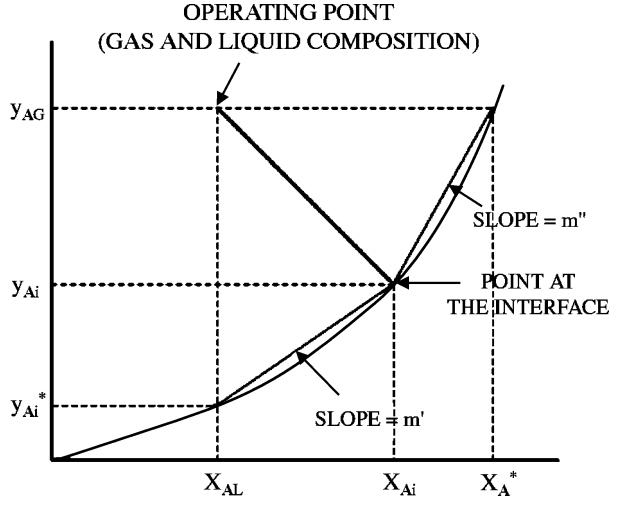

Fig. 2 Equilibrium curve and its slopes—two-resistance model.

PENETRATION THEORY IN MASS TRANSFER

The thickness of the fictitious film in the film theory can never be measured. The film theory predicts that the convective mass transfer coefficient k_c is directly proportional to the diffusivity whereas experimental data from various studies show that k_c is proportional to the two-third exponent of the diffusivity. In addition, the concept of a stagnant film is unrealistic for a fluid–fluid interface that tends to be unstable. Therefore, the penetration theory was proposed by Higbie[3] to better describe the mass transfer in the liquid phase

during gas absorption. In this theory, the liquid surface is assumed to consist of small fluid elements that contact the gas phase for an average time, after which they penetrate into the bulk liquid. Each element is then replaced by another element from the bulk liquid. The mass transfer into the liquid phase is under unsteady-state diffusion with zero concentration at an infinite depth in the bulk liquid. Thus, Fick's second law of diffusion in one dimension can describe this transfer process, from which the average molar flux can be obtained:

$$N_A|_{avg} = 2\sqrt{\frac{D}{\pi t_{exp}}}(C_{Ai} - C_{Ab}) \quad (14)$$

where t_{exp} is the exposure time of the fluid elements. Eq. (14) indicates that the mass transfer coefficient is proportional to the square root of the diffusivity.

One of the boundary conditions of the penetration theory is that the concentration at an infinite distance from the interface is equal to zero. This restricts the applicability of the penetration model to systems with a sufficiently large bulk of liquid. In a gas–liquid contactor, such as a packed column, there only exists a thin layer of liquid flowing over packing particles. Hence, the boundary conditions of the penetration theory are modified to have zero solute concentration at the solid surface of the packing.[4]

Although the penetration theory better describes the gas–liquid mass transfer than the film theory, its advantage is only significant with physical absorption. For gas absorption with fast chemical reactions in the liquid phase, the entire mass transfer process is gas-phase-controlled rendering the penetration theory inapplicable.[5]

SURFACE RENEWAL THEORY

The exposure times of all liquid elements are usually not the same as assumed in the penetration model. To address this matter, Danckwerts proposed the surface renewal theory. In this theory, an average exposure time, which is determined from an assumed time distribution, is used in place of the constant exposure time in the penetration theory.[6] The average molar flux is given as below:

$$N_A|_{avg} = \sqrt{\frac{D}{\pi}}(C_{Ai} - C_{Ab}) \int_0^\infty \frac{\tau(t)}{t^{0.5}} dt \quad (15)$$

where $\tau(t)\,dt$ represents the fraction of the liquid surface that consists of liquid elements with an exposure time span from t to $(t + dt)$. Therefore, the sum of the fractions is equal to unity:

$$\int_0^\infty \tau(t) dt = 1.0 \quad (16)$$

Dankwerts proposed the exposure time distribution function as:

$$-\frac{d\tau}{dt} = s\tau \quad (17)$$

where s is the surface renewal rate, which is inversely proportional to the exposure time of the liquid elements.

By integrating Eq. (17), substituting the resulting expression for τ in terms of s into Eq. (16), and integrating the resultant equation, the following relationship is obtained:

$$\tau = s e^{-st} \quad (18)$$

and the average molar flux is then given by:

$$N_A|_{avg} = \sqrt{\frac{D}{\pi}}(C_{Ai} - C_{Ab}) \int_0^\infty \frac{s e^{-st}}{t^{0.5}} dt = \sqrt{sD}(C_{Ai} - C_{Ab}) \quad (19)$$

The values of s are generally not known. However, they can be determined from the experimental data of the mass transfer coefficients for various gas–liquid systems.

APPLICATIONS OF GAS-TO-LIQUID MASS TRANSFER PROCESS

Gas–liquid mass transfer is applied in a wide variety of processes in the chemical industry, biochemical processes and wastewater treatment systems. The following widely used processes are reviewed:

- Gas absorption in a packed column.
- Gas–liquid mass transfer in a three-phase fluidized bed reactor.
- Gas–liquid mass transfer in an airlift reactor.
- Liquid–gas bubble reactors.
- Trickle-bed reactors.

Distillation is also a common transport process involving gas-to-liquid mass transfer.

GAS ABSORPTION IN A PACKED COLUMN

Packed columns have been used in chemical industry for more than a century. The packing in a packed column provides a large surface area over which the gas contacts the liquid and the gas-to-liquid (and vice versa) mass transfer occurs (Fig. 3). As a result, the gas–liquid mass transfer process in a packed column is very efficient. Research and development on packed column has received much attention. One of the earlier and original literatures reported by Leva[7] covers the principles of gas–liquid mass transfer in a packed bed, as well as packed column design and column internals. Recent reported literatures on gas absorption in a packed column from Fair et al.,[5] Strigle,[8] and Billet[9] are excellent references on transport phenomena in a packed column and packed column design.

The performance of a packed column is determined by the ultimate contact of gas and liquid in the column. The effective surface area of the packing (hydraulic area or wetted area), where mass transfer may occur, is usually lower than the physical surface of area of the packing (specific area, a). Liquid distribution affects the effective surface area in a packed bed. Several research groups have measured liquid distribution for various packing heights, packing materials and sizes, and liquid distributors.[10,11] The quality of liquid distribution is dependent on the initial liquid distribution (from the liquid distributor), liquid flow rate, packing type and size, and packing height. Poor initial liquid distribution because of a small number of liquid nozzles on a liquid distributor or a poor liquid distributor design causes dry packing zones in the top section of the packed bed. This is reflected by a higher mass transfer variation index, which is defined as an average deviation of local mass transfer coefficients in the packed bed, for a single-point distributor as compared to that for a multiple-point liquid distributor.[12] Smaller packing has a tendency to spread out liquid quicker; hence, liquid distribution with smaller packing is better than that with larger packing. It is a common practice to use the packing of a size less than one-tenth of the tower diameter, to avoid severe wall flow. For most industrial applications of packed columns, liquid flow rate is usually sufficiently high, such that liquid distribution does not change with the liquid flow rate significantly. Liquid distribution has also been shown to be independent of the gas flow rate below loading point. In general, liquid distribution is improved when the packing height is increased. For 2 in. metallic Pall rings, liquid distribution is improved with increases in the ratio of packing height to tower diameter, x/D, up to 5. For x/D in the range from 5 to 6.5, liquid distribution reaches a steady pattern.[13] Nevertheless, it has been reported that when the packing height is increased to about 20 ft, liquid maldistribution may occur; hence the use of liquid redistributors is recommended.[14]

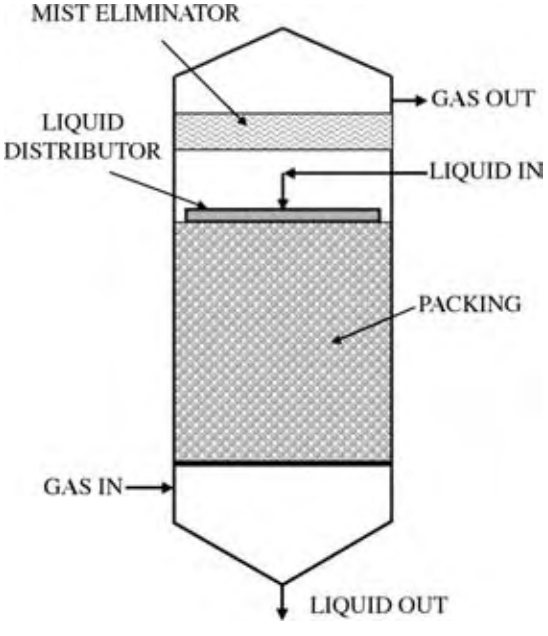

Fig. 3 Schematic diagram of a packed column.

The relationship between the specific area a and the hydraulic area a_h of several packing types was studied and the following correlations were reported:[9]

$$\frac{a_h}{a} = C_h \mathrm{Re}_L^{0.15} \mathrm{Fr}_L^{0.1} \quad \text{for } \mathrm{Re}_L < 5 \tag{20}$$

$$\frac{a_h}{a} = 0.85 C_h \mathrm{Re}_L^{0.25} \mathrm{Fr}_L^{0.1} \quad \text{for } \mathrm{Re}_L \geq 5 \tag{21}$$

where C_h is the packing constant as shown in Table 1, Re_L the liquid Reynolds number that is defined as $(u_L \rho_L)/(\mu_L a)$, Fr_L the Froude number that is defined as $(u_L{}^2 a)/g$, a the specific area of packing, g the gravitational acceleration, u_L the liquid superficial velocity, ρ_L the liquid density, and μ_L the liquid viscosity.

However, there is significant deviation among the values of a_h estimated from different correlations. Therefore, the mass transfer coefficients, k_L and k_G, are often lumped with the specific area a in most reported literatures. Published data have often been obtained from investigating mass transfer in small columns (less than 0.254 m diameter) in which gas flow patterns may be different from those in a large industrial-scale column.[15] In addition, the entrance section below the packing support can be accounted for about 17% of the overall mass transfer over the entire packed column. This may vary with different mechanical designs of packed columns.[16] The uncertainty in scaling up laboratory and pilot-plant data to large towers is significant. Therefore, mass transfer

(From Ref.[9].)

coefficient correlations available in literature should be used with care and reservation. There are literally hundreds of equations. However, the most widely used correlation to predict $k_L a$ is still that developed by Sherwood and Holloway[17] as below:

$$\frac{k_L a}{D} = \alpha\left(\frac{L}{\mu_L}\right)^{1-n}\left(\frac{\mu_L}{\rho_L D}\right)^{0.5} \quad (22)$$

where D is the diffusivity of the solute in liquid, and L is the liquid mass flux. The constants α and n for various types of packing are given in Table 2. Au-Yeung and Ponter[18] reported a comprehensive review of empirical and theoretical correlations for $k_L a$, published since 1940.

GAS–LIQUID MASS TRANSFER IN THREE-PHASE FLUIDIZED BED REACTORS

Three-phase fluidized bed reactors are widely used in petrochemical, metallurgical, environmental, and coal liquefaction processes. In some cases, such as liquid-phase methanol process, these reactors are also referred to as ebulliated reactors with suspended catalyst particles in inert liquid. Three-phase catalytic reaction is also applied to liquid-entrained reactors where a slurry of small catalyst particles and inert liquid is pumped to the reaction zone, where gas is fed separately. Liquid-entrained reactors alleviate catalyst attrition, which often occurs in a three-phase fluidized bed reactor, especially under high solid loading.[19,20] In three-phase fluidized bed reactors, solid particles catalyze reactions involving species in gas and liquid phases. The particles are fluidized by the upward flow of these phases (Fig. 4). Gas bubbles are formed and dispersed in the continuous liquid phase.[21] The gas–liquid mass transfer is affected by the presence of solid particles, and is controlled by the liquid phase. In general, the volumetric gas–liquid mass transfer coefficient increases with gas as well as liquid velocity, particle size, and density. On the other hand, the transfer coefficient decreases with the surface tension and viscosity of liquid.

Table 2 Constants α and n for use in the Sherwood and Holloway correlation

Packing	Size (in.)	α	n
Rings	2.0	341	0.22
	1.5	383	0.22
	1.0	426	0.22
	0.5	1392	0.35
	3/8	3116	0.46
Saddles	1.5	732	0.28
	1.0	778	0.28
	0.5	686	0.28
Tile	3.0	503	0.28

(From Ref.[17].)

The mass transfer coefficient increases with gas velocity because the gas–liquid interfacial area and the mixing of solid particles increase with gas velocity. However, skewed bubble-size distribution occurs when gas velocity is increased beyond a certain value, and the interfacial area does not increase further. The solid mixing also approaches a constant level. The transfer coefficient has been reported to be proportional to gas velocity to an exponent in the range of 0.44–0.98.[22]

The increase in liquid velocity enhances turbulence that helps in breaking up gas bubbles and creating more smaller-sized gas bubbles by solid particles. This leads to increases in the gas–liquid interfacial area, thereby increasing the mass transfer rate and the volumetric mass transfer coefficient. On the other hand, the holdup of solid particles and bubbles decreases with increases in liquid velocity, which has a negative effect on gas–liquid mass transfer. Beyond a critical value,

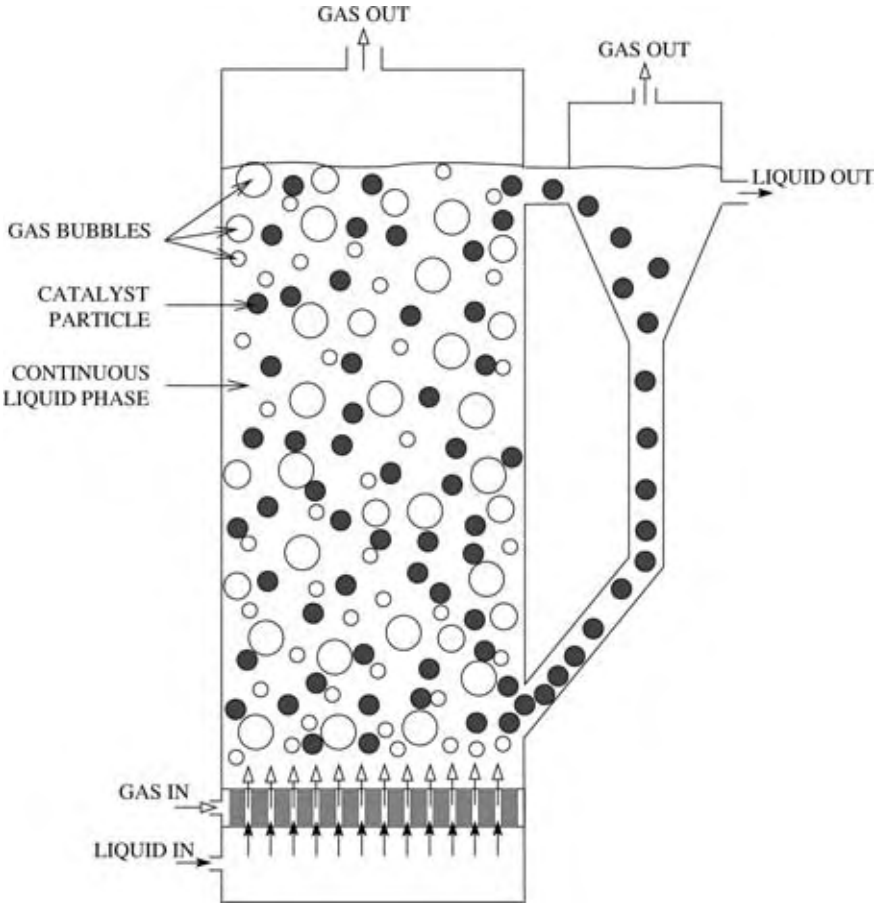

Fig. 4 Schematic diagram of a three-phase fluidized bed.

the transfer coefficient begins to decrease with increases in liquid velocity. The transfer coefficient has been reported to be proportional to liquid velocity to an exponent in the range of 0.42–0.97.[22]

The effect of particle size and particle density on the volumetric gas–liquid mass transfer coefficient is more complicated. Although larger particles promote the breakage of large gas bubbles into small bubbles, a higher minimum fluidization velocity is required, resulting in the reduction of gas and solid holdups and changes of bubble regime. The transfer coefficient increases with particle size, as long as there are enough holdups of gas bubbles and solid particles in the bubble disintegration regime. Nevertheless, for porous solid that is used to provide higher surface area for the catalytic reaction in a three-phase fluidized bed reactor, larger particles may have a negative effect on the reaction rate because intraparticle diffusion is usually slower because of long porous paths of larger particles when compared to smaller particles. The effect of particle density in this regime is insignificant. However, in bubble coalescence regime, the transfer coefficient has been found to increase with decreases in particle density because lighter particles circulate more vigorously, and break up more gas bubbles.

The increase in liquid viscosity reduces the gas holdup and restricts the movement of gas bubbles, thereby decreasing the mass transfer coefficient. The transfer coefficient has been reported to be inversely proportional to the liquid viscosity to an exponent in the range of 0.34–0.67.[22] The transfer coefficient has also been found inversely proportional to the liquid surface tension to an exponent of 1.532 and 2.273 in the bubble disintegration and coalescence regimes, respectively because higher liquid surface tensions hinder bubble formation.[23]

Based on different experimental studies for superficial gas velocities from 0.005 to 0.19 m/s, superficial liquid velocities from 0.008 to 0.175 m/s, average solid particle diameters from 0.76 to 8 mm, and liquid viscosities from 0.001 to 0.0967 Pa s; Kim and Kang reported the following correlation for gas–liquid mass transfer in a three-phase fluidized bed:[22]

$$\mathrm{Sh} = 2.694\mathrm{Sc}^{1.3}\mathrm{Re}_{\mathrm{b}}^{0.196} \tag{23a}$$

The Sherwood number Sh in Eq. (23a) is defined as:

$$\mathrm{Sh} = \frac{(k_{\mathrm{L}}a)d_{\mathrm{b}}^2}{6\varepsilon_{\mathrm{G}}D} \tag{23b}$$

where $k_L a$ is volumetric gas–liquid mass transfer coefficient, d_b the mean bubble diameter, ε_G the gas phase holdup, and D the molecular diffusivity of gas in liquid. The Schmidt number Sc is defined in terms of kinematic viscosity of liquid, ν_L:

$$\mathrm{Sc} = \frac{\nu_L}{D} \tag{23c}$$

and the Reynolds number, Re_b, is defined as:

$$\mathrm{Re}_b = \frac{E d_b^4}{\nu_L^3} \tag{23d}$$

where E is the energy dissipation rate per unit mass of liquid phase.

GAS–LIQUID MASS TRANSFER IN AIRLIFT REACTORS

An airlift reactor is a column divided into two sections, a riser and a downcomer, interconnected at top and bottom (Fig. 5). Gas entering the bottom of the riser lifts the liquid and any accompanying solid particles (for a three-phase reactor) upward, which subsequently enter the top of the downcomer and then flow downward to the bottom of the riser again.[24] This circulation within the reactor enhances mixing and mass transfers without the use of mechanical agitators. While an internal-loop airlift reactor has the riser and the downcomer in the same column, an external-loop airlift reactor has separate tubes for the riser and the downcomer. Airlift reactors are used in multiphase chemical reactions and biotechnological processes.

Compared to bubble columns, airlift reactors have better liquid circulation but lower rates of mass transfer and mixing. These rates are enhanced in modified airlift reactors with perforated single or coaxial draft tubes.[25] This enhancement is because of the breakup of gas bubbles into smaller bubbles when crossing perforated tubes. The gas–liquid interfacial area and the gas–liquid mass transfer coefficient increases. Similar effect can be achieved with the addition of packing to the riser.[26]

The volumetric gas–liquid mass transfer coefficient in an airlift reactor increases with gas velocity and its holdup. Based on the penetration theory and the isotropic turbulence theory, the following theoretical

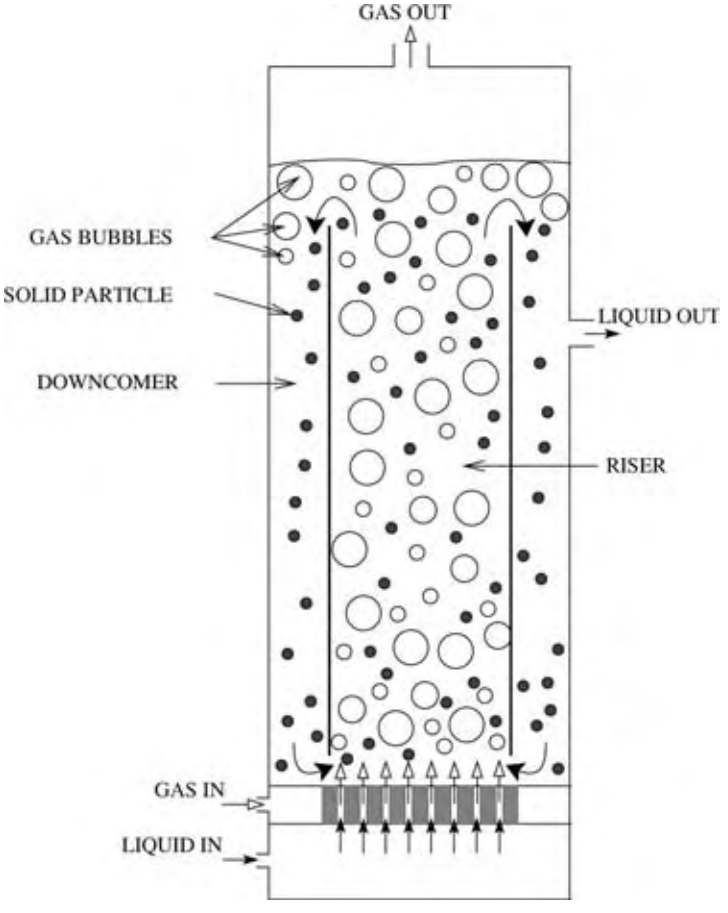

Fig. 5 Schematic diagram of an airlift reactor.

model was developed for air–water system:[27]

$$k_L a = 2\sqrt{\frac{D}{\pi}}\left(\frac{v_G \rho_L g \varepsilon_G}{\mu_L}\right)^{0.25} \frac{6\varepsilon_G}{d_B(1 - \varepsilon_G)} \quad (24)$$

where $k_L a$ is the volumetric gas–liquid mass transfer coefficient, D the diffusivity, v_G the slip gas velocity, g the gravity, ε_G the gas holdup, μ_L and ρ_L are the viscosity and density, respectively, of liquid, and d_B is the average diameter of gas bubbles.

However, for a given gas velocity, any change in gas or liquid properties, downcomer and riser geometry, phase separation conditions, liquid volume, reactor height, or gas distribution causes changes in liquid velocity and gas holdup. Therefore, no generalized model or correlation for the volumetric gas–liquid mass transfer coefficient in airlift reactors exists.

LIQUID–GAS BUBBLE REACTORS

Liquid–gas bubble reactors are divided into two main groups: gas–liquid bubble columns and gas–liquid continuous stirred reactors (Figs. 6 and 7). Gas–liquid bubble columns are operated under either of the two characteristic modes: particulate or homogeneous regime, and aggressive or heterogeneous regime. The rates of mass transfer and mixing are quite different in these two regimes. Agitation is done to enhance mass transfer in stirred reactors in a similar fashion as in mechanically agitated slurry reactors where the mass transfer from liquid or gas to solid particles increases with the mechanical agitation.

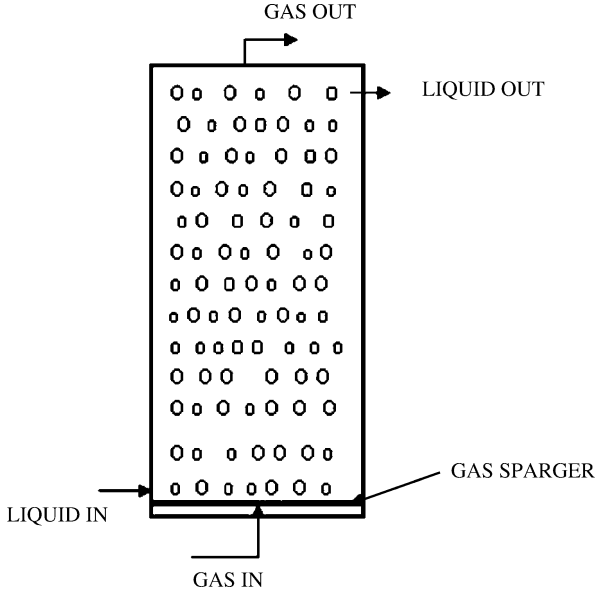

Fig. 6 Schematic diagram of a liquid–gas bubble column.

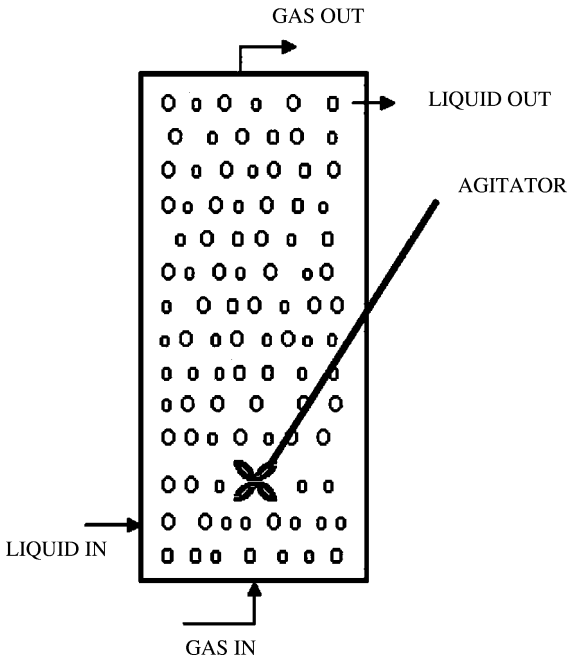

Fig. 7 Schematic diagram of a gas–liquid continuous stirred reactor.

In bubble columns, gas is dispersed in a continuous liquid phase. Uniform bubble size and bubble concentration characterize the homogeneous regime, particularly in the traverse direction indicating the absence of bulk liquid circulation. In contrast, the heterogeneous regime is characterized by a nonuniform bubble concentration, especially in the traverse direction, because of liquid circulation.

A bubble coming out of a hole in a sparger grows until the buoyant force overcomes the surface tension force, and the bubble breaks away from the sparger. The bubble expands as it rises in liquid because of the reduction of the hydrostatic pressure. The bubble diameter may also increase because of mass transfer from liquid to gas and coalescence or decrease because of breakage. In the homogeneous regime with a low gas flux, gas is sparged uniformly at the bottom of the column, and it remains uniformly distributed all over the column. Eventually, all bubbles rise vertically with minor traverse and axial oscillations, and particularly, there is no coalescence or dispersion. The size of the bubbles in the homogeneous regime is, thus, almost entirely dictated by the type and design of the sparger and the physical properties of the system. On the other hand, for the heterogeneous regime, there exists a wide bubble size distribution in the column. The average bubble size is governed by coalescence and redispersion phenomena, which in turn are controlled by the energy dissipation rate in the bulk liquid. The intensity of turbulence is also much higher. Such highly turbulent recirculation results in substantially high values

of eddy diffusivity for mass transfer. As a result, the rates of mass transfer and mixing are quite different between homogeneous and heterogeneous regimes. Therefore, it is important to know the range of physical properties and operating parameters over which a particular regime prevails. As the transition from the homogeneous to the heterogeneous regime starts, there is an onset of liquid circulation that is upward in the central region and downward near the column wall. More bubbles enter the central region because it offers lower resistance to the flow. As a result, a transverse holdup profile begins to build up, which in turn intensifies liquid circulation. Therefore, the beginning of transition regime is very important, and further development is self-propagating.[28,29]

In bubble columns and gas–liquid stirred reactors, the estimation of parameters is more difficult than in gas–solid or liquid–solid fluidized beds. Solid particles are rigid, and hence the fluid–solid interface is nondeformable, whereas the gas–liquid interface is deformable. In addition, the effect of surface-active agents is much more pronounced in the case of gas–liquid interfaces. This leads to uncertainties in the prediction of all major parameters, such as the terminal bubble rise velocity, the bubble diameter, the gas holdup, and the relation between the bubble diameter and the terminal bubble raise velocity.

TRICKLE-BED REACTORS

Trickle-bed reactor is a type of three-phase reactor in which a gas and liquid stream flow concurrently, usually downward, over a fixed bed of catalyst particles at such a velocity that the liquid trickles down at the surface of the solid matrix while the gas fills the available porous space in the bed. Downward operation is normally preferred because of mechanical stability, lower axial mixing and less flooding, which can support higher liquid and gas flow rates, i.e., higher reactor capacity. Ideally, fluid stream should be a plug flow for better mass transfer rate and reaction rate. However, some axial intermixing is inevitable in practice. In some cases, a concurrently upward liquid and gas flow is used to provide better radial and axial mixing. This can be an advantage in the case with highly exothermic reactions.

In general, when a fixed bed is selected, the issue whether to employ a concurrent upflow or downflow operation must be considered. Operating a randomly packed bed reactor in the countercurrent mode is usually not feasible because flooding occurs at gas velocities far below industrial relevance. In a concurrent upflow, complete catalyst wetting is obtained at the expense of much larger liquid holdup compared to a concurrent downflow. High liquid holdup increases the liquid film mass transfer resistance for gaseous reactants and is undesirable if homogeneous liquid phase side-reactions occur. Because of complete catalyst wetting and a higher liquid holdup, heat transfer characteristics are much better (more uniform heat transfer rate and no hot spots) in a concurrent upflow operation. However, in a concurrent upflow, the flow may induce local vibration or movement of the particles, which possibly results in the attrition of the catalyst.[30]

Low liquid holdup, low pressure drop, and lack of foaming in high liquid flow rates are some of the advantages of downward trickle-bed reactors. For downward type reactors, the modulation of both gas and liquid flow rates has a profound effect on the hydrodynamics of the reactor. The hydrodynamics of the reactor in turn can influence the kinetics of the reaction.[31] On the other hand, poor liquid distribution, partial wetting of catalyst, poor mixing, difficulties in controlling the temperature of highly exothermic reactions, and low gas–liquid interaction resulting in lower mass transfer coefficients are some of the disadvantages of downward trickle-bed reactors.

Trickle-bed reactors can be operated in several flow regimes. The four main flow regimes are trickle flow, pulsing flow, mist flow, and bubble flow. Trickle flow regime prevails at relatively low gas and liquid flow rates. Liquid flows as a laminar film and/or in rivulets over the packing, while gas passes through the remaining void space. At high gas and low liquid flow rates, transition to mist flow occurs, where liquid mainly travels down the column as droplets entrained by the continuous gas phase. Bubble flow regime appears at high liquid flow rates and low gas flow rates, and is opposite in structure to mist flow. Liquid is the continuous phase and gas moves in the form of dispersed bubbles. At moderate gas and liquid flow rates, pulsing flow regime is obtained, which is characterized by the successive passage of liquid-rich and gas-rich regions through the bed. Pulsing flow is a kind of self-organization through which the bed is periodically run through with waves of liquid followed by relatively quiet periods of continuous gas and liquid flow. The pulses are characterized by high particle-liquid mass and heat transfer rates, large gas–liquid interfacial areas, complete catalyst wetting, mobilization of stagnant liquid, and diminished axial dispersion.

Trickle-bed reactors are widely used in hydrotreating processes, i.e., hydrodesulfurization of gasoline and diesel fuel, in petroleum refining, chemical, petrochemical, and biochemical processes. The knowledge of hydrodynamic parameters is vital in the design of a TBR because the conversion of reactants, reaction yield, and selectivity depend not only on reaction kinetics, operating pressure, and temperature, but also on the hydrodynamics of the reactor. Special care is also required to prevent flow maldistribution, which can cause incomplete catalyst wetting in some parts

of the bed.[32] This may result in reduced overall production rates and poorer selectivity. For strong exothermic reactions, more severe consequences can occur because of hot spot formation and possibly even runaway reaction.

CONCLUSIONS

The fundamental principles of the gas-to-liquid mass transfer were concisely presented. The basic mass transfer mechanisms described in the three major mass transfer models: the film theory, the penetration theory, and the surface renewal theory are of help in explaining the mass transport process between the gas phase and the liquid phase. Using these theories, the controlling factors of the mass transfer process can be identified and manipulated to improve the performance of the unit operations utilizing the gas-to-liquid mass transfer process. The relevant unit operations, namely gas absorption column, three-phase fluidized bed reactor, airlift reactor, liquid–gas bubble reactor, and trickled bed reactor were reviewed in this entry.

Geothermal Energy

Sunggyu Lee
H. Bryan Lanterman
Department of Chemical Engineering, University of Missouri–Columbia, Columbia, Missouri, U.S.A.

INTRODUCTION

The natural heat of the earth is called geothermal energy. ''Geothermal'' is a hybrid word combining geo(earth) and thermal (of heat). In total, geothermal energy includes all the thermal energy contained in the entire volume of the earth except for a relatively thin, comparatively cool outer surface. This represents about 260 billion cubic miles of rocks and metallic alloys at or near their melting temperatures. Geothermal resources are available ranging from shallow ground to hot rock and water several miles below the earth's outer surface, and even farther down toward the earth core to the region of extremely high temperatures from molten rock called magma.

Geothermal energy is the second largest source of heat to the earth after solar energy. Geothermal energy that is available using current technology is concentrated in underground reservoirs, usually in the forms of steam, high-temperature water, and/or hot rocks. The three applicable technology categories include geothermal heat pumps (GHPs), direct-use applications, and electric power plants. GHPs use the earth near its surface as a heat sink and heat source for heating and cooling. Direct-use applications utilize naturally occurring geothermally heated water for heating. Electric power plants use electric turbines fed by geysers to generate electricity. Similar to solar energy, the ability to use geothermal energy is hampered by its distribution over the earth's surface in amounts that are too small or of too low intensity.[1] This is especially true for the generation of electricity.

The most obvious forms of geothermal energy are geysers, boiling pools of mud, fumaroles, and hot springs. However, a greater potential exists in regions not yet deemed valuable for their energy possibilities—these are hot dry rocks (HDRs).

Besides the vast resource availability and the unique distribution pattern of the resources, geothermal energy is very clean and environment friendly. The utilization or conversion of geothermal energy generates no or little greenhouse gases, since the conversion or utilization process does not involve any chemical reaction, in particular combustion. Geothermal fields produce only about one-sixth of the carbon dioxide that a natural-gas-fueled power plant produces, and very little, if any, of the nitrous oxide or sulfur-bearing gases. Furthermore, geothermal energy is available 24 hr a day and 365 days a year, independent of the outside weather conditions. This is in sharp contrast to other green energy technologies such as wind and solar. In fact, geothermal power plants typically have average availabilities of 95% or higher, much higher than most coal and nuclear plants. Even this high availability can be further enhanced to a level that is practically near 100%, with advances and enhancements in the process technology.

GEOTHERMAL ENERGY AS RENEWABLE ENERGY

Need of Geothermal Energy

The development and importance of new clean energy sources such as geothermal energy have become intensified not only due to the depletion of petroleum resources, but also due to the environmental problems involved with conventional energy processes. Environmental problems associated with the utilization of fossil fuel sources involve (a) emission of greenhouse gases such as CO_2, CH_4, and N_2O; (b) emission of SO_x and H_2S; (c) discharge of nitrogen oxides; (d) potential emission of mercury and selenium; (e) emission of volatile and semivolatile organic compounds; (f) emission of particulate matters; and (g) contamination of soils and ground water resources with hazardous wastes.

At a depth of about six miles from the earth surface, the temperature is higher than 100°C; thus the total amount of geothermal energy in storage far exceeds, by several orders of magnitude, the total thermal energy accountable in all forms of nuclear and fossil fuel resources of this planet. Solar energy is the only comparable resource of such vast quantities of energy. Therefore, it is very logical, if not imperative, that our energy priorities must incorporate a resource such as geothermal energy.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007789

Renewability and Sustainability of Geothermal Energy

The U.S. Department of Energy (DOE) classifies geothermal energy as renewable. Its source is the continuously emanated thermal energy generated by the earth's core. Each year rainfall and snowmelt supply new water source to geothermal reservoirs, and production from individual geothermal fields can be sustained for decades and perhaps for centuries. An accurate prediction for sustainable service life of each field is very difficult.

Occurrence of Geothermal Energy

a. The occurrence of geothermal heat (also known as geoheat) can be explained by one of the following theories:[2] The first theory is that about six billion years ago, the earth was a hot molten mass of rock and this mass has been cooling through the epochs of time, with the outer crust formed as a result of a faster cooling rate.
b. The second theory presupposes that the earth is like a giant furnace. The decaying of radioactive materials within the earth provides a constant heat source.
c. The third theory is based on the presumption that geothermal heat originates from the earth's fiery consolidation of dust and gas over four billion years ago.

Even though a generally agreeable explanation for the natural occurrence of geothermal energy is unavailable, some sort of combination of the aforementioned theories are widely offered.

The interior of the earth consists of a molten fluid of rocks at extremely high temperatures, called magma. This magma is cooling and/or expelling heat to the earth's surface according to the second law of thermodynamics. The flow of heat is from the hot source (earth core) toward the cold sink (earth surface). The cold sink (i.e., heat sink in thermodynamics) consists of the earth's crust, surface, and atmosphere. This may be regarded as a very slow process of heat transfer.

Fig. 1 shows a typical geological setting of a geothermal energy source. Thermal energy from the earth core continuously flows outward. The heat transfer from the core to the surrounding layers of rock, the mantle, is principally via conduction. As the temperature and pressure of the system become high enough, some mantle rocks melt and form magma. Since the magma as a liquid phase is less dense and more fluid-like than the surrounding rock, it slowly rises and moves toward the earth's crust, thus convecting the heat from the core. This is why a slow convective heat transfer often represents the overall heat transfer process. Sometimes, the hot molten magma reaches all the way to the earth's surface, where it is known as lava. However, in most cases, the magma remains well below the earth's crust, heating neighboring rocks and water that originates from rainwater seeped deep into the earth. The temperature of the water can be as hot as 380°C, which is even higher than the critical temperature of water, 374°C.

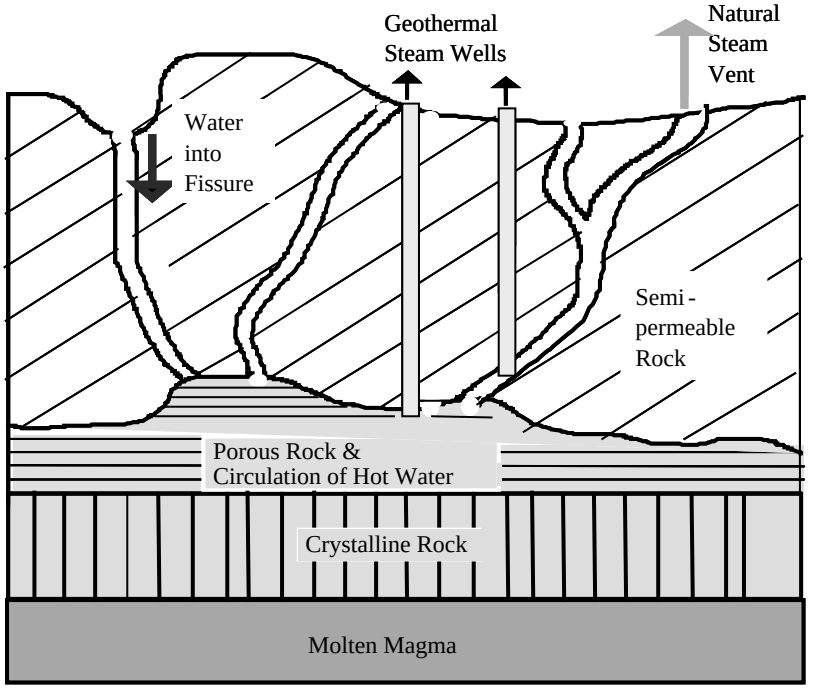

Fig. 1 A geothermal energy source. *(View this art in color at www.dekker.com.)*

The water at this depth is subjected to high pressure and temperature. Depending upon the imposed conditions, water may exist as a supercritical fluid. It then rises to the surface through fissures as a result of its density change and in effect, it vents from the system, thereby reducing the pressure of the system. When the pressure decreases, the water boils, turns into steam, and rises to the surface through fissures and/or wells. Some of the best-known examples of hot geothermal water are hot springs or geysers. However, most of the hot geothermal water remains deep underground, typically trapped in cracks and porous rocks. This natural collection of hot underground water is called a geothermal reservoir.

The immenseness of the geothermal energy of the earth cannot be properly determined. The total energy content of the rocks above the depth of 10 km has been estimated to be 3×10^{26} cal. At the earth core, i.e., 6400 km deep, the temperature may reach over 5000°C. However, based on current technology, only a fraction of this heat is available as a recoverable resource. A mere 0.03% or 10^{23} cal of this energy is considered hot enough and near enough to the earth's surface to be recoverable, the rest of the energy is too dispersed throughout the crust or too deep to be practical.

Geothermal resources may be classified into several categories principally based on their phases and forms, as shown in Table 1.

While all resources are not viable to produce electricity, they are still useful in many industrial, agricultural, and domestic needs. Research conducted by the U.S. Geological Survey identifies the significant research areas that need to be accomplished for full utilization of the geothermal resources.[3]

Table 1 Classification of geothermal resources

Types of geothermal resources	Temperature (approx. °C)
(a) *Convective hydrothermal resources*	
Vapor dominated	240
Hot water dominated	30–350
(b) *Other hydrothermal resources*	
Sedimentary basins/regional aquifers (hot fluid in sedimentary rocks)	30–150
Geopressured (hot fluid under pressure that is greater than hydrostatic)	90–200
Radiogenic (heat generated by radioactive decay)	30–150
(c) *Hot rock resources*	
Part still molten (magma)	>600
Solidified (hot dry rock)	90–650

Advantages of Geothermal Energy

Geothermal energy resources are continuous and reliable, sustainable, clean, and can be cost-competitive in meeting baseload capacity needs. Specific advantages of geothermal systems include:

1. Indigenous energy—geothermal energy helps reduce dependence on fossil or nuclear fuels and as such helps keep the economic benefits in the region.
2. Clean energy—use of geothermal energy helps reduce combustion-related emissions.
3. Diversity of use—geothermal energy has three common economic uses—electricity generation, direct use of heat, and GHPs.
4. Long-term resource potential—with optimum development strategies, geothermal energy can provide a significant portion of a nation's long-term energy needs.
5. Flexible system sizing—current power generation projects range in capacity from a 200 kW system in China to 1200 MW at The Geysers in California. Additional units can be installed in increments depending upon the growth of the electricity demand.
6. Power plant longevity—geothermal power plants are designed for a life span of 20–30 yr. With proper resource management strategies, life spans can exceed design periods.
7. High availability and reliability—''Availability'' is defined as the percentage of time that a system is capable of producing electricity. Availability of 95–99% is typical for modern geothermal plants compared to maximum 80–85% for coal and nuclear plants.[6]
8. Combined use—geothermal energy can be simultaneously used for both power generation and direct-use applications.
9. Low operating and maintenance costs—the annual operation and maintenance costs of a geothermal electric system are typically 5–8% of the capital cost.
10. Land area requirement—the land area required for geothermal power plants is smaller per megawatt than that for almost every other type of power generation plant.
11. Enhanced standard of living—geothermal systems can be installed at remote locations without requiring other industrial infrastructure. The region can grow without pollution.

Global Geothermal Energy

The current total installed capacity of geothermal power stations throughout the world is over

8200 MW.[4] The United States remains the biggest producer of electricity from geothermal energy as shown in Table 2. The developing countries accounted for 35% of the total for 1995 and 46% for 1999. About 2850 MW of electricity generation capacity is available from geothermal power plants in the western United States. The major geothermal fields along with their capacities are shown in Table 3.[5] Direct-use geothermal technologies utilize naturally hot geothermal water for commercial greenhouses, crop dehydration, fish farming, bathing, and district community heating. GHPs use the constant temperature of the top 50 ft of earth's surface to heat buildings in winter and cool them in summer. Table 4 shows the direct use of geothermal heat in various categories in the United States.[6]

Fossil fuels, namely oil, coal, and gas, provide 85% of all the energy used in the United States. Renewable energy sources supply just 8%, most of which comes from hydropower and the burning of biomass while only 4% comes from geothermal sources. Fig. 2 shows the history and projections of the U.S. energy consumption by fuel sources for the period of 1970–2020.

(From Ref.[5].)

As shown in Fig. 2, the projected future growth in the area of nonhydro and nonnuclear renewable energies is substantial. As the relative cost of electricity generation from geothermal sources decreases, the popularity of the geothermal power generation will undoubtedly increase.[7] Fig. 3 shows a cost comparison among various modes of power generation.

HISTORY OF GEOTHERMAL ENERGY DEVELOPMENTS

Ancient people regarded the depths of the earth with horror, as the seat of hell and of malignant Gods, due to natural phenomena like earthquakes and volcano eruptions. In ancient times the Romans and in modern times the Icelanders, Japanese, Turks, Koreans, and others have used it for baths and for space heating.

The Larderello field in Tuscany, Italy, first began to produce electricity in 1904 and developed over the next 10 yr to a capacity of 250 KW. In Japan, Beppu was the first site for experimental geothermal work in 1919 and these experiments effected a pilot plant in 1924 producing 1 KW of electricity. Somewhat earlier than this the Japanese began to use geoheat to heat their greenhouses. In Iceland, municipal heating was

Table 4 U.S. geothermal direct-use projects

provided using hot thermal waters in the 1930s and is still the major source of heating today.

It was not until the early 1920s that the United States examined the possibilities of the commercial usage of geothermal steam. However, the competition from hydroelectric power was too keen to promote further development at that time. Today, the largest geothermal power plant in the world is located in California at The Geysers, which is probably the largest reservoir of geothermal steam in the world.[8] In recent years, U.S. DOE's GeoPowering the West (GPW) program has been working to further geothermal energy efforts.[9]

Growing concerns about the global effects of increasing CO_2 and methane in the atmosphere are working to enhance the role of geothermal resources worldwide. Hence the utilization of geothermal energy to generate electric power dominates all other applications.

A number of factors that have boosted the production of geothermal energy are:[10]

i. The economics of geothermal energy became more favorable due to the increase in petroleum and natural gas prices.
ii. The cost of producing geothermal energy decreased from 1980 to 2000.
iii. Legislative actions and measures encouraging geothermal developments have been in place for many countries. Examples in the Unites States include the Energy Policy Act and the National Geologic Mapping Act in the early 1990s.[11]
iv. The implementation of the Clean Air Act Amendments of 1990 also provides an economic benefit because of the well-developed technology for control of gas emissions from geothermal power plants.
v. Amendment of the Public Utilities Regulatory Act removed the 80 MW limit from independent power plants selling electricity to utilities and is expected to help competitiveness of geothermal energy.

GEOTHERMAL PROCESSES AND APPLICATIONS

Geothermal Power Plants

Geothermal resources may be described as hydrothermal, HDR, or geopressured. Hydrothermal resources contain hot water, steam, or a mixture of water and

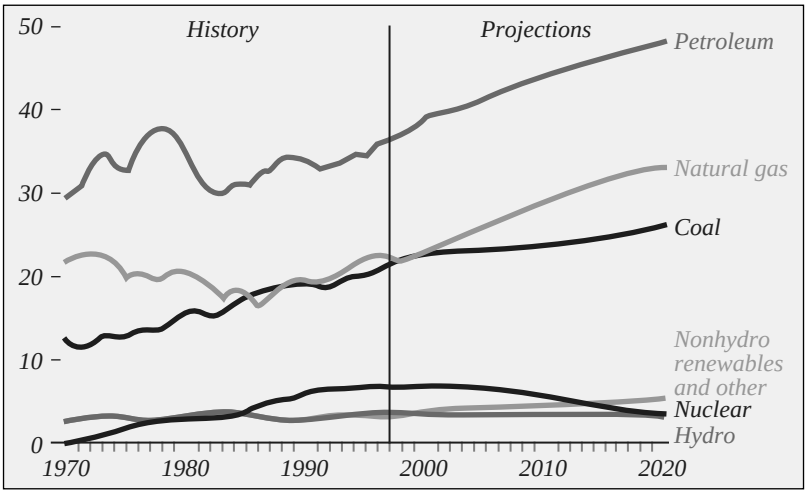

Fig. 2 U.S. energy consumption by fuel sources; past, current, and future forecast. Unit used is in quadrillion BTUs. (U.S. Department of Energy,[11] 1999.) *(View this art in color at www.dekker.com.)*

steam. Although research and development continue to look for ways to efficiently extract and use the energy contained in HDR and geopressured resources, virtually all current geothermal power plants operate on hydrothermal resources.

The characteristics of the hydrothermal resource determine the power cycle of the geothermal power plant. A resource that produces dry steam uses a direct steam cycle. A power plant for a liquid-dominated resource with a temperature above 165°C typically uses a flash steam cycle. For liquid-dominated resources with temperatures below 165°C, a binary cycle is the best choice for power generation. Power plants on liquid-dominated resources often benefit from combined cycles, using both flash and binary energy-conversion cycles.

Direct steam cycle[12]

Direct steam is also referred to as dry steam. As the term implies, steam is routed directly to the turbines, thus eliminating the need for the boilers used by conventional natural gas and coal power plants. Fig. 4 shows a schematic of a direct steam cycle power generation process. In a direct steam cycle power plant, a geothermal turbine can operate with steam that is far from pure. Chemicals and compounds in solid, liquid, and gaseous phases are transported with the steam to the power plant. At the power plant, the steam passes through a separator that removes water droplets and particulate before it is delivered to the steam turbine. The turbines are of conventional design with special materials, such as 12Cr steel and precipitation-hardened stainless steel, to improve reliability in geothermal services.

The other components present in the direct steam geothermal cycle include:

a. A condenser used to condense turbine exhaust steam. Both direct contact and surface condensers are used in direct steam geothermal power plants.
b. Noncondensable gas-removal system, to remove and compress the noncondensable gases. A typical system uses two stages of compression. The first stage is a steam jet ejector. The second stage is another steam jet ejector, a liquid ring vacuum pump, or a centrifugal compressor.

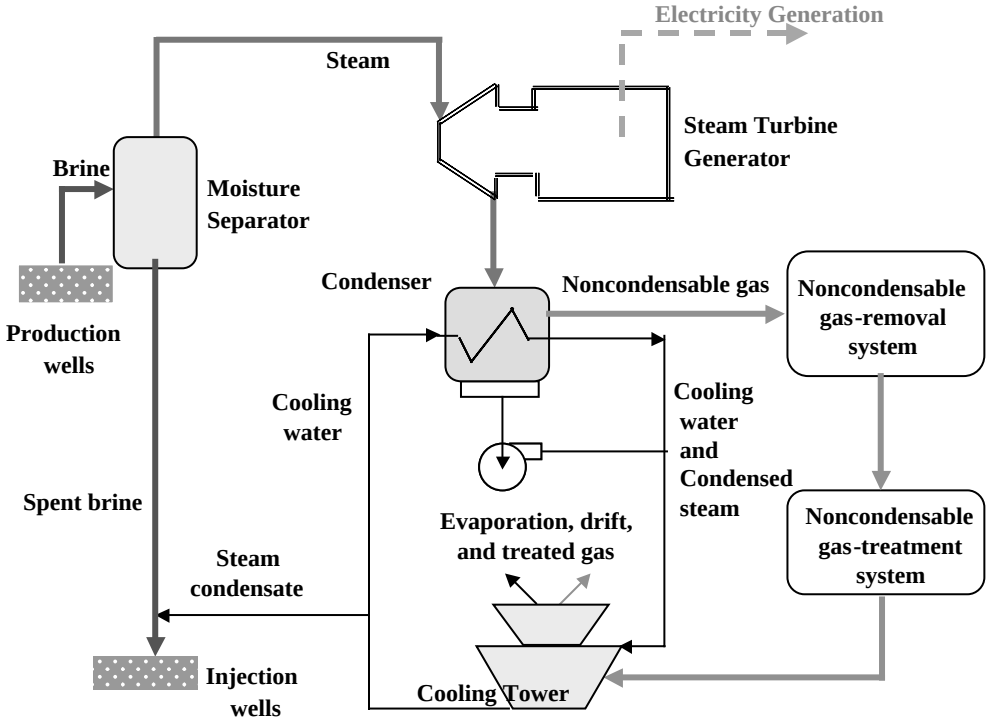

Fig. 4 Direct steam cycle geothermal power plant. *(View this art in color at www.dekker.com.)*

c. Cooling tower, which is a multicell wet mechanical draft design. Cooling is accomplished primarily by evaporation. Water that is lost from the cooling system to evaporation and drift is replaced by steam condensate from the condenser.
d. Excess water is returned to the geothermal resource in an injection well.

The direct steam cycle is typical of power plants at The Geysers in northern California, the largest geothermal field in the world. The primary operator of The Geysers is Pacific Gas and Electric.

Flash steam cycle[12]

Flash steam is the steam produced when the pressure on a geothermal fluid is reduced. A flash steam cycle for a high-temperature liquid-dominated resource is shown in Fig. 5. This dual-flash cycle is typical of most larger flash steam geothermal power plants. Single-flash cycles are frequently selected for smaller facilities.

Geothermal brine or a mixture of brine and steam is delivered to a flash vessel at the power plant by either natural circulation or pumps in the production wells. At the entrance to the flash vessel, the pressure is reduced to produce flash steam. The steam is delivered to the high-pressure inlet to the turbine. The remaining brine drains to another flash vessel where the pressure is again reduced to produce low-pressure flash steam.

The other components present in double-flash steam geothermal cycle include:

a. Direct contact condenser, as hydrogen sulfide is not produced in large quantities.
b. A cooling tower. This cycle also uses a multicell wet mechanical draft cooling tower. The water lost to evaporation and drift is replaced by steam condensate.
c. The excess water and spent brine from the flash vessels are injected back into the geothermal resource in an injection well.

Binary cycle[4]

A binary-cycle geothermal power plant employs a closed-loop heat exchange system in which the heat of geothermal fluid (''primary fluid'') is transferred to a lower-boiling heat transfer fluid (''secondary fluid'') that is thereby vaporized and used to drive a turbine/generator set. In other words, a binary cycle uses a secondary heat transfer fluid instead of steam in the power generation equipment. Binary geothermal plants have been in service since the late 1980s. A binary cycle is the economic choice for hydrothermal resources with temperatures below approximately 165°C. A typical binary cycle is shown in Fig. 6.

The binary cycle shown in Fig. 6 uses isobutane (i-C_4H_{10}) as the binary heat transfer fluid. Heat from

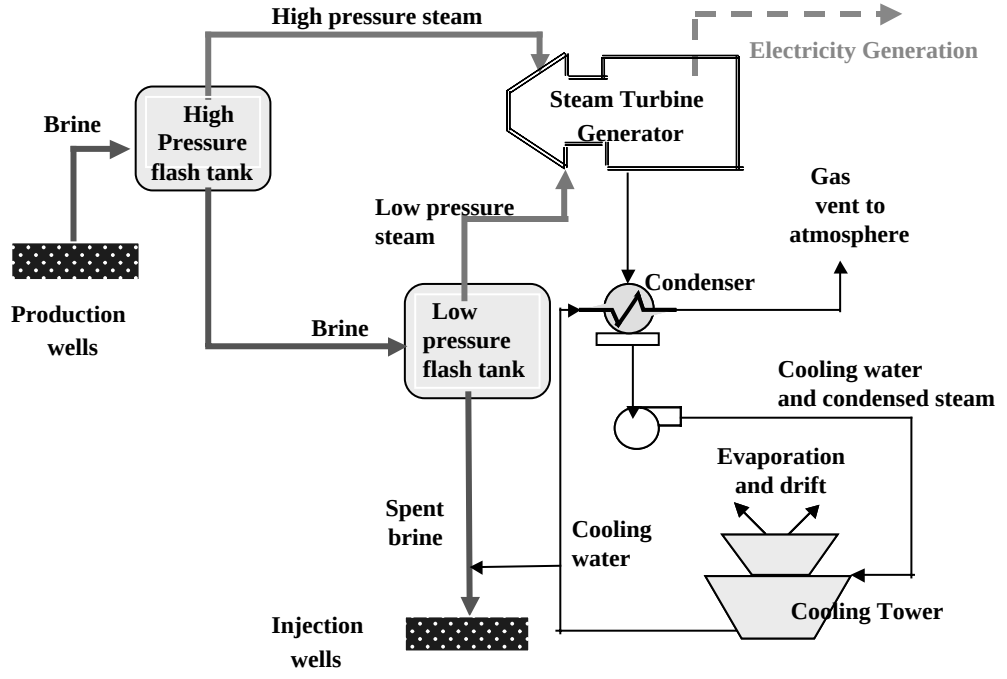

Fig. 5 Double-flash steam cycle geothermal power plant. *(View this art in color at www.dekker.com.)*

geothermal brine vaporizes the binary fluid in the brine heat exchanger. Spent brine is returned to the resource in injection wells, and the binary fluid vapor drives a turbine generator. The turbine exhaust vapor is delivered to an air-cooled condenser, where the vapor is condensed. Liquid binary fluid drains to an accumulator vessel before being pumped back to the brine heat exchangers to repeat the cycle. The brine heat exchangers are typically shell-and-tube units fabricated from carbon steel.

HDR (dry geothermal sources) systems[2,13,14]

Since the vast majority of the geothermal heat resources of the world exists in forms of HDR sources rather than water (hydrothermal) systems, it is only

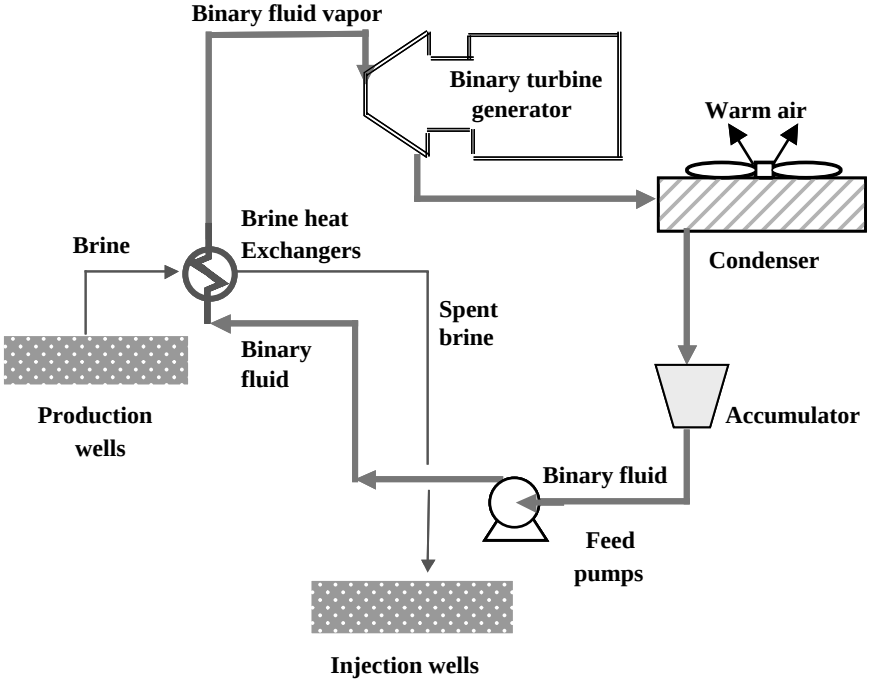

Fig. 6 Binary cycle geothermal power plant. *(View this art in color at www.dekker.com.)*

natural for this energy source to receive more attention from geothermalists. The more accessible HDR resources in the United States alone would provide an estimated 650,000 quads of heat, one quad (one quadrillion BTUs) being equivalent to the amount of energy contained in 171.5 million barrels of oil. Since the annual U.S. energy consumption is approximately 84 quads, whoever figures out how to economically tap even a fraction of the potential in HDR could earn a place in history.

HDR is a deeply buried crystal rock at a usefully high temperature. Current engineering designs plan to tap its heat by drilling a welbore, fracturing or stimulating pre-existing joints around the welbore, and directionally drilling another welbore through the fracture network. Cold water then flows down one welbore, pushes through the fractured rock, warms, returns up the other welbore, and drives a power plant. The major technical uncertainty is establishing the fracture network between the two welbores. If adequate connectivity can be established and sufficiently large fracture surface area can be exposed between the two welbores, HDR can be a very competitive source of energy.

Fig. 7 is a schematic diagram of the experimental Los Alamos System in New Mexico. Water at 65°C and 1000 psia is pumped into hydraulic fracture network, approximately 3000 ft in diameter and circulated at 7500 ft where temperatures range between 260°C and 320°C. The pressure is around 4100 psia. The water is then pumped out of the ground and when it reaches the surface its temperature is 230°C at 1250 psia.

In this experimental system, the hot water is circulated through an air-cooled heat exchanger with the extracted heat dissipated to the atmosphere.

Fresh water production

Less than 2% of the earth's retained water supply is available for drinking. The oceans, atmosphere, rocks or rock formations, and polluted resources contain the remaining 98%. From the standpoint of water shortage, all the systems recognized to date (desalination, recycling, and/or transportation over long distances) consume enormous amounts of energy and have also proven to be uneconomical. Geothermal resources, on the other hand, contain vast reservoirs of hot water and steam, and some of these are producing electricity and fresh water as a byproduct. The geothermal resource satisfies two main criteria for alleviating water shortages, viz.

a. An energy source for distillation process such as multistage flash and vertical tube evaporator.
b. An ample supply of water.

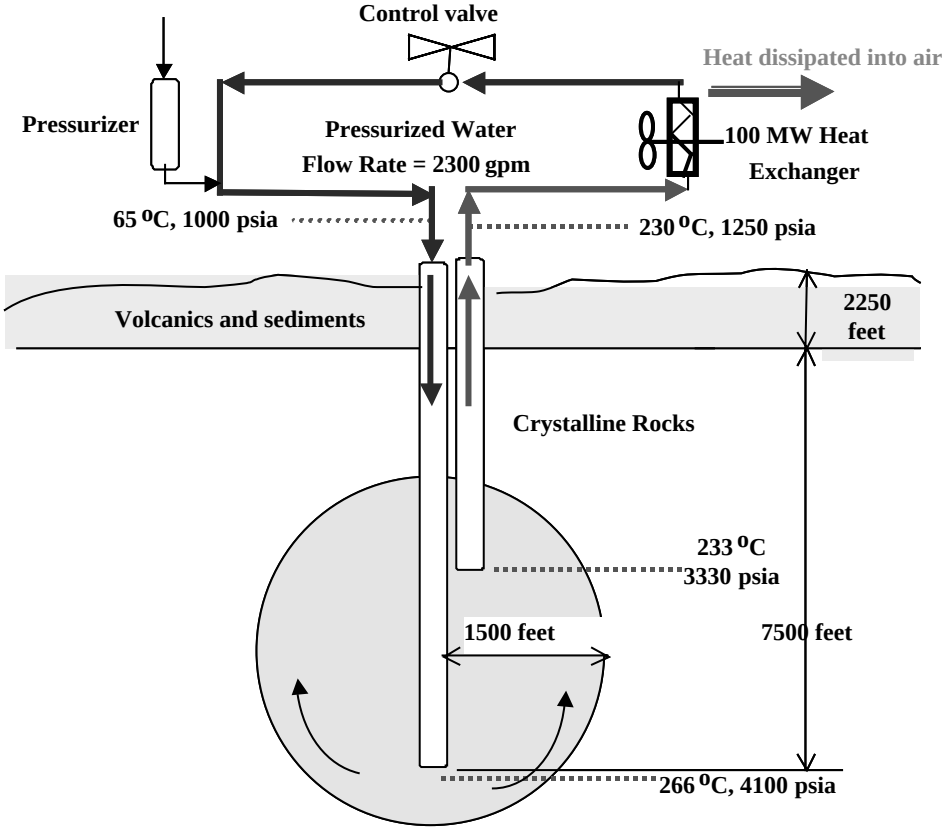

Fig. 7 Experimental configuration and operating conditions Los Alamos hydraulic fracture network. *(View this art in color at www.dekker.com.)*

Direct Use of Geothermal Heat

Direct heat use is one of the oldest, most versatile, and also the most common form of utilization of geothermal energy. The term, direct use, means that geothermal heat is used directly without first converting it to electricity. The warm water or steam exiting the ground will be piped into the dwelling or structure to provide warmth. Direct heating is obviously an older technology than geothermal power generation and is widely practiced.

Space and district heating

Direct heating can be applied in what are known as either district or space heating systems, the distinction being that space heating systems serve only one building, while district heating systems serve many structures from a common set of wells. Direct heating has made the greatest progress and development in Iceland, where the total capacity of the operating geothermal district heating system is 800 MW.[15] Fig. 8 shows an example of a district heating system.

Each system has to be adapted to the local situation, depending on the type of geothermal resource available, the population density of the area and the predicted population growth, the type of buildings requiring heating/cooling and, above all, the local climate. Geothermal district heating pumps are capital intensive in the early stages. The principal costs are initial investments for production and injection wells, down-hole and circulation pumps, heat exchangers, and pipelines, as well as the distribution network. A high load density usually makes district heating economically more feasible, because the cost of the distribution network transporting hot water to consumers is shared. Importantly, operating costs are comparatively low, thus making the long-term cost much more favorable. Geothermal district heating systems offer significant life cycle cost savings to consumers, as much as 30–50% of the cost of using natural gas or oil.

At present, a very successful district heating system exists in San Bernardino, California. The water production system, consisting of two wells, yields an average flow of 5200 L/min at 54°C water. The system currently serves 33 buildings including government centers, a prison, a new blood bank facility, and other private buildings.

Agricultural applications

One specific application of direct heating is greenhouse heating. This is one of the most common worldwide applications of geothermal energy. Fruits, vegetables, flowers, and ornamental plants are successfully grown year-round, in geothermally heated greenhouses using low-temperature sources (<38°C). Geothermal energy can extend short growing seasons and significantly reduce fuel costs. One example is a 650 m^2 greenhouse in California utilizing a geothermal well 150 m deep that supplies 67°C water. The well is capable of supplying heat for an additional 1800–3700 m^2 of greenhouse.

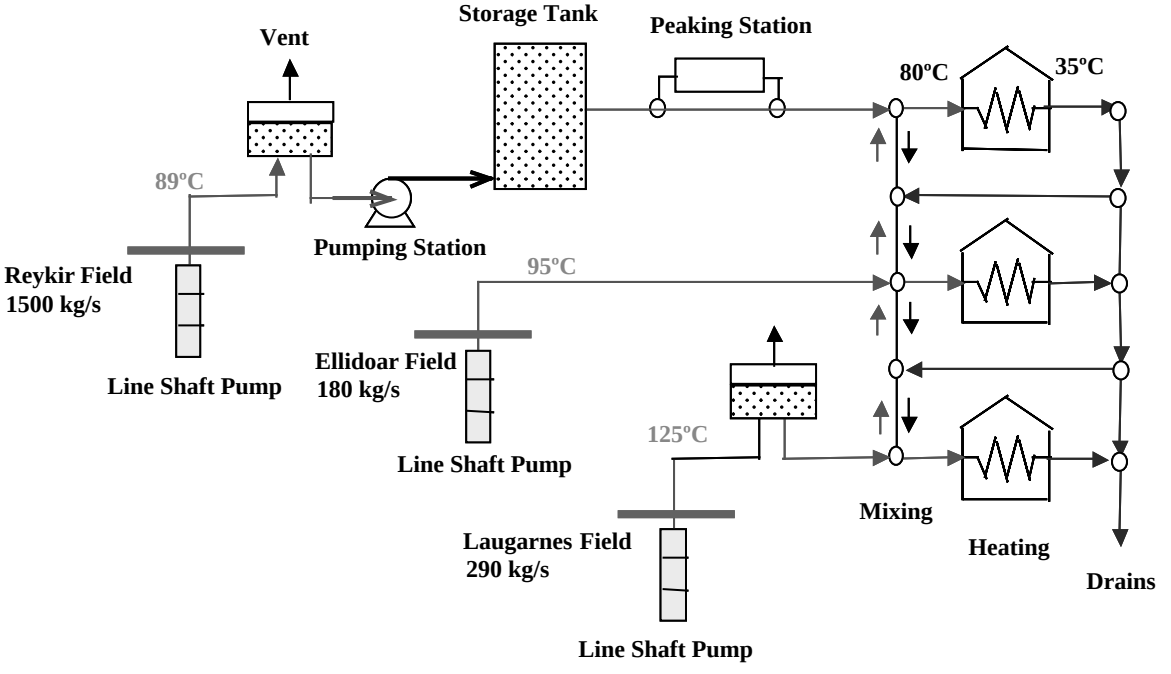

Fig. 8 A schematic of Hitaveita Reykjavikur (Reykjavik district heating system). *(View this art in color at www.dekker.com.)*

It should be noteworthy that the energy crisis experienced in California in 2001 rendered a very severe threat to greenhouse farmers who relied on electricity or natural gas heating.

Another direct heating application involves aquaculture, which is the raising of freshwater or marine organisms in a controlled environment. Geothermally heated water produces excellent yields of high quality fish and crustacean under accelerated growth conditions. Furthermore, geothermal aquaculture permits breeding in the winter, allowing fish farmers to harvest their products when product availability is low and market prices are high. California has six geothermal aquaculture operations as of late 1990s. The largest, the Hot Creek Hatchery near Mammoth, uses water from four springs with temperatures of 11–16°C.

Balneology

Balneology involves the use of geologically heated water/brine/mud sources for bathing purposes while also being alleged to possess healing and prophylactic properties. Balneology is centuries old and has been practiced by Etruscans, Romans, Greeks, Turks, Mexicans, Japanese, Koreans, Americans, and undoubtedly others.

Industrial process heat

Industrial processes can be heat intensive, and they commonly use either steam or superheated water with temperatures of 150°C or higher. This makes industrial processes the highest-temperature users of geothermal direct-heat applications. However, lower temperatures can suffice in some cases, especially for some drying applications. Two of the largest industrial users of geothermal heat are a diatomaceous-earth drying plant in Iceland, and a paper and pulp processing plant in New Zealand.

Geothermal Heat Pumps

The GHP, also referred to as the ground source heat pump (GSHP), uses the earth as a heat source for heating and as a heat sink for cooling. The GSHP uses a reversible refrigeration cycle combined with a circulating ground loop to efficiently provide either heating or cooling from electricity. The basic mechanism is the same as that of an air-source heat pump, but operates more efficiently since the temperature of the ground is more favorable than that of the air, i.e., the ground is warmer in the winter and cooler in the summer than the air. Additionally, the ground temperature is fairly constant throughout the year, even at depths of as little as 5–10 ft.

The typical components of a residential GSHP during heating and cooling cycles are shown in Figs. 9 and 10. The major components of the system are the ground loop and a refrigeration unit composed of the compressor, primary heat exchanger, expansion valve, and secondary heat exchanger. The refrigeration cycle utilizes the same unit operation steps as that of an air-source heat pump or typical home air-conditioning unit. In what is referred to as a closed-loop system, a water and antifreeze mixture circulates through a pipe buried in the ground and transfers thermal energy between the ground and the primary heat exchanger in the heat pump. Depending on the mode of operation, either heating or cooling is provided based on the reversible valve that allows the refrigerant to reverse the order of the operations of the cycle. Therefore, the primary heat exchanger, which consists of a water-to-refrigerant loop, can act as an evaporator or a condenser. Also included in this system is a heat exchanger following the compressor that provides heat to a hot water heater, this is often referred to as a de-superheater. The Geothermal Heat Pump Consortium, Inc., offers technical, educational, and promotional support for Geoexchange systems.[16]

GHPs offer a distinct advantage over the use of air as a source or sink, since the ground is at a more favorable temperature. Compared to atmospheric air, the ground is warmer in winter and cooler in summer. Therefore, GHPs demonstrate better performance over air-source heat pumps. They also reduce electricity consumption by approximately 30% compared to air-source heat pumps. Aided by utility sponsored programs, GHPs are becoming increasingly popular throughout the world. In the U.S., the GHP industry is expanding at a growth rate of 10–20% annually. As of 2004, more than 200,000 GHPs are being operated in U.S. homes, schools, and commercial buildings.[17]

The industrial and other potential applications of geothermal energy suggest that the great economic advantages could be gained from dual- or multipurpose plants combining power production with one or more other applications. Such plants would enable the costs of exploration drilling and certain other items to be shared among two or more end users.

SCIENTIFIC AND TECHNOLOGICAL DEVELOPMENTS

Major Research Efforts

The following major activities are examples of U.S. Government funded research being conducted in accordance with its R&D strategy:[6,9]

a. Advanced techniques to detect and delineate hidden geothermal resources are being developed,

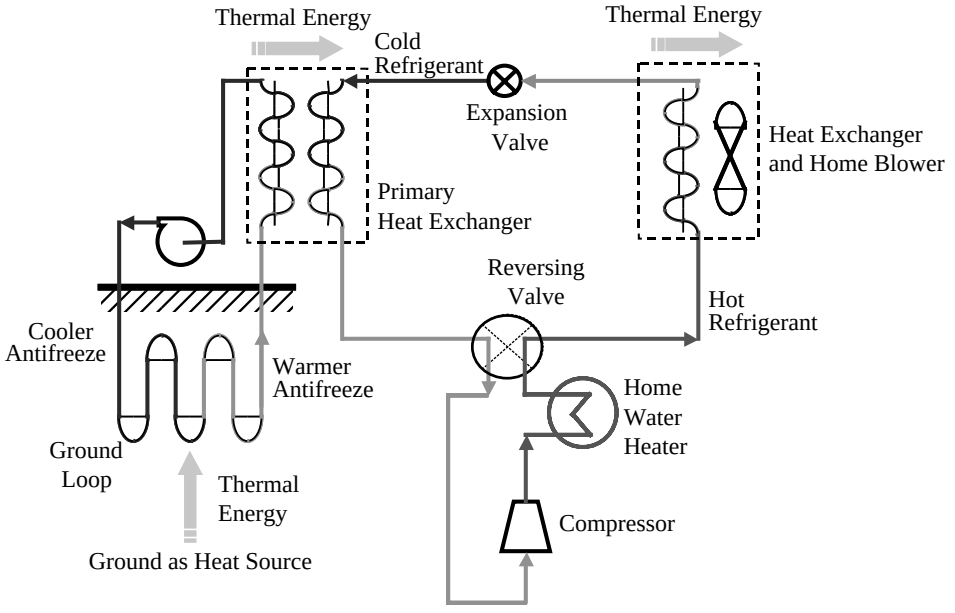

Fig. 9 GSHP during heating cycle. *(View this art in color at www.dekker.com.)*

including remote sensing techniques and improvements of various electric and acoustic methods.

b. Slim-hole drilling/coring, a cost effective option for exploratory drilling, needs to be improved. This research includes developing slim-hole reservoir engineering techniques and logging tools.
c. Improved materials that are capable of withstanding the high temperature and corrosive nature of geothermal brines are being developed.
d. Methods to increase the net brine effectiveness of geothermal power plants are being pursued, as are ways to reduce power plant costs.

Significant research activities ongoing at National Laboratories and Universities in the United States and the world include those of, Sandia National Laboratory,[9,18] Lawrence Berkeley National Laboratory,[9] Brookhaven National Laboratory,[4,9] National Renewable Energy Laboratory,[17] Los Alamos National Laboratory,[19–21] The Geysers,[10] Camborne School of Mines,[4] European Hot Dry Rock Industries,[4] Stanford University and Leningrad's Mining Institute,[4] Electric Power Research Institute (EPRI), Geo-Heat Center of the Oregon Institute of Technology, Southern Methodist University Geothermal

Laboratory, and Virginia Polytechnic Institute and State University.

Technology Updates

The development of a successful geothermal energy project relies on a variety of specialized technologies as well as their cost effectiveness.

Exploration technology

Exploration is a key to the discovery of new geothermal resources. It identifies geothermal resources, estimates resource potential, and establishes resource size, depth, and potential production. It relies on surface measurements of subsurface geological, geochemical, and geophysical conditions to develop a conceptual model of the system. Geothermal exploration of unmapped regions typically proceeds in two basic phases, reconnaissance and detailed exploration. During the reconnaissance phase, regional geology and fracture systems are studied, such as young volcanic features, tectonically active fault zones (as deduced from seismic information), and overt or subtle geothermal manifestations. If the reconnaissance phase confirms that the province has geothermal potential and that specific sites in the province should be explored further, the second phase focuses on one or more individual prospects covered in the reconnaissance phase.

Brine handling technology

Brine is a geothermal solution containing appreciable concentrations of sodium chloride or other salts. The chemical composition including the salinity of geothermal fluids varies greatly from one reservoir to another. Variations in chemistry and salinity affect the design, maintenance, and longevity of wells and surface equipments. Recent advances in this area include:[6]

i. Use of scale-inhibiting chemicals to reduce carbonate scaling of flashing wells.
ii. Development of pH modification to control silica scaling in power plants.
iii. Development of highly effective computer programs to estimate and predict chemistry effects in geothermal systems.
iv. Continued development of polymeric cement coating to reduce corrosion in heat exchangers and process piping.

Environmental issues of geothermal energy utilization

Even though geothermal energy is one of the cleanest and safest means for generating electric power, its effects on water resources, air quality, and noise during geothermal development and operation must be understood and mitigated. Among these are emissions to air (particularly of hydrogen sulfide), land use, and disposal of solid wastes. Effects can vary greatly from site to site.

Steam and flash plants emit mostly water vapor (steam). Binary power plants run on a closed-loop system, therefore zero discharge of gases is accomplished. The geothermal industries have developed advanced technologies to recycle minerals in geothermal fluid so that little or no disposal or emissions occur. The examples are found from The Geysers power plants in northern California that separate and use sulfur for sulfuric acid production, and also from the Salton Sea power plants in southern California recycling salts from geothermal brine, recovering silica from mineralized brine for use as fillers in concrete, and extracting zinc for additional plant profitability.

CONCLUSIONS

Geothermal resources are continuously renewable sources of energy regardless of climate or weather conditions, unlike wind or solar energy. Reliability, sustainability, and cleanness make geothermal energy especially attractive as a source for baseload electricity generation or for direct-use applications that need constant heat or energy. Geothermal power plants compete well economically with coal, oil, and nuclear plants in meeting baseload capacity needs with significant environmental advantages. The next generation of geothermal power plants will be designed using long-term projections for resource production as the basis for cycle selection, optimization, and system design.

Current HDR technology is competitive with modern coal-fired plants in regions with geothermal gradients exceeding 60°C/km.[13] Reasonable improvements in reservoir performance or reductions in drilling and completion costs may substantially lower the effective cost of HDR power. In areas with steep geothermal gradients, the use of HDR may demonstrate a substantial cost advantage over coal. This advantage may increase over time allowing the use of HDR to produce a significant portion of the future electricity of the world.

Due to its practicality and low operating costs, direct application of geothermal energy is expected to grow in popularity, especially in geothermally favored regions. Diverse applications are expected to be developed in this field and more advances in GHP technology are also expected. Advances in materials, process integration and design, resource management, instrumentation, and drilling technology will undoubtedly enhance the global utilization of geothermal energy.

Greenhouse Gas Management for Multiplant Complexes

Ralph W. Pike
Department of Chemical Engineering, Louisiana State University, Baton Rouge, Louisiana, U.S.A.

INTRODUCTION

The relationship between greenhouse gases and climate changes has been studied extensively.[1,2] The conclusion is that greenhouse gases can induce global climate warming and emissions should be reduced, especially of carbon dioxide, which accounts for 83% of the total emissions as shown in Fig. 1.[3]

A summary of the two sources of carbon dioxide and the carbon dioxide cycle is illustrated in Fig. 2. Natural sources from plants and soils emit 1.6 Gt C/yr, and anthropogenic sources account for 5.5 Gt C/yr, mainly from the burning of fossil fuels and deforestation as shown in Table 1.[4] The CO_2 emissions from the consumption and flaring of fossil fuels in the United States in 1999 have been estimated as 1526 million metric tons carbon equivalent accounting for 24% of worldwide emissions. The carbon emissions from industrial sources in the United States were reported to be 630 million metric tons carbon equivalent, with 524 and 473 million metric tons carbon equivalent from buildings and transportation, respectively, as shown in Table 1.[5] The manufacturing industries' total was reported to be 402 million metric tons carbon equivalent, and the petroleum and coal products industry and the chemical industry had 175 million metric tons carbon equivalent or 43% of the total.[3] British Petroleum reported that 90% of the CO_2 emissions were from energy generation, 7% from flaring, and 3% from process (noncombustion) sources in refineries.[6] Worldwide, CO_2 emissions from the consumption and flaring of fossil fuels were estimated to be 6320 million metric tons carbon equivalent per year.[9]

There have been extensive discussions about separating, capturing, and converting carbon dioxide to useful products from industrial emissions. These evaluations include sequestering carbon dioxide in geological formations, oceans, and natural systems.[10] These concepts have been summarized by Kim and Edmonds, and they estimated the sequestering costs to range from US $120 to US $340 per metric ton of carbon equivalent.[11] Also, they estimated that this cost could drop to US $50 per ton of carbon equivalent by 2015.

Approximately, 110 million metric tons of carbon dioxide per year (30 million metric tons carbon equivalent) are used as a raw material for the production of urea, methanol, polycarbonates, cyclic carbonates, and specialty chemicals.[8] The largest use is for urea production, which reached about 90 million metric tons per year in 1997.[12]

Ammonia production consumes hydrogen that is obtained from synthesis gas after separating carbon dioxide. However, ammonia plants in the United States produce about 6.8 million tons of carbon dioxide per year, and urea and methanol plants only consume 4.0 million tons per year.[13] This leaves an excess of 2.8 million metric tons of high-purity carbon dioxide per year that is vented to the atmosphere in the United States as shown in Table 1.

Also, there is approximately another 19 million metric tons of relative high-purity carbon dioxide from refineries and other chemical plants in the United States that use hydrogen from synthesis gas and discharge carbon dioxide to the atmosphere.[13,14]

A potential upper limit of carbon dioxide used as a raw material has been estimated by Song.[15] This total of 650 million metric tons of carbon dioxide included traditional processes for urea and methanol in addition to plastics, fibers, rubber, and other uses. This total is comparable to carbon dioxide emissions from fossil fuel power plants.

In the chemical production complex in the lower Mississippi River corridor shown in Fig. 3, there are about 150 plants that consume 1.0 quad (10^{15} BTU/yr) of energy and generate about 215 million pounds of pollutants per year.[16] There is a carbon dioxide pipeline that connects plants. Currently, there is approximately an excess 1.0 million metric tons of high-purity carbon dioxide per year from ammonia production that is being vented to the atmosphere. The cost of carbon dioxide as a raw material is essentially the pumping cost to a plant, about US $2–3 per metric ton.[17]

The chemical production complex in the lower Mississippi River corridor is one of the several worldwide complexes that can benefit from using carbon dioxide as a raw material and the resulting reduced energy consumption. In Fig. 4, a list of some of these

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120018372

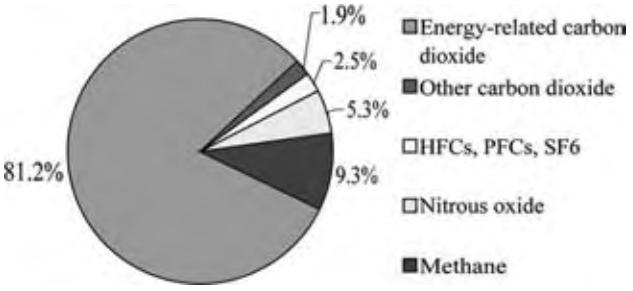

Fig. 1 Greenhouse gas composition in the United States 2002, revised from Energy Information Administration (EIA), 2001. (From Ref.[3].) *(View this art in color at www.dekker.com.)*

complexes is given, and the one in Houston, TX, is the largest complex in the world.

GREENHOUSE GASES AS RAW MATERIALS

There have been a book, five international conferences, and numerous articles in the past 20 yr on carbon dioxide reactions that consider using it as a raw material.[12,15,18–21] The diagram in Fig. 5 is a convenient way to show the range of reactions for carbon dioxide. It can be used as a whole molecule in reactions and can be used as a carbon source or as an oxygen source.

In Fig. 6 carbon dioxide reactions are categorized by industrially important products. Hydrogenation reactions produce alcohols, hydrocarbon synthesis reactions produce paraffins and olefins, and amine synthesis produces methyl and higher-order amines. Hydrolysis reactions can produce alcohols and organic acids. Carbon dioxide serves as an oxygen source in the ethyl benzene to styrene reaction. It can be used in dehydrogenation and reforming reactions.

For the reactions shown in Fig. 6, there are nearly 100 reports of new methods and catalysts to produce these commercially important products.[7] An important reaction is the direct catalytic reaction of carbon dioxide and methane to produce acetic acid, and this reaction has been used in a new process that was evaluated using the Chemical Complex and Cogeneration Analysis System, which is described in the next section.

New processes using carbon dioxide will provide alternate methods for manufacturing chemical intermediates used to produce building materials, motor vehicles, tires, paper, plastics, apparel, fertilizer, furniture, and appliances.[22] Essentially, all of these products are sequestered because at the end of their useful life they end up in landfills. The carbon from fertilizers ends up in plant tissue and will eventually be released to the atmosphere.

EVALUATION OF NEW PROCESSES FOR CARBON DIOXIDE USE

Chemical Complex and Cogeneration Analysis System

The Chemical Complex and Cogeneration Analysis System is an advanced technology for energy conservation and pollution prevention. The System has been developed by industry–university collaboration and used by corporate engineering groups for regional economics, energy, environmental and sustainable development planning to design energy efficient and environmentally acceptable plants and produce new products from greenhouse gases. The System assists in overcoming growth and productivity limitations in the chemical industry by inefficient power generation and greenhouse gas emission constraints. Results from using the System demonstrate how new processes can be integrated into existing chemical complexes to convert greenhouse gases into useful products and to reduce energy consumption and emissions by cogeneration.

This System combines the Chemical Complex Analysis System with the Cogeneration Design System. The Chemical Complex (Multi-Plant) Analysis System is a new methodology to determine the best configuration

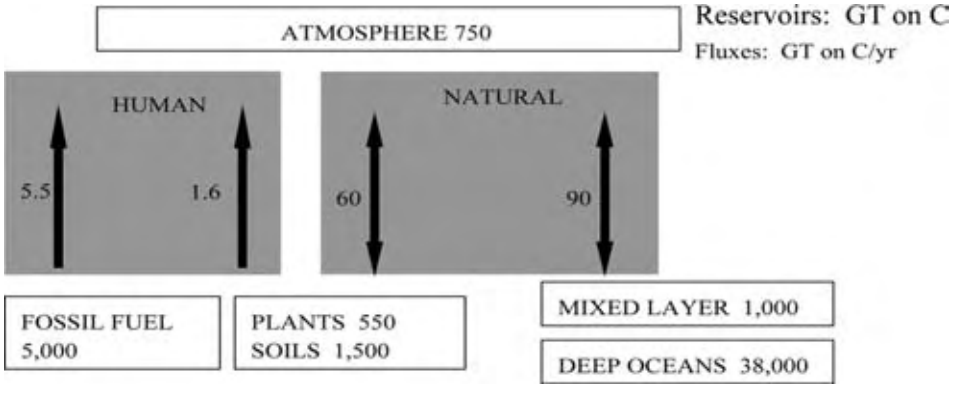

Fig. 2 The carbon cycle, from Intergovernmental Panel on Climate Change (IPCC). (From Ref.[1].)

of plants in a chemical complex based on the AIChE Total Cost Assessment (TCA) for economic, energy, environmental, and sustainable costs, and incorporates the Environmental Protection Agency (EPA) Pollution Index methodology (WAR) algorithm. The Cogeneration Design System examines corporate energy use in multiple plants and determines the best energy use based on economics, energy efficiency, regulatory emissions, and environmental impacts from greenhouse gas emissions. It uses sequential layer analysis to evaluate each plant's current energy use as at an acceptable level or cost-effective improvements if possible. It includes cogeneration as a viable energy option and evaluates the cogeneration system operating optimally.

The structure of the System is shown in Fig. 7, and the System output includes evaluating the optimum configuration of plants in a chemical production complex by determining the maximum profit and minimum energy use and emissions. The input includes incorporating new plants that use greenhouse gases as raw materials in the existing complex of plants. The integrated cogeneration sequential layer analysis determines cost-effective improvements for individual plants using heat exchanger network analysis and cogeneration opportunities. Then, these results are used to determine the optimum complex configuration and utilities integrated with the plants.

The System has an interactive Windows program that integrates existing programs. All interactions with the System are through a graphical user interface designed and implemented with Visual Basic. As shown in Fig. 7, the process flow diagram for the complex is constructed, and equations for the process units and variables for the streams connecting the process units are entered and stored in an Access database using interactive data forms. Material and energy balances, rate equations, and equilibrium relations for the plants are entered as equality constraints using the format of the GAMS programming language, which is similar to Excel, and stored in the database. Process unit capacities, availability of raw materials, and demand for product are entered as inequality constraints and stored in the database. The System takes the equations in the database and writes and runs a GAMS program to solve the mixed integer nonlinear programming problem for the optimum configuration of the complex. Then, the important information from the GAMS solution is presented to the user in a convenient format, and the results can be exported to Excel, if desired. Features for developing flowsheets include adding, changing, and deleting the equations that describe units and streams and their properties. Usual Windows features include cut, copy, paste, delete, print, zoom, reload, update, and grid, among others.

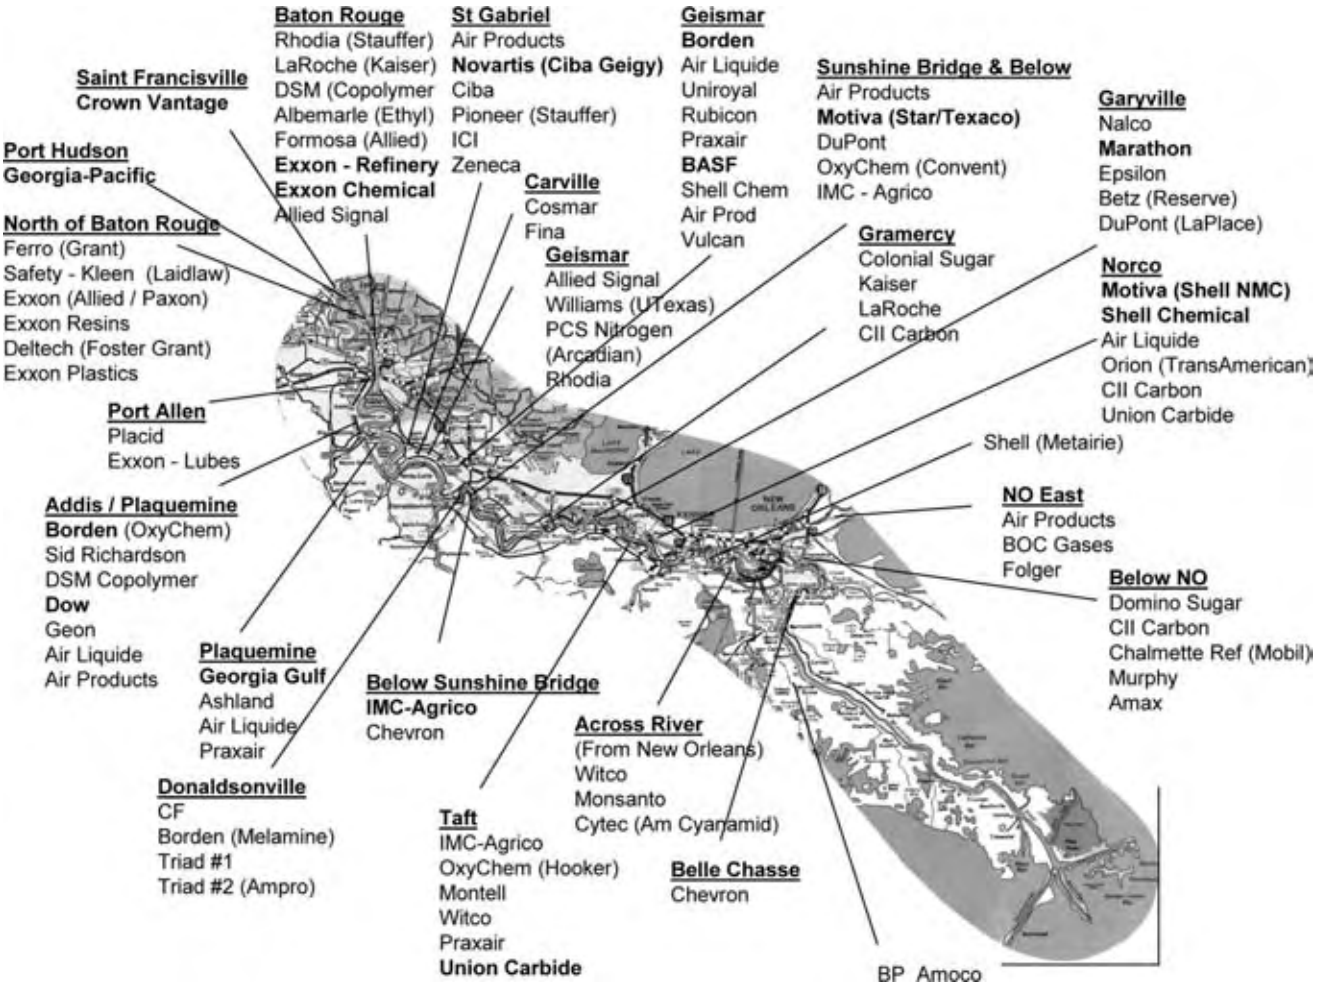

Fig. 3 Plants in the lower Mississippi River corridor. (From Ref.[16].)

A typical window for entering process information is shown in Fig. 8, and in this figure a material balance equation for the acetic acid process, U15, has been entered as an equality constraint. Typical output from the cogeneration analysis is shown in the diagram in Fig. 9 for the results from the prototype. A detailed description of these operations is provided in an interactive user's manual with help files and a tutorial. All of this is available from the Louisiana State University Minerals Processing Research Institute's web site www.mpri.lsu.edu.

The system has been applied to the agricultural chemical production complex in the lower Mississippi River corridor, and the process flow diagram of plants in this complex is shown in Fig. 10 and is called the base case of existing plants. There are 11 production units plus associated utilities for power, steam and cooling water, and facilities for waste treatment. A production unit contains more than one plant; for example, the sulfuric acid production unit contains five plants owned by two companies.[17] This base case includes a standard acetic acid plant with methanol as feedstock, and this is a step to extend the agricultural chemical complex into the petrochemical complex focusing on the CO_2 reuse. For this base case there were 334 equality constraint equations describing the material and energy balances and chemical conversions. Also, there were 19 inequality constraint equations describing the demand for product, availability of raw materials, and range of capacities of the individual plants in the complex.

A diagram comparable to Fig. 10 showing the superstructure of all plants is too detailed to include here, and a convenient way to show the plants in the base case and the plants added to form the superstructure is given in Fig. 11. The superstructure included three options for producing phosphoric acid. Acetic acid can be produced by the conventional process in the base case, and a new catalytic process is included in the superstructure. There are new plants to produce

Continent	Name and Site	Notes
North America	•Gulf coast petrochemical complex in Houston area (U.S.A.) and •Chemical complex in the Baton Rouge-New Orleans Mississippi River Corridor (U.S.A.)	•Largest petrochemical complex in the world, supplying nearly two-thirds of the nation's petrochemical needs
South America	•Petrochemical district of Camacari-Bahia (Brazil) •Petrochemical complex in Bahia Blanca (Argentina)	•Largest petrochemical complex in the southern hemisphere
Europe	•Antwerp port area (Belgium) •BASF in Ludwigshafen (Germany)	•Largest petrochemical complex in Europe and world wide second only to Houston, Texas •Europe's largest chemical factory complex
Asia	•The Singapore petrochemical complex in Jurong Island (Singapore) •Petrochemical complex of Daqing Oilfield Company Limited (China) •SINOPEC Shanghai Petrochemical Co. Ltd. (China) •Joint-venture of SINOPEC and BP in Shanghai under construction (2005) (China) •Jamnagar refinery and petrochemical complex (India) •Sabic company based in Jubail Industrial City (Saudi Arabia) •Petrochemical complex in Yanbu (Saudi Arabia) •Equate (Kuwait)	•World's third largest oil refinery center •Largest petrochemical complex in Asia •World's largest polyethylene manufacturing site •World's largest & most modern for producing ethylene glycol and polyethylene
Oceania	•Petrochemical complex at Altona (Australia) •Petrochemical complex at Botany (Australia)	
Africa	petrochemical industries complex at Ras El Anouf (Libya)	one of the largest oil complexes in Africa

Fig. 4 Some major chemical production complexes in the world. (From Ref.[7].)

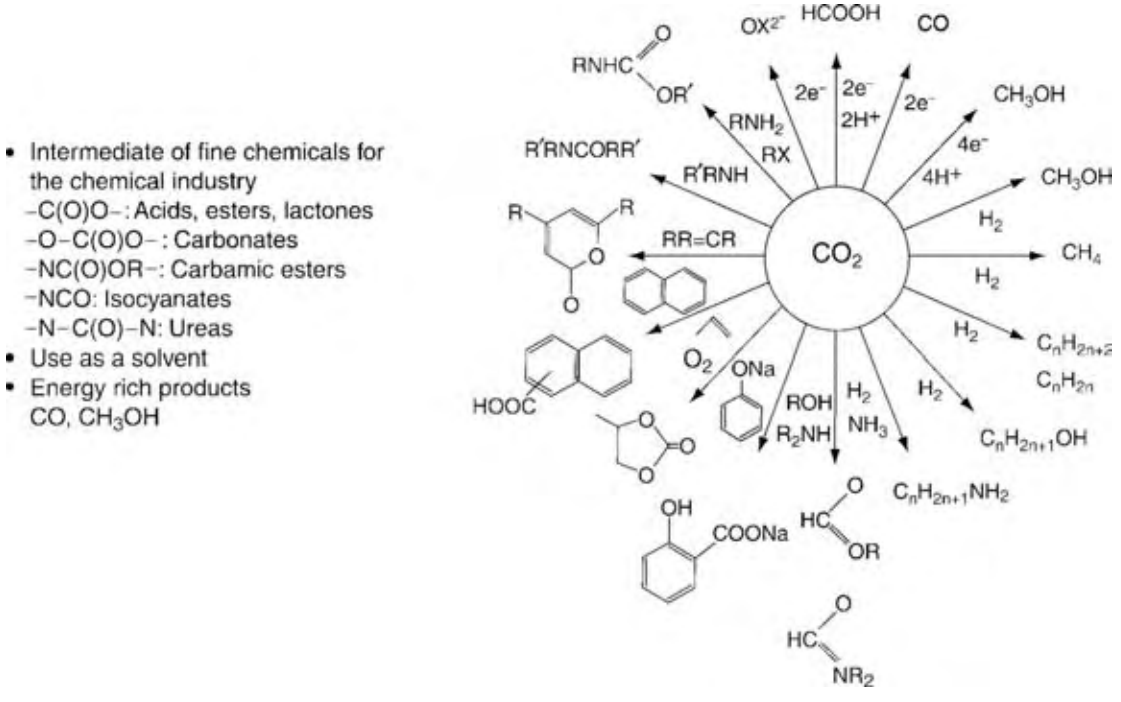

Fig. 5 Utilization of carbon dioxide in synthetic chemistry. (From Ref.[12].)

Hydrogenation

$CO_2 + 3H_2 \rightarrow CH_3OH + H_2O$ methanol
$2CO_2 + 6H_2 \rightarrow C_2H_5OH + 3H_2O$ ethanol
$CO_2 + H_2 \rightarrow CH_3\text{-}O\text{-}CH_3$ dimethyl ether

Hydrolysis and Photocatalytic Reduction

$CO_2 + 2H_2O \rightarrow CH_3OH + O_2$
$CO_2 + H_2O \rightarrow HC{=}O\text{-}OH + 1/2O_2$
$CO_2 + 2H_2O \rightarrow CH_4 + 2O_2$

Hydrocarbon Synthesis

$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O$ methane and higher HC
$2CO_2 + 6H_2 \rightarrow C_2H_4 + 4H_2O$ ethylene and higher olefins

Carboxylic Acid Synthesis

$CO_2 + H_2 \rightarrow HC{=}O\text{-}OH$ formic acid
$CO_2 + CH_4 \rightarrow CH_3\text{-}C{=}O\text{-}OH$ acetic acid

Graphite Synthesis

$CO_2 + H_2 \rightarrow C + H_2O$
$CH_4 \rightarrow C + H_2$
$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O$

Other Reactions

CO_2 + ethylbenzene $\rightarrow$ styrene
dehydrogenation of propane
$CO_2 + C_3H_8 \rightarrow C_3H_6 + H_2 + CO$
reforming
$CO_2 + CH_4 \rightarrow 2CO + H_2$

Amine Synthesis

methyl amine and higher amines

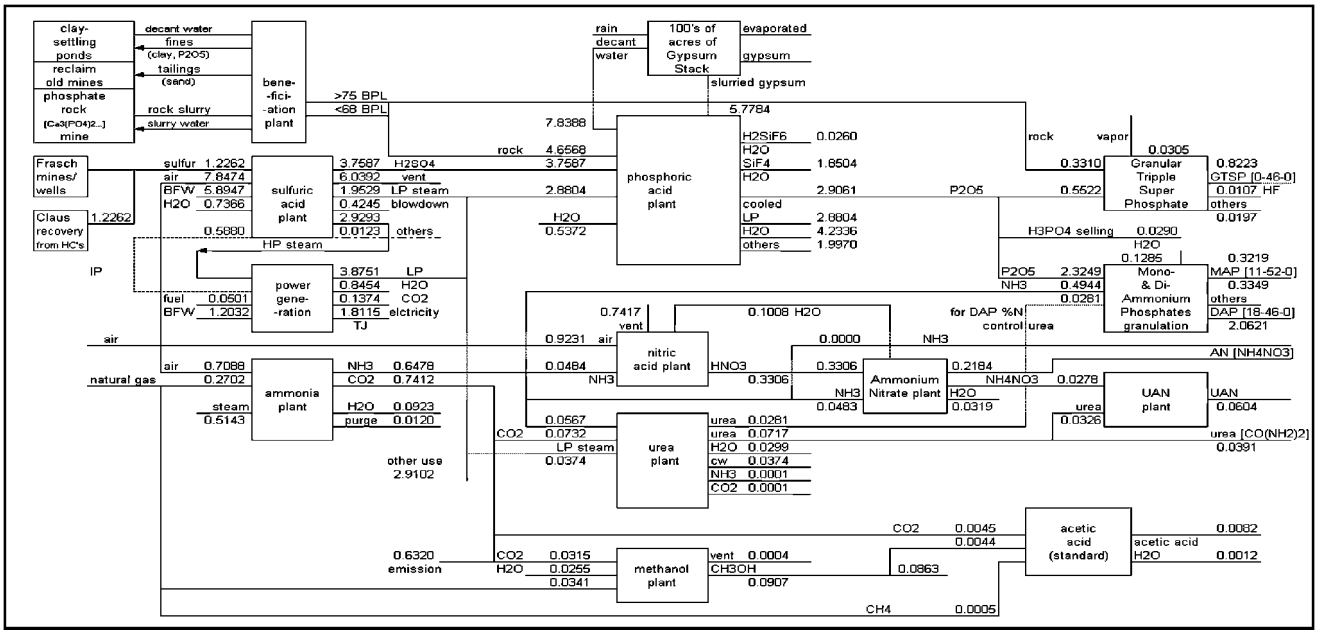

Fig. 10 Base case of plants in the chemical production complex in the lower Mississippi River corridor. (From Ref.[22].)

ammonium sulfate and to recover sulfur and sulfur dioxide. The model of the superstructure has 594 continuous variables, 7 integer variables, 505 equality constraint equations for material and energy balances, and 27 inequality constraints for availability of raw materials, demand for product, and capacities of the plants in the complex.

The System solves the mixed integer nonlinear programming problem using the economic data shown in Fig. 12. This table gives the sale prices for products and costs of raw material that were used in the economic model of the complex. Also shown are sustainable costs and credits. Environmental costs were estimated as 67% of the raw material costs, which is based on the data provided by Amoco, DuPont, and Novartis in the American Institute of Chemical Engineers/ Center for Waste Reduction Technologies (AIChE/ CWRT) report.[23] This report lists environmental costs as approximately 20% of the total manufacturing costs and raw material costs as approximately 30% of total manufacturing costs. Sustainable costs were estimated from the results given for power generation in the AIChE/CWRT report where carbon dioxide emissions had a sustainable cost of US $3.25 per ton of carbon dioxide. A cost of US $3.25 per ton was charged as a cost to plants that emit carbon dioxide, and plants that consume carbon dioxide were given credit of twice this cost or US $6.50 per ton. This credit was included for steam produced from waste heat by the sulfuric acid plant displacing steam produced from a package boiler firing hydrocarbons and emitting carbon dioxide. These costs are arbitrary but a conservative approach. Emissions trading costs of carbon dioxide are about US $50 per ton, and costs to sequester carbon dioxide have been estimated to be US $120–340 per ton.

Results from the System are shown in Fig. 13 as a comparison of the base case and optimal structure

Processes in Superstructure	
Processes in Base Case	Electric furnace process for phosphoric acid

for the chemical production complex. The profit that includes the economic, environmental, and sustainable costs increased about 66.74% from the base case to the optimal solution. Also, environmental cost decreased about 31.27%, and sustainable costs increased about 9.18%. Energy requirements decreased from 2912 to 1344 TJ/yr. The standard acetic acid plant consuming more energy in the base case was replaced by the new acetic acid plant in the optimal solution to reduce energy consumption. The system selected plants for the complex with less energy requirement. Production rates for the products in the optimal solution were constrained by their capacity limit. It was optimal to operate the ammonium sulfate. The energy requirement of the ammonium nitrate plant based on the unit product in the optimal structure was different from the base case. The reasons are the different production rates of two types of ammonium nitrate, ammonium nitrate solution and granular ammonium nitrate.

SELECTION OF NEW PROCESSES FOR CARBON DIOXIDE USE

For the reactions shown in Fig. 6, there are nearly 100 published articles of laboratory experiments for new methods and catalysts to produce these commercially important products.[7] These articles summarize the types of reactions with values for the heat of reaction, ΔH°, and the Gibbs free energy, ΔG°. Negative values for ΔH° indicate that a reaction is exothermic, i.e., heat is released; and positive values indicate that a reaction is endothermic, i.e., heat is absorbed. The Gibbs free energy, ΔG°, is related to the equilibrium constant for a chemical reaction, K, by the equation, $\Delta G^\circ = -RT\ln K$, where $\Delta G^\circ = \Sigma \nu_i G_i^\circ$ is the difference between the Gibbs energies, G_i°, of the products and reactants (weighted by their stoichiometric coefficients, ν_i). The reactants and products are in their standard state as a pure substance at the standard-state pressure but at the system temperature.[24]

In an ideal solution, for example, the equilibrium constant $K = \pi(x_i)^{\nu_i}$, where x_i is the mole faction of the products and reactants. This equation is equivalent to writing the concentration of the products in the numerator and the concentration of the reactants in the denominator of a fraction. If $\Delta G^\circ = 0$, then $K = 1$, and the reaction proceeds to a considerable extent before equilibrium is reached. The extent of reaction is smaller at equilibrium if ΔG° increases in a positive direction [$K = \exp(-\Delta)G^\circ/RT$)]. According to Dodge (1944) reactions are said to be less feasible as ΔG° increases in a positive direction, but there is no definite value that can be chosen as clearly indicating that a reaction is not feasible from the standpoint of industrial operations. For example, the methanol synthesis reaction is +11,000 cal/gm mol at 600 K, and this reaction is certainly feasible. Dodge provides the following guidelines for the purpose of ascertaining quickly and only approximately if any given reaction is promising at a given temperature:[25]

- The $\Delta G^\circ > 0$ reaction is promising.
- The $0 < \Delta G^\circ < 10{,}000$ cal/gm mol reaction is doubtful but warrants further study.

		Base case		Optimal structure	
Profit (U.S.$/year)		148,087,243		246,927,825

Fig. 13 Comparison of the base case and optimal structure for the chemical production complex. (From Ref.[22].)

- The $\Delta G^\circ < 10{,}000$ cal/gm mol reaction is unfavorable and would be feasible only under unusual circumstances.

For reactions with a positive ΔG° there are ways to increase the conversion. One standard method is to remove products in an intermediate step. This procedure is used in the double absorption contact process for sulfuric acid where sulfur trioxide is removed after the gas passes through two-packed bed reactors before entering the last two reactors.

The basis for this analysis is given in Fig. 14 and includes conversion and selectivity, cost and life (time onstream to deactivation), and methods to regenerate catalysts; hydrogen consumption for hydrogenation reactions; energy requirement for reactions, ΔH°, and equilibrium conversion based on Gibbs free energy, ΔG°. Moreover, the following are considered: raw material costs, energy, environmental, sustainable, and other manufacturing costs, product sales, and market penetration, among others.

The procedure to evaluate a potential process for incorporation into the Chemical Complex Analysis System is shown in Fig. 15. A flowsheeting program, HYSIS or other comparable one, is used to develop the process flow diagram. The flowsheeting program determines the operating conditions and the utilities required—steam and cooling water. Then, a value-added economic analysis is performed to estimate the profitability of the plant. If the profitability is acceptable,

Catalyst
- **conversion and selectivity**
- **life (time on stream to deactivation)**
- **methods to regenerate**
- **hydrogen consumption for hydrogenation reactions**
- **energy requirement for reactions,ΔH°**
- **equilibrium conversion based on Gibbs free energy, ΔG°**

Sales
- **product sales and market penetration**

Costs
- **catalyst, raw materials, energy, environmental, sustainable and other manufacturing costs**

Fig. 14 Bases for analysis of new energy efficient processes using carbon dioxide as a raw material. (From Ref.[7].)

- Simulate process using HYSYS.
- Estimate utilities required.
- Perform economic analysis.
- Obtain process constraint equations from HYSIS simulation.
- Maximize the profit function to find the optimum process configuration with the system.
- Incorporate into superstructure.

Fig. 15 Procedure for new process evaluation for use in the Chemical Complex and Cogeneration Analysis System.

then the process is entered in the System using the material and energy balances, rate equations, and equilibrium relations. These are entered as equality constraints, and demand for product, availability of raw material, and capacities of the process units are entered as inequality constraints. Results from the System give the optimum configuration of the process. Then, this information is included in the superstructure of the complex.

There are four areas for potentially significant energy savings that can be used for selecting designs to evaluate new energy-efficient processes for carbon dioxide consumption:

1. Potential energy savings through improved catalyst using Pacific Northwest National Laboratory (PNNL) estimates for 26 commercial chemicals with 14 of these chemicals shown in Fig. 16.[26]
2. Actual vs. theoretical energy consumption for 16 chemicals and 3 industry groups as shown in Fig. 17 and energy performance levels in Fig. 18.[26,27]
3. Replacement of hazardous substances: An example is a new route to dimethyl carbonate by reacting carbon dioxide and methanol. The current route that reacts carbon monoxide and chlorine to produce phosgene, an extremely toxic intermediate, which is then reacted with methanol to produce dimethyl-carbonate and hydrochloric acid.[15]
4. Other potential uses: For example, applications as a solvent in separations and reactions, expanding markets for chemicals from carbon dioxide, enhanced recovery of oil, natural gas, and coal bed methane.

For the first area, the Chemical Industries of the Future (IOF) Report identified the potential energy savings though improved catalysts for 26 chemicals. This information is given in Fig. 18, and it shows the rank and energy savings.[26] Acetic acid is on this list with a potential savings of 2.0 trillion BTU/yr. Based on this potential, a new acetic acid process has been evaluated as discussed below, and energy savings were found to be 275 billion BTU/yr based only on heat and power savings for a 100 million pound per year plant. Using this new process to replace the 5540 million pounds per year of U.S. acetic acid capacity could generate 15 trillion BTU/yr in energy savings.[28]

The second method of evaluation for actual vs. theoretical energy requirements will use the results in the Chemical IOF Report and the AIChE/CWRT report on Energy Level Performance by the Chemical Industry (Figs. 17 and 18).[26,27] For example, the IOF report states that production of ethylene glycol, vinyl chloride, and styrene all require 5–10 times the theoretical energy, and by industry groups, organic chemicals require about three times the theoretical energy, as shown in Fig. 17. In the energy efficiency evaluations in Fig. 18, it was shown that optimized energy integration can reduce energy consumption by 10% and aggressive process redesign can reduce energy consumption by 10–50%.

	Energy Consumed in Production				Potential Energy Savings	
	Heat & Power Feedstock					
Chemical	Rank	Energy	Energy	Rank	Savings	Energy
Ammonia	2	290	460	1	294	
Propylene	3	160	540	2	98	
p-Xylene	13	60	140	3	94

Fig. 16 Energy consumed in the production of major chemicals and potential energy savings through improved catalysts for potential products from carbon dioxide (trillion BTUs). (From Ref.[26].)

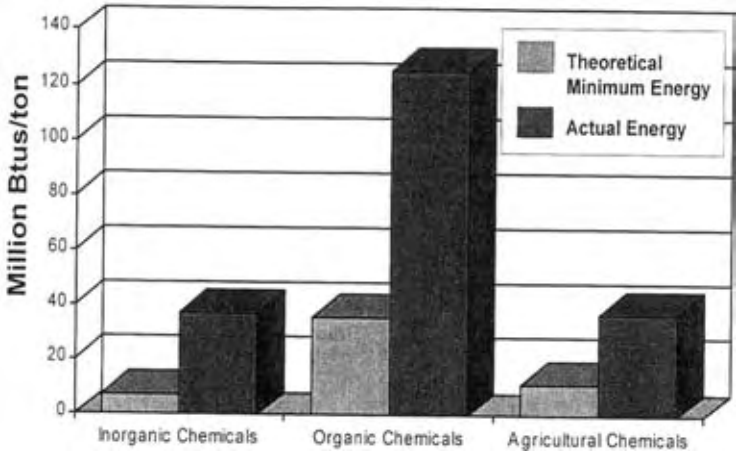

Fig. 17 Theoretical energy minima vs. operating practice in selected chemical industry segments. (From Ref.[26].)

CONCLUSIONS

These results illustrated the capability of the Chemical Complex and Cogeneration Analysis System to select an optimum configuration of plants in an agricultural chemical complex and incorporate economic, environmental, and sustainable costs. With this System, engineers have a new capability to consider projects in depths significantly beyond current capabilities to convert the company's goals and capital into viable projects that are profitable and to meet energy and environmental requirements by developing and applying a regional methodology for cogeneration, and conversion of greenhouse gases to saleable products. The System is available at no charge from the Louisiana State University Minerals Processing Research Institute's web site www.mpri.lsu.edu along with a user's manual with help files and a tutorial.

Heat Exchanger Operation and Troubleshooting

T. Reg. Bott
School of Engineering, Chemical Engineering, University of Birmingham, Birmingham, U.K.

INTRODUCTION

Heat exchangers are employed in many industrial processes, including petroleum refining, large-scale chemical and plastics manufacture, pharmaceutical production, power generation, food processing, desalination, metal production, etc. It is probably true that the manufacture of virtually all products available to modern society involves the transfer of heat. Apart from the need to control temperatures, a heat exchanger has a vital role in process economics and conserving energy, with the associated implications for the environment and global warming.

It is imperative that a heat exchanger is maintained and operated efficiently and effectively to meet all the criteria. As most operate on a continuous basis 24 hr a day, 365 days a year—the greatest hindrance to efficient operation is that the heat-transfer surfaces become dirty, usually referred to as ''fouling,'' with consequent reduction in heat-transfer capability. The choice of heat exchanger and its basic design are fundamental to satisfactory operation with the minimum of trouble. It sometimes represents optimization between operating and initial capital costs. Design of shell and tube heat exchangers must recognise the potential problem of tube failure from metal fatigue and fretting, due to tube oscillation in response to the fluid flow conditions.

It is, however, generally heat exchanger fouling that leads to difficulties in operation. This fouling leads to an increased pressure drop with the potential to produce inlet pressures greater than expected tolerance. As a result leakages may occur between streams, leading to contamination problems and even increased fouling. The increased pressure drop may also increase the maintenance requirements of the associated pumps. A further problem can be the development of corrosive conditions beneath the deposit.

Changes in operating conditions due to changed product demand or changed feed stock quality must be carefully considered to prevent the introduction of operating problems, particularly as these changes can affect the extent of surface fouling.

DESIGN, COMMISSIONING, AND OPERATION OF HEAT EXCHANGERS

Clearly the choice of heat exchanger and its basic design have an impact on its operation and ease of maintenance, particularly the extent of the fouling that accrues and its effect on efficiency. If severe fouling problems are anticipated, it may be necessary to specify a self-cleaning design such as a fluidized bed heat exchanger. It has to be recognized that most heat exchangers are unique in terms of process conditions and the quality of the material being processed, so that the extent of actual fouling is not accurately known at the design stage. Furthermore, during the life of the heat exchanger, the operating conditions may be modified in response to changes in the required product specification or in the origin of the raw material.

An allowance for anticipated fouling is incorporated into the design as an additional resistance to heat transfer. It could be argued that the choice of fouling allowance (often referred to as fouling factor) is little more than an inspired guess. The best guide for fouling allowance is experience, but for reasons already mentioned, experience may not be directly applicable to the design in hand.

To facilitate the design of shell and tube heat exchangers, the Tubular Exchanger Manufacturers Association (TEMA) in the U.S.A. has issued recommended fouling allowances for a variety of heat exchangers. In a survey[1] of the design and operation of tubular heat exchangers in the petroleum refining industry, six of nine heat exchangers were over-designed; one under-designed; one of a reasonable design; and one over-designed at the start of operations and under-designed at the end. An alternative to recommended values of fouling resistance is to use the company experience obtained from previous operations or to review published data. Careful scrutiny,[1] however, revealed many shortcomings in the use of published data relating to petroleum refining.

Allowance for fouling in design results in an increase of heat-transfer area and over-performance of the heat exchanger during early stages of operation. To provide the required temperature of, say, the cold stream, it might be necessary to reduce the velocity in the hot stream, but this could have a serious detrimental effect on the fouling of the heat-transfer surface on the hot side. It might be prudent, therefore, to recommend a ''pump around'' system so that velocity is maintained at the design level, but temperatures are controlled by suitable valve adjustment.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120016837

During commissioning of the process plant, it is important to avoid subjecting the heat exchanger to conditions different from those taken into account during the design; high temperature and low velocity are to be avoided as this may create deposits that are difficult to remove.

Once the plant is accepted and fully operational, it becomes important to operate heat exchangers according to the conditions laid down in the design. Again attention to the temperature of operation and the fluid velocities is necessary to avoid accelerated fouling. Excursions of temperature particularly, even over short periods of time, may give rise to serious problems of deposits that are difficult to remove, affect performance, and are costly to remedy. Low velocity also may give rise to similar problems.

Slack management of operations and poor maintenance may give rise to accelerated and unexpected fouling. For instance, leaks across a heat exchanger, from one stream to the other, may introduce an unexpected and severe fouling problem, because of corrosion or chemical reactions. Again this can result in poor performance and may be expensive to rectify.

FOULING CONTROL

In general, the major problem in heat exchanger operation is the accumulation of deposits on surfaces. To avoid taking the exchanger out of service for cleaning, on-line fouling control is often employed. The choice of method will, of course, very much depend on the fouling problem encountered. There are two basic methods: control may be achieved by the use of chemical additives and by physical methods, or in some instances, with a combination of the two.

Every fouling problem is likely to be unique, so that it is impossible to cover all counter-fouling techniques as they apply to specific examples. The general approach, however, will indicate the technologies available and their potential application.

Chemical Additives

Chemical additives have been developed to tackle different fouling problems based on the mechanisms involved. In some instances, proprietary additives are designed to combat mixed fouling where two or more mechanisms are present. In the following, additives associated with individual mechanisms only are covered.

Particle deposition

The discussion will be centered on cooling water that may contain particulate matter, but the technology may be applied to other liquid systems.

The particles in the fluid passing through a heat exchanger are not always a problem, provided that settlement is avoided by imposing a velocity that ensures that they are kept in suspension. Avoidance of ''dead spots'' in the design is essential where particulate deposition is a possibility. Particle deposition often occurs in combination with other deposit-forming mechanisms, such as biofouling or scale formation. Particulate fouling is likely in cooling water circuits, the particles being introduced with the raw water or scrubbed from the atmosphere in a cooling tower. In aqueous systems, it is possible to use a flocculating agent and settle out the agglomerates formed. However, in a large ''once through'' system such as that in some power stations, this may not be feasible.

An alternative to coagulation and flocculation is to disperse fine particles by adding a dispersion agent; the particles remain in suspension and pass through the heat exchanger without deposition. The additive imparts similar charges to particles and surfaces so that settlement is prevented or reduced. Agents that are used for the purpose include surfactants and low molecular weight polymers. Dispersants may be used for other fouling problems such as biofouling in cooling water systems where the microorganisms are held away from the heat exchanger surface. Fouling from the corrosion of the heat-transfer surface may be restricted in this way, by preventing the laying down of deposits under which corrosion is promoted. Modification of the system pH may also reduce or eliminate particle deposition, but a change in pH may not be acceptable for the following reasons:

1. The process chemistry may not be compatible with the required pH change.
2. An aggressive environment may be created that replaces particle deposition with corrosion fouling.
3. There may be health and safety problems with handling large volumes of acid or alkali.
4. Additional costs may result if the pH of used cooling water must be neutralized before disposal.

Scale formation

The conventional chemicals used for the prevention or limitation of scale formation (the deposition of inverse solubility salts) include threshold agents, crystal modifiers, dispersants, and surfactants.

Threshold agents, in relatively small amounts, have the ability to inhibit or retard the precipitation of alkaline salts and scaling compounds. Even if the precipitation is not prevented, the action of the chemical additives often produces a ''softer'' sludge-like precipitate, which is more easily removed from the heat-transfer surface. Polyphosphate chain polymers such as hexametaphosphate have been used to control $CaCO_3$

scale formation in cooling water by threshold treatment. Inorganic polyphosphates are generally used for potable water applications, and organophosphates are used with cooling water. Sodium salts of ethylenediaminetetracetic acid (EDTA) and nitrilotriacetic acid (NTA) have been found to be effective for the control of scale formation in modern steam-raising equipment, where the temperatures of the superheater wall tend to be high. The action of the additive is to form chemical complexes with the calcium and magnesium salts. The higher cost of the EDTA compared with the cheaper phosphates usually limits the use of these chelating agents to waters with low hardness.[2]

To prevent or reduce the risk of robust crystalline structures forming on heat-transfer surfaces, it is helpful to employ a crystal modifier. The action of these chemical compounds is to interfere with the crystal structure, so that the scale is more susceptible to the removal forces created by the liquid flow across the deposit. Crystal modifiers including polymaleic acid are widely used in cooling water circuits.

Dispersants have been used successfully to reduce the potential for scaling of heat-transfer surfaces. The action is to impart a charge to crystallites to hold them apart, thereby preventing crystal growth. Organophosphorous compounds and polyelectrolytes are included in this group of chemicals. Surface-active agents may also be used to emulsify potential scale-forming contaminants to keep them in suspension or alternatively to establish a charge on the heat exchanger surface to repel depositing species.

Corrosion control

Control of fouling because of corrosion is possible by the employment of additives. For corrosion to occur, all the elements of the electrochemical circuit must be complete, so that an imposed electrical barrier in the circuit prevents the movement of ions and electrons, which is fundamental to the fouling mechanism. A thin layer of metal oxide can act as such a barrier, provided that the layer is continuous. The protective layer is itself a product of limited corrosion, its presence inhibiting further attack.

As described in the discussion of heat exchanger fouling elsewhere in this encyclopedia, anodic and cathodic reactions occur. Chemicals may be added to prevent these reactions; they are termed anodic and cathodic inhibitors. Cathodic inhibitors form a barrier at the cathode reducing or eliminating H^+ or O_2 transport to the cathode. They include nitrites, silicates, tannins, and orthophosphates. Anodic inhibitors prevent or restrict electron transfer and include polyphosphates, polyphosphonates, and molybdates. Some of these chemicals represent nutrients for aquatic life and may encourage the growth of microorganisms. Blends of anodic and cathodic inhibitors may be employed to maximize the effectiveness of the treatment.

Amines and other long-chain compounds may be added as alternatives to anodic and cathodic protection to form a protective film on metal surfaces. The group is generally known as ''filming amines.'' The long-chain molecules have ends that are hydrophilic and hydrophobic. Through the attachment of the hydrophilic group to the metal surface, the hydrophobic end repels water. The principle is that, through this arrangement, the surface becomes nonwettable and creates a barrier against the attack by water containing CO_2, NH_3, or O_2. The film-forming compounds are generally surfactants, so that when applied they tend to clean the surfaces with which they are in contact. The resulting particles, however, may represent a fouling potential downstream in the process plant. In addition, there is a tendency for the filming amines to react with the hardness salts and iron ions to produce a sludge that by itself represents a potential fouling problem. Before treatment, an estimate of the surface area to be protected is helpful to limit the extent of these unwanted chemical reactions.

Another method of introducing an electrical barrier is what is known as ''controlled scaling.'' It involves allowing limited scale deposits to form on the metal surfaces. A major drawback to the application of this technique is the lack of knowledge of the scaling potential in different parts of the system that allows adequate protection to be given, without excessive deposition. With inadequate information, the result could be scaling in one place and corrosion in another! An alternative is to raise the pH of the water by the use of neutralizing amines. These agents react with the H^+ ions released by the reaction of dissolved CO_2 with the water.

In steam condensers, such as may be found on power stations, the reduced pressure may induce air ingress into the condenser. The oxygen present in the air may represent a corrosion agent. Filming amines may be necessary to control corrosion under these circumstances. Alternatively hydrazine or another volatile oxygen scavenger may be used for oxygen and pH control.

The brief survey of chemical additives for the control of corrosion illustrates the many ways in which control can be achieved. The choice of method will depend on the effectiveness required, coupled with the costs involved.

Chemical reaction fouling

Fouling as a result of chemical reaction is generally associated, although not exclusively, with the processing of crude oil and petroleum fractions. The mechanisms involved include polymerization of components because of the presence of metal ions, and oxygen and coking (break-down reactions) reactions. Chemical

additives have been developed to deal with these problems:

1. Antioxidants scavenge free radicals which may be formed in the process stream and hence reduce the possibility of chain reactions. Suitable additives include phenols and organic compounds containing phosphorus and sulfur.[3]
2. Metal deactivators prevent the initiation of reactions catalyzed by transition metal ions, e.g. Ca^{2+}, Fe^{2+}, Zn^{2+}, and Mn^{2+}. Unless the activity of the metal ions is curtailed, they can give rise to free radicals for oxidation chain reactions to occur.
3. Dispersants and detergents may be added to impart an electric charge to particulate matter that may be the result of chemical reactions, so that the particles are prevented from agglomeration and deposition. The solubilizing property of detergents is the most important factor in reducing deposit formation. A wide range of complex organic chemicals are available that meet this requirement.

In a program to combat fouling from chemical reactions, it is usual to employ a blend of chemicals to offer wide-ranging protection. Many of the additives available are proprietary and it will be necessary to seek the advice of the suppliers before applying to the process stream.

Biofouling

The problem of biofouling, which involves microorganisms often occurs in cooling water systems. An effective way to control the deposition and growth of biofilms on heat exchangers is the use of chemical additives that act either as a biostat that limits the activity of the organisms or as a biocide that kills the organisms. The actions of these two additives are different. A biostat is considered to interfere with the metabolic processes within the organism, whereas a biocide, the use of which is more common, causes some irreversible damage to a vital cell component or function. Chemical dispersants may be employed to reduce the possibility of attachment to the heat exchanger surfaces. The discussion will concentrate on the application of biocides.

The use of chemicals for the control of biological growth has strong environmental connections, as the water is often taken from, and returned to, natural sources such as a river, lake, or sea. Unless proper steps are taken, the discharged water, containing the additive chemicals, could become an environmental hazard and a threat to the local ecology.

The final selection of biocide will require attention to the following points:

1. The water quality, which is likely to change with the season.
2. The concept of the system, whether recirculating or ''once through.''
3. Potential leaks from the process stream on the other side of the exchanger, which may provide nutrients for organisms, act as a biocide or react with the other added chemicals.

The activity of the biocide will very much depend on temperature and pH. Water velocity will affect the mass transfer of biocide to the biofilm and the shear forces acting to remove the biofilm.

Chlorine has been the preferred biocide for many years on account of its availability and relatively low cost. It has the drawback that it is stable and the products of its reaction with organic material are considered to be carcinogenic. It is possible to remove the chlorine from the water before discharge, and in some countries this is a legal obligation. Dechlorination techniques include air stripping, adsorption onto activated carbon, and the use of reducing chemicals. All these techniques impose a cost burden that might prove prohibitive. To meet the concern and accompanying legislation that is being imposed on the use of biocides, so-called ''environmentally biocides'' are being developed. In general, the cost of these biocides is relatively high, reflecting the manufacturing costs involved. There are, however, some biocides that are naturally environmentally friendly, such as hydrogen peroxide, which readily decomposes into water and oxygen. Ozone reverts to oxygen during use.

In view of the costs involved, it is necessary to develop biocide-dosing regimes that maximize biocide effectiveness for minimum cost.[4]

Freezing fouling

The usual method of controlling freezing fouling is by temperature adjustment, so that the heat-transfer surface is above the freezing point of the liquid in contact with it. Crystal modification is an alternative possibility for controlling freezing fouling, e.g., wax crystallization from waxy crude oils, but the high cost and possible contamination effects tend to preclude this technology.

Gas-side fouling

The use of chemicals to control fouling in gas systems, essentially flue gas, is less common and less researched than chemical control of fouling in liquid systems. The major difficulty with this fouling is that all the fouling mechanisms are likely to be present except biological growth, giving rise to a complex situation. Furthermore, the fuel quality is variable, depending on the origin of the fuel, and may even vary between individual

batches from the same source. Because of these difficulties, it is virtually impossible to estimate the required dose or to carry out laboratory tests to provide data. Effective control is achieved through plant trials that may cause severe operational problems in their own right, quite apart from the fouling problem in itself. The additives were originally developed to combat fouling from fuel oils, but the technology has been transferred to other systems such as coal and domestic refuse incineration. In general, the purpose of the additive is to modify the deposit so that it becomes easier to remove, either on-line or more likely on shut-down for cleaning. Relatively cheap additives are necessary, because of the large quantities required. The additive can be a solid as a powder or a liquid as a suspension. Effective mixing with the fuel can present problems, hence the additive is usually applied separately. Additives that are used include magnesium oxide (or hydroxide), limestone, silica, vermiculite, borax, aluminum oxide (or hydroxide), manganese compounds, and rare earth compounds. A large measure of success has been obtained by the use of copper oxychloride. It is usually applied as a suspension in oil, and small quantities can be effective.

The employment of additives for fouling control in combustion systems has a potentially excellent future, but a great deal more research work is required to put the technology on a sound footing.

Physical Methods of Control

Whereas the use of chemicals for fouling control is specific to a particular fouling mechanism, physical methods of control have a more general application. The simplest use of physical control is to increase the fluid velocity across the deposit to increase the shear forces acting on the deposit. The technique is only really feasible where the deposit is loosely bound, such as might be the case with magnetite in boiler water. It also has to be remembered that this technique would increase the pumping energy requirements and hence the operating cost.

A well-established technology that has been particularly successful in controlling fouling in the cooling water side of power station condensers is to circulate sponge rubber balls; the Taprogge system. The condensers contain a large number of tubes with the same internal diameter, which makes them ideal for the circulation of the balls. The balls are slightly larger than the internal diameter of the tubes and are therefore ''squeezed'' as they are forced through the tubes with the water flow. The wiping action of the balls pressed against the internal tube wall removes any deposit as it is formed. Problems that might accompany the application of the technique include potential erosion of the tube surface and the possibility that balls might become stuck at the tube entrance or inside the tube, causing water distribution problems and, if extensive, severe loss of efficiency.

The ''brush and cage'' system is similar in concept to the circulation of sponge rubber balls. It involves the use of a ''brush'' that fits the inside of each tube of a shell and tube heat exchanger. The brush is made of wires or polymer filaments and is made to oscillate between the ends of the tube by flow reversal. A cage is fitted at either end of the tube to ''catch'' the brush as it reaches the end of the tube. The cage and brush would offer a resistance to flow and hence increase the pressure drop through the exchanger. The movement of the brush against the surface of the tube tends to remove any deposit residing on the tube surface since the last sweep. The frequency of flow reversals will depend on the severity of the fouling problem. A major difficulty with this technology is the interruption in flow because of the reversal process, which may affect the stability of the process of which the heat exchanger is a part. The high cost of the brush and cage system may also be a drawback.

An alternative physical method for fouling control uses inserts within the tubes of a shell and tube exchanger. An example is the ''Spirelf'' system that consists of a spiral flexible metal device that is inserted and fixed into the tubes.[5] The action of the device is to vibrate in response to the flow of fluid through the tube in which it is situated, thereby keeping the tube surface clean. The vibration is controlled to avoid erosion of the tube surface. It is claimed[5] that the payback time is low; of the order of months.

An alternative insert for tubes is the spiral insert produced by Cal Gavin. The device consists of a matrix of wire loops on a twisted wire core. The diameter of the coils is such that it is a ''push fit.'' Laboratory studies using these wire matrix inserts with an Arabian crude oil demonstrate that the steady asymptotic value of the fouling resistance is reached in only 10 hr from start up and only of the order of 2–7% of the recommended TEMA value. The presence of the wires, particularly those in contact with the heat-transfer surface, creates turbulence that is largely responsible for the beneficial effects on the fouling.[6] The benefits are not without the potential penalty of increased pressure drop and hence increased pumping costs. By suitable design for the same duty, this penalty can be substantially reduced.

The potential for fouling on the shell side of shell and tube heat exchangers is well known. The problem arises largely because the fluid in the shell does not flow uniformly across the tubes. As a result, it is possible that deposits will form where the velocity is low. By the use of helical baffles, it is possible to redirect the fluid flow so that dead spaces are eliminated.[7]

The use of ultraviolet light

Ultraviolet light kills microorganisms and is, therefore, a candidate for the control of biofouling in cooling water and other water systems that may become contaminated. The technology involves exposing the organisms carried in the water stream to a beam of ultraviolet light, with the aim of killing them before they enter the heat exchanger. It will require a transparent section through which the light passes. The principal problem with the technique, apart from keeping the transparent section clean, is that although the majority of the microorganisms will be killed, some survivors can reach the heat-transfer surfaces and develop a fouling biofilm.

Magnetic devices

A recent publication[8] has several papers that expound the value of magnetic fields on the problem of fouling of heat-transfer surfaces. In general, these discussions cover applications in buildings, for hot water systems and tanks and the like. A successful application was recently reported[9] for control of precipitation of $CaCO_3$ in the hot water system in apartments by formation of soft aragonite, rather than hard scale of calcite. There appears to be little published about applications in the process industries. The considerable skepticism that surrounds the technology has probably directed engineers and technologists away from the use of magnetic fields. If a reliable theory concerning the operation of the technology is developed, it would certainly find a place in the armory of those whose work is to maintain the efficiency of heat exchangers.

The control of corrosion

There are two ways that are employed to control corrosion fouling: the so-called sacrificial anode and impressed current techniques. In the former technology, a sacrificial anode can be any metal that is anodic to the metal to be protected. When an electrical circuit is established, a galvanic cell is set up between the metal to be protected, and the sacrificial anode corrodes, providing a circuit to allow electrons to flow. The electrons could be provided by some direct current supply such as storage batteries, rectifiers, or DC generators, through an auxiliary anode. The electrochemical reactions at the cathode will be complementary to those at the sacrificial anode. The choice of anodic metal and the technology employed depends on a number of factors, but in most applications the major consideration is cost, related to which is the life of the anodic material. In the sacrificial anode technology, the presence of dissolved products from the corrosion of the anode may be unacceptable. Nonconsumable electrodes include such alloys as silicon–iron and platinum–titanium, and they are expensive. It is possible by the use of imposed currents to ''over-protect'' the system, but it may give rise to alternative problems comparable to corrosion.

An alternative is to employ anodic protection that relies on the formation and maintenance of protective films on metal surfaces by means of externally applied anodic currents.

Surface modification

It is possible to reduce corrosion by coating surfaces of heat exchangers. Furthermore, changes in the surface characteristics have the potential to reduce the incidence of fouling in general. In addition, the surfaces are generally smoother and therefore energy losses because of friction are lowered and the associated pumping costs are reduced. In general also coated surfaces facilitate off-line cleaning. Coating materials include vitreous enamels, plastics and polymers, and special paints. Recent technologies of surface modification, which have proved experimentally attractive, involve ion implantation.[10]

The major concern in respect of surface modification is the integrity and resistance to erosion. It could be a serious problem if cracks or local ''peeling'' occur that might facilitate localized corrosion or the buildup of deposits. It has to be remembered also that the presence of a film or coating on the heat exchanger surfaces could be regarded as a fouling layer that by itself imposes a resistance to heat transmission.

Nonmetallic heat exchangers and special designs

It may be feasible to fabricate a heat exchanger from a material that is not a metal or alloy, provided of course that it can withstand the temperatures and pressures of operation, and that it is durable. Flexible plastic tubes in a shell and tube exchanger allow the tubes to oscillate in response to the fluid turbulence in the shell, which helps to eliminate the problem of fouling inside the tubes. A limitation is that, in general, these alternative materials of construction have low thermal conductivities, so that a larger resistance to heat transfer is imposed compared with the traditional metal heat exchanger. Because carbon has inherent corrosion resistance, for potentially severe corrosion conditions it might be worthwhile to consider specially designed heat exchangers fabricated from graphitic carbon. It must be recognized however that these exchangers are less robust than those made conventionally from metal.

A special design of heat exchanger, which was originally introduced to handle viscous liquids, is the scraped surface heat exchanger. In the design, rotating

blades remove the viscous sublayer from the heat-transfer surface, and at the same time keep the surface clean.

Some physical methods of fouling control that are still in the development stage are the use of ultrasound and the circulation of polymer fibers.[11] The latter shows excellent promise for fouling control in cooling water.

The use of physical methods of control in cooling water systems has a major drawback in that it does not control the presence of *Legionella* that is demanded by legislation in many countries. It is necessary when using physical methods of fouling control to treat the water to kill bacteria before the water reaches the cooling tower or spray pond, where droplets of water are released into the atmosphere.

Gas-side fouling in combustion

A number of physical methods are available for handling fouling in combustion systems. So-called ''soot blowers'' that consist of directing a jet of air or steam at the heat-transfer surfaces, where fouling is likely to occur, have been employed for many years. The force created by the jet on the deposit weakens it and ''knocks'' it off the surface. Because of the need for the jets to be close to the surface, and the extent of the heat-transfer surfaces usually involved, it is necessary to use a number of soot blowers in a particular system. To be effective, the device has to be able to rotate or move relative to the heat-transfer surfaces so that they are fully covered; movement may be manual or motorized automatic.

Sonic energy is also used to dislodge deposits from the surfaces in combustion systems. Good results can be obtained in connection with loose friable deposits, but the efficiency is reduced if the deposits are sticky and tenacious.

The manual operation of water jets for on-line cleaning has been used for the removal of fouling deposits for many years, although modern soot blowing equipment is often preferred. Similarly shot cleaning, which involves the release of metal shot so that as it falls under the influence of gravity, it impacts the heat-transfer surface and removes any accumulated deposits. The technique is not widespread on account of the potential damage that could occur.

OFF-LINE CLEANING

Some heat exchangers operate continuously without fouling problems, but the majority, despite efforts to control the incidence of fouling, will require off-line cleaning at some stage. Often this can be accomplished at the annual (or periodic) shut-down, when major maintenance work is put in hand. But more frequent cleaning may be required, depending on the severity of the fouling problem and the cost of mitigation. In some processes such as milk sterilization, off-line cleaning may be required as frequently as twice a day! Under such circumstances, it is desirable to devise optimal cleaning schedules. The technique becomes more complex for the heat exchanger networks that may be found in crude oil preheat trains on refineries. It involves reliable simulation of the network, representative fouling data, and a robust optimization routine.[12] An alternative is to duplicate the heat-transfer system, so that one set is down for cleaning while the other is operating. The capital outlay involved could be considerable, possibly prohibitive for complex heat exchanger systems, but for individual heat exchangers it might be a reasonable solution. Clearly, the choice of heat exchanger type will have a bearing on the management of the cleaning cycle. In some instances, however, milk pasteurization for instance and food processing in general, it has to be recognized that in addition to fouling there is a question of hygiene that has to be met.

It is not possible to discuss the various methods of heat exchanger cleaning in detail, but the following gives a broad overview:

1. Manual cleaning may be carried out in a wet or dry condition. It may involve wiping, brushing, or scraping. It is generally a labor-intensive process and as a consequence it could be costly.
2. Water washing may be acceptable for many forms of deposit, but pressure steam or air lances may be found to be more effective for tenacious deposits. Detergents may be added to facilitate cleaning and it may be necessary to use high velocity blast cleaning with abrasive particles for effective deposit removal in some instances.
3. For the inside of tubes in shell and tube heat exchangers, where accessibility into the tubes is limited, it may be necessary to use drilling or rodding techniques. Lubrication may be afforded by water passing through the special drill.
4. Bullets, scrapers, or scrubbers may be ''fired'' into the tubes of shell and tube heat exchangers, propelled by high-pressure water or air. The projectiles dislodge deposits as they travel at high speed down the length of the tube.
5. Explosives have been used to clean combustion spaces in boiler plant.
6. Steam ''soaking'' involves allowing intimate contact between steam and the surface to be cleaned. The technology depends on the penetration of the deposit by steam and hot condensate, in addition to the effects of the differences in thermal expansion of metal and deposit, which produces ''spalling'' of the deposit.
7. Osmotic shock may be used for the destruction of biofilms, using the properties of the

semi-permeable membrane that microorganisms employ to imbibe nutrients. It is possible to subject the microorganisms to internal pressures that kill the cells by immersing the biofilm in a concentrated salt solution. A long time scale may be required for the full effects to be obtained.

8. Chemical cleaning is a method that employs the ''fill and soak'' principle. The chemical agents include acids, bases, and organic solvents. Circulation of the chemicals through the exchanger may be required to assist the cleaning process by imposing shear forces on the deposit and to carry away the debris.

It has to be emphasized that health and safety regulations will apply to many of these cleaning techniques. Of equal importance is the compatibility of the material of construction of the heat exchanger to be cleaned with the method of cleaning, to avoid physical and corrosive damage.

More details of cleaning techniques are to be found in books by Bott[13] and Muller-Steinhagen.[8]

CONCLUSIONS

The basic design of a heat exchanger, its installation, and commissioning lay the foundation for acceptable operation. The maintenance of efficient and reliable performance is likely to have a profound influence on the overall operating cost and hence on the profitability of the associated process. Recognition of likely operating problems, particularly the possible incidence of deposit formation on the heat-transfer surfaces, is essential. For many heat exchangers, fouling will occur and steps will be required to counter or reduce the adverse effects on heat-transfer efficiency. Most fouling problems can be tackled by on-line methods, but off-line cleaning is likely to be required as part of the overall maintenance program. The frequency of cleaning should ideally be determined by a logical examination of fouling experience and operating conditions, so that costly unscheduled ''shut-downs'' for restoration of efficient operation are avoided.

Heat Transfer Fluids

Satish C. Mohapatra
Advanced Fluid Technologies, Inc., Dynalene Heat Transfer Fluids, Whitehall, Pennsylvania, U.S.A.

INTRODUCTION

Heat transfer fluid (HTF) is a very important component of many industrial systems. There are numerous processes in which thermal energy is transferred to or from an object through the physical contact with a heat transfer fluid, which is at a temperature either hotter or colder than the object. Some examples of such applications are in chemical manufacturing, breweries, industrial refrigeration/heating, ventilation, and air-conditioning (HVAC), environmental chambers, plastic manufacturing, supermarket refrigeration, pulp and paper industry, food and pharmaceuticals, oil and gas industry, ice rinks, and engine cooling.

Proper selection of an HTF is crucial to process engineers for a variety of reasons. Different properties of HTFs will impact the design, size, and, ultimately, the cost of the system. Following are some examples of how HTFs can influence a heat transfer process:

1. Lower viscosity and density of the fluid results in smaller pressure drop, therefore smaller pumps.
2. Higher heat transfer coefficient yields smaller heat exchanger, higher bulk temperature of the fluid, and lower flow rate.
3. Reactivity and instability of fluid can disrupt customer production by system fouling and corrosion.
4. Affinity for moisture can freeze system components in low-temperature applications.
5. Low surface tension of a fluid leads to leakage.

Because of the above considerations, selection of a low- or high-temperature HTF for a given application depends on a number of factors.[1] The choice of a particular fluid is invariably a compromise that best suits the specific application and economics. Following is a list of criteria that should be used while selecting a fluid:

1. Freezing point at least 10°C lower than the lowest operating temperature.
2. Low viscosity at low temperatures.
3. Good thermal properties (high specific heat and thermal conductivity).
4. Low flammability (high flash and fire points).
5. High boiling point (low vapor pressure at the highest operating temperature).
6. Noncorrosive toward the materials of construction.
7. Minimal environmental concerns (preferably nontoxic).
8. Good fluid service life (includes excellent thermal and oxidation stability).
9. Economical.

Based on the temperature range they use, the HTFs can be divided into four categories: 1) ultra-low-temperature fluids (lowest operating temperature of −50°C to −120°C or even lower); 2) low-temperature fluids (lowest operating temperature of 0°C to −50°C); 3) high-temperature fluids (highest operating temperature of 200–400°C); and 4) ultra-high-temperature fluids (highest operating temperature of >400°C).

ULTRA-LOW-TEMPERATURE FLUIDS

The current technologies to obtain lower than −50°C include direct use of a refrigerant or a liquefied gas and secondary cooling technology using various low-temperature fluids. In a secondary cooling process (Fig. 1), a primary refrigerant or a liquefied gas (liquid nitrogen or CO_2) is used for the cooling of the heat transfer fluid first, and then the cold heat transfer fluid is circulated through the customer process to enable uniform temperature distribution. This secondary cooling or refrigeration process uses a smaller amount of refrigerant to cool the HTF but may require additional capital expenditure because of the incorporation of another fluid loop. The general advantages associated with secondary cooling are:

1. Fewer refrigerant leaks because there is substantially less refrigerant piping (environmental benefit).
2. Significant reduction in the primary refrigerant charge.
3. Fewer service calls.
4. More stable and uniform process temperature.

Following are some fluid chemistries developed for ultra-low-temperature applications.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007798

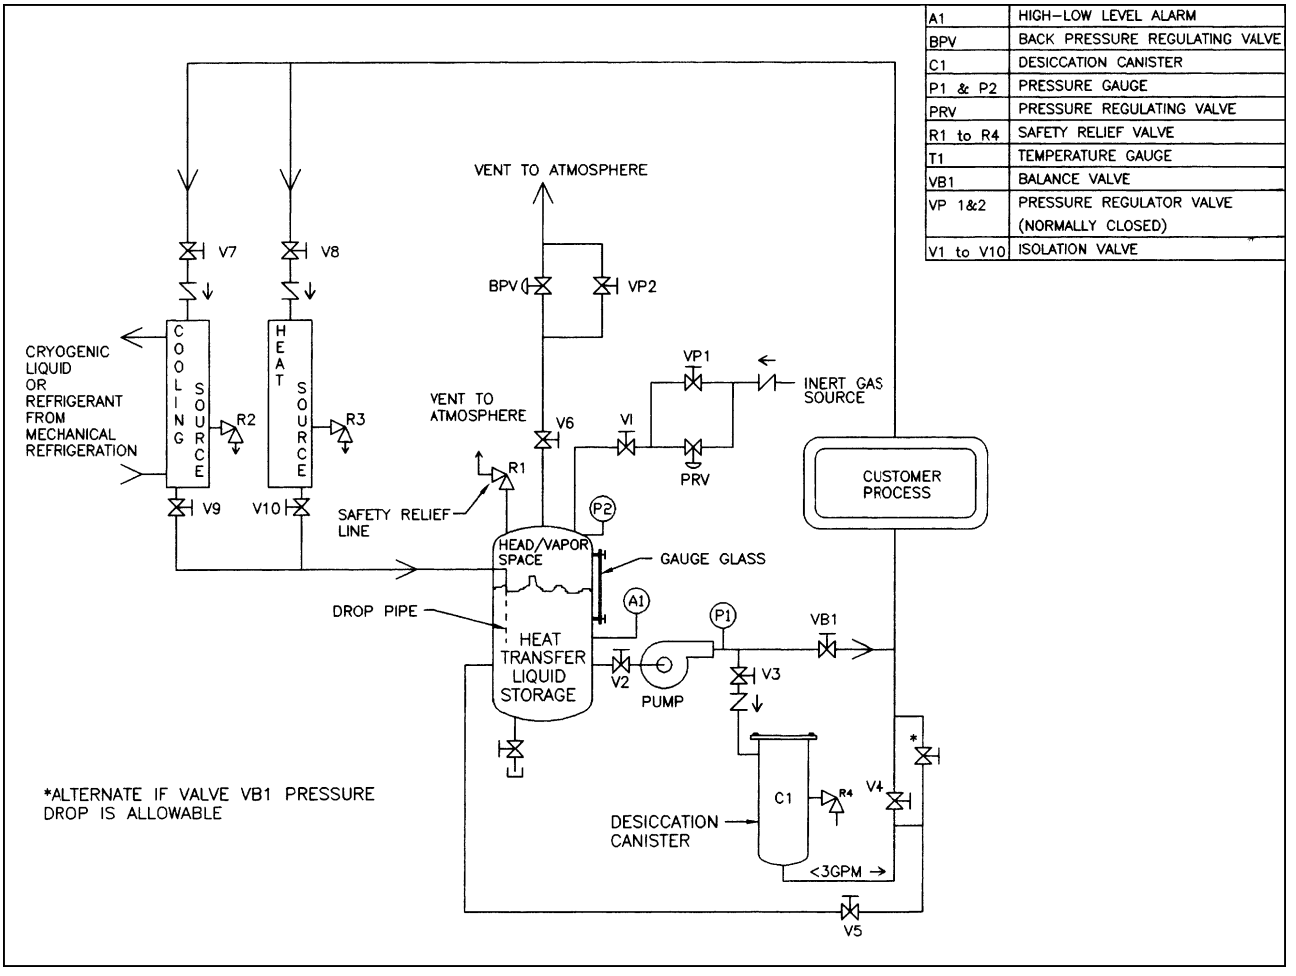

Fig. 1 Flow diagram of a typical secondary cooling/heating process.

Halocarbons

Certain halocarbons such as methylene chloride, trichloroethylene, (TCE) and fluorocarbons can be used as a secondary cooling medium at temperatures lower than −50°C. These fluids are nonflammable and noncorrosive under normal operating conditions. However, chlorinated compounds such as methylene chloride or TCE are very toxic and regulated by the Environmental Protection Agency (EPA).[2] So, these fluids will be removed from the existing systems in the next few years.

Fluorinated compounds such as hydrofluoroethers and perfluorocarbon ethers have certain unique properties that made these fluids compete in the low-temperature HTF market. First, these fluids are nonflammable and nontoxic. Some fluorinated compounds have zero ozone depleting potential and other environmental properties. Second, some of these fluids have a very low freezing point and low viscosity at low temperatures. However, these fluids are much more expensive compared to their counterparts. Also, because of the extremely low surface tension, leaks can develop around fittings causing an increase in the operating cost. Also, fluorocarbons with low freezing point posses a much lower boiling point than other HTFs. Therefore, these compounds are not suitable for applications where both low and high temperatures are desired. Typical applications of fluorocarbon-based fluids are in the pharmaceutical and semiconductor industries within a temperature range of −100°C to 150°C.

Hydrocarbons

Aromatics: Aromatic hydrocarbons such as diethyl benzene are common low-temperature HTFs in the temperature range of −70 to +260°C. The low-temperature heat transfer characteristics as well as the thermal stability of aromatic compounds are excellent. However, these alkylated benzene compounds cannot be classified as nontoxic. Also, these fluids have a strong odor, which can be irritating to the personnel handling it. Also, very few aromatic compounds have

a freezing point lower than −80°C. Hence, aromatic-based low-temperature HTFs are used above −70°C in closed, airtight systems and are typically found in chemical processing and industrial refrigeration.

Aliphatics: Aliphatic hydrocarbons of paraffinic and *iso*-paraffinic type are also used in some systems as low-temperature HTF. Many petroleum-based aliphatic compounds meet the Food and Drug Administration (FDA) and United States Department of Agriculture (USDA) criteria for ''incidental food contact.'' In addition, these petroleum-based fluids do not form hazardous degradation by-products. Most of these fluids have an nondiscernible odor and are nontoxic in case of contact with skin or ingestion. Even with all the above advantages, these fluids are not very common in low-temperature applications, the reason being the high viscosity at low temperatures, and the thermal stability of aliphatic compounds not being as good as that of aromatic compounds. Some of the *iso*-paraffinic based fluids (with 12–14 carbons) can be used from −60°C to 150°C. These fluids are preferred in food and pharmaceutical applications where toxicity is a major issue.

D-Limonene: Another class of low-temperature HTF is based on naturally derived terpenes such as D-limonene. U.S. Patent 3,597,355 describes D-limonene as being particularly preferred among all the monocycloterpenes because of its characteristic properties such as low viscosity at low temperatures.[3] D-Limonene is the major component in the oil of citrus fruit and is present in trace quantities in orange juice. It is recovered in commercial quantities by distilling orange oil obtained from citrus peels. Being derived from the citrus industry, D-limonene is considered a safe and environmentally friendly HTF, and hence it is preferred in many food and pharmaceutical processes. However, the melting point of D-limonene is about −78°C. Below this temperature, it becomes a thick white gel like substance that is impossible to pump. Therefore, the use of D-limonene is limited to only about −60°C. In addition, at temperatures above 50°C, D-limonene oxidizes rapidly in the presence of air. This oxidation triggers the acidification and polymerization of the molecules. Because of this effect, D-limonene is not recommended for use above 50°C.

Terpene Mixtures: Recently, U.S. Patent 5,847,246 has described the use of eutectic mixtures of monocycloterpenes for low-temperature applications.[4] These new environment friendly HTFs have a melting point lower than −110°C and thermophysical properties comparable to many other HTFs. Because the ingredients of these new HTFs are biobased and obtained from renewable sources, these fluids conserve energy for production as compared with the other synthetic HTFs. With the addition of proper antioxidants and using an inert gas such as N_2, these fluids can be used from −100°C to +150°C in a variety of applications.

Silicones

Another class of popular low-temperature HTF is dimethyl polysiloxane, commonly known as silicone oil. Because this is a synthetic polymeric compound, the molecular weight as well as the thermophysical properties can be adjusted by varying the chain length. Silicone fluids can be used at temperatures as low as −100°C and as high as +260°C. These fluids have excellent service life in closed systems in the absence of oxygen. Also, with essentially no odor and very low toxicity, silicone fluids are known to be workplace friendly. However, with low surface tension these fluids have the tendency to leak around pipe fittings, although this low surface tension improves the wetting property. Silicones are usually priced higher than the aromatic- and aliphatic-based HTFs. Because silicone fluids are virtually nontoxic, major applications are seen in the pharmaceutical industry.

More information on ultra-low-temperature HTFs can be obtained from the manufacturers.[5–10] Table 1

Table 1 Comparison of thermophysical properties of various low-temperature HTFs

	TCE	Aromatic	Aliphatic	Silicone	Terpene mixture
Freeze point (°C)	−86	<−84	<−101	<−110	<−110
Flash point (°C)	None	58	59−60	47	55
Viscosity (mPa sec)	1.4	3.9	15.0	6.9	4.3
Density (kg/m^3)	1560	920	815	927	885
Specific heat ($kJ/kg \cdot K$)	0.885	1.636	1.880	1.625	1.620
Thermal conductivity ($W/m \cdot K$)	0.140	0.143	0.115	0.125	0.144
RHTEF	1.0	0.54	0.23	0.37	0.51
Environmental and toxicity concerns	Yes	Yes	No	No	No

Viscosity, density, specific heat, and theermal conductivity of different fluids were obtained at –50°C. The RHTEF values are calculated with respect to TCE.

lists some of the properties and relative heat transfer efficiency factors (RHTEFs) with respect to TCE of commonly used low-temperature HTFs. Relative heat transfer efficiency factors was calculated based on Refs.[1,11], which shows the overall efficiency of an HTF. It is apparent that at −50°C, TCE has the highest RHTEF (equal to 1.0 because it is compared to itself) followed by aromatics and terpenes. However, it has already been discussed before that TCE is not more favorable because of environmental concerns. Therefore, aromatics, terpenes, silicones, and, in some cases, aliphatics and fluorocarbons are preferred as ultra-low-temperature HTFs.

LOW-TEMPERATURE FLUIDS

Low-temperature HTFs are routinely used in various process cooling applications. Examples of these HTFs can be found in the literature.[1,12] Some of these fluids are aqueous (or water based) and some are nonaqueous. In this category, the lowest operating temperature of the fluids is in the range of 0 to −50°C. Different chemistries that are utilized in this temperature range include mainly water-based fluids.

Water is the best HTF in the temperature range of 0–100°C because it has a high thermal conductivity, a high specific heat, and a low viscosity, which are all essential to provide excellent heat transport and transfer. In addition, water is the most inexpensive HTF, is abundant, nonflammable, and nontoxic. The problem arises only when temperatures lower than 0°C or higher than 100°C are encountered. For more than 100°C, the system needs to be pressurized to keep water in liquid form or superheated steam can be utilized. For temperatures lower than 0°C, a freeze point suppressant such as a water-soluble organic compound or a salt is added to water to lower the freezing point to the desired level. Examples of such freeze point suppressants are glycols such as ethylene and propylene glycol; alcohols such as methanol, ethanol, and isopropanol; brines such as chlorides, formates, and acetates of lithium, sodium, potassium, and cesium.

When a freeze point suppressant is added to water, it loses its heat transfer characteristics to some extent, which depends on the concentration of the suppressant. However, water-based fluids still exhibit a very high heat transfer coefficient compared to nonaqueous fluids. Nonaqueous fluids such as aromatics, aliphatics, and silicones are used in such applications when an aqueous fluid exhibits very high viscosity (>50 cP) at the lowest operating temperature or its freezing point is very close to the refrigerant temperature in the evaporator.

Some examples of low-temperature water-based fluids are discussed below.

Aqueous Solution of Organic Compounds

Ethylene Glycol: Commonly used as an antifreeze, ethylene glycol also has found use in refrigeration service. Common applications include process cooling at lower temperatures. Ethylene glycol is colorless and practically odorless and is completely miscible with water. When properly inhibited, it has a relatively low corrosivity, which is a major advantage when compared to salt-based brines. Ethylene glycol solutions can be used as a refrigeration system brine as low as −40°C. However, because of the high viscosity at low temperatures, this is used effectively at −10°C or above. Ethylene glycol is also toxic, hence it is not suitable for open baths or in the food and pharmaceutical industries.

The quality of water used to prepare a glycol solution is very important for the system. Typically, water with low chloride and sulfate ion concentration (<25 ppm) is recommended. Also, a monitoring schedule should be maintained to ensure that inhibitor depletion is avoided and pH of the solution is consistent. Once the inhibitor has been depleted, it is recommended that the old glycol be removed from the system and a new charge be installed.

Propylene Glycol: In its inhibited form, propylene glycol has the same advantages of low corrosivity shown by ethylene glycol. In addition, propylene glycol is considered nontoxic, hence it can be used in food applications. Other than lack of toxicity, it has no advantages over ethylene glycol, being higher in cost and more viscous. Because of the high viscosity at low temperatures (Fig. 2), it is used at −10°C or above.

Methanol/Water: This is a low-cost antifreeze solution, finding use in refrigeration services and ground source heat pumps. Similar to glycols, this can be inhibited to stop corrosion. This fluid can be used down to −40°C owing to its relatively high rate of heat transfer in this temperature range. Its main disadvantages as an HTF are its toxicological considerations. It is considered more harmful than ethylene glycol and consequently has found use only for process applications that are located outdoors. Also, methanol is a flammable liquid and, as such, introduces a potential fire hazard where it is stored, handled, or used.

Ethanol/Water: This is an aqueous solution of denatured grain alcohol. Its main advantage is that it is nontoxic. Therefore, it has found application in breweries, wineries, chemical plants, food freezing plants, and ground source heat pumps. As a flammable liquid, it requires certain precautions for handling and storage.

Salt Brines

Sodium Chloride: Water solutions of this salt are used for refrigeration services and other low-temperature

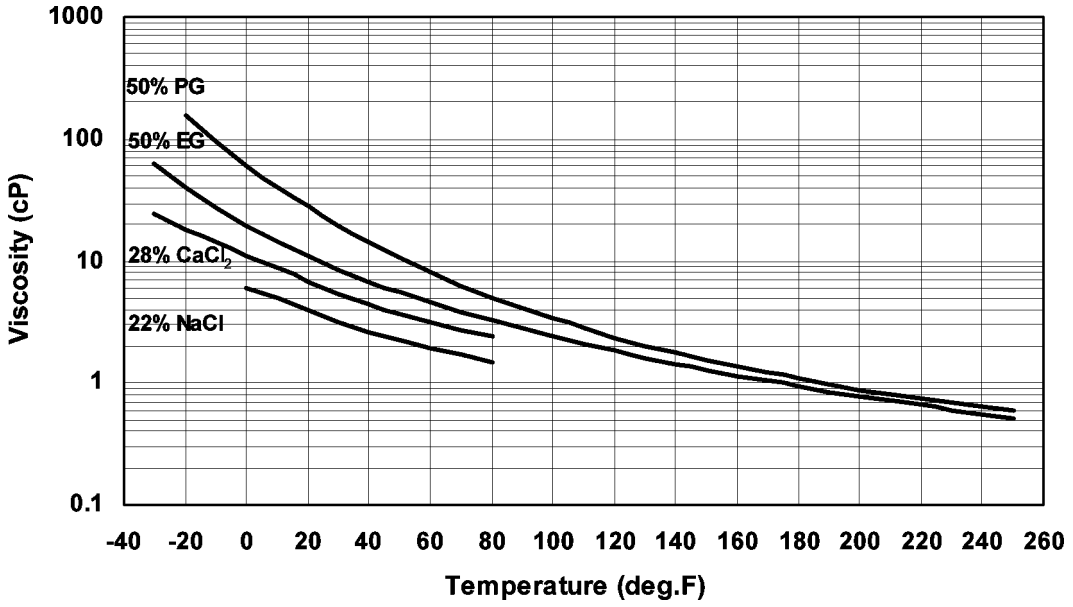

Fig. 2 Viscosity of various water-based low-temperature fluids.

applications. It can be used in applications involving contact with food and in open systems because of its low toxicity and nonflammable characteristics. A high heat transfer coefficient can be obtained with this fluid because of its good thermophysical properties. However, it has two main drawbacks: 1) it has a relatively high freezing point, which limits its application to about $-10^{\circ}C$ and 2) it is highly corrosive, requiring inhibitors that must be checked on a regular basis and replenished to prevent an acid condition from occurring in the system.

Calcium Chloride: Aqueous solutions of calcium chloride find wide use as a circulating brine. Similar to sodium chloride solution, it is nonflammable and nontoxic. It has a lower freezing point than sodium chloride solution and can be used down to $-37^{\circ}C$. The main disadvantages are that 1) it is highly corrosive; 2) it has a reduced heat transfer coefficient below $-20^{\circ}C$; and 3) it cannot be used in direct contact with foods.

Viscosity of calcium chloride and sodium chloride solutions is compared with ethylene and propylene glycol solutions in Fig. 2. It is apparent that there is a major difference in the viscosity of these fluids at low temperatures, which is very important for equipment design.

Dealing with Low-Temperature HTFs

As discussed before, low-temperature HTFs are used in several applications such as reactor cooling, industrial and supermarket refrigeration, lyophilization, and environmental chambers. Both aqueous and nonaqueous HTFs have been developed for these applications. Engineers routinely deal with various issues and challenges while designing, retrofitting, and using these fluids. Such issues are 1) flammability; 2) environmental concerns; 3) corrosion (material compatibility); 4) fluid contamination; 5) bioactivity, etc.

Flammability

A big advantage of water-based fluids over hydrocarbon or silicone fluids is that most of these are either nonflammable or have a relatively high flash point. Salt-based brines are nonflammable. Glycols are nonflammable only when there is at least 20% (v/v) water in the mixture. As discussed before, alcohol-based fluids are normally flammable, irrespective of the water concentration.

Environmental concerns

An important characteristic of a good HTF is that it should be nontoxic and environment friendly. The ideal candidate is the one that can be classified as food grade and also satisfy the USFDA and USDA criteria for ''incidental food contact.'' Additionally, its vapor should neither contribute to the greenhouse effect nor to the depletion of the ozone layer.

Ethylene glycol and methanol are toxic whereas propylene glycol and sodium chloride solutions can be used in direct contact with food. Other brines and alcohol-based fluids are nontoxic and can be used safely in the food and pharmaceutical industries. While many salt-based brines are safe to dispose off into the drains after sufficient dilution, local sewer authorities should be contacted to verify the local laws.

Corrosion (material compatibility)

Aqueous fluids are normally formulated with corrosion inhibitors. Because these fluids are ionic, improper selection of corrosion inhibitors can lead to severe corrosion. Glycols and brines are normally not recommended with galvanized steel and soft solder. Aluminum systems are not recommended above a certain temperature. Sodium and calcium chloride brines are very corrosive toward most of the metals even with the inhibitors.

Most plastics, rubbers, and elastomers are compatible with water-based fluids. However, they should be checked with the fluid manufacturer as well as the plastic/rubber/elastomer manufacturer to ensure compatibility.

Fluid contamination

Water-based fluids can be contaminated in various ways. In new systems, debris from welding, pipe joints, and other residues previously left over from the installers may be present. If not cleaned properly they can contaminate the water-based fluids. Fluxes used for soldering may contain chloride salts that are highly corrosive to metals including stainless steel.

Another way fluid contamination can occur is during fluid retrofit. If the original fluid is not completely removed from the system, it will contaminate the new fluid causing certain problems. In many cases a fluid can be contaminated by mistake. An operator may unintentionally add a wrong fluid into the tank to top off the original fluid. This can be a serious problem if the two fluids are incompatible. How to clean a system is discussed in the following section.

Bioactivity

Microbial activity is a major concern in systems in which water-based fluids are used. Particularly, glycol fluids provide a good source of nutrition to some types of biological species. In salt-based brines, however, microbes do not survive because of high osmotic pressure. When microbes start to grow inside a system, they create a layer known as ''biofilm'' on the walls of the pipes and heat exchangers. This reduces the heat transfer rate. Some microbes are capable of creating acids and hence cause a substantial amount of corrosion in the system.

The problem of bioactivity can be reduced or eliminated by the use of biocides. There are different types of biocides and one must be aware of the toxicity level of these to decide the most suitable biocide for that application. Already affected systems can be treated with biocides but it is very difficult to release the biofilm once it is formed. In that case a biocide treatment followed by a complete cleaning of the system with an acid (hydrochloric acid), alkali (trisodium phosphate), and deionized water is recommended.

HIGH-TEMPERATURE FLUIDS

At temperatures above 100°C, the saturation pressure of water may require the use of expensive equipment to contain the HTF. Glycol/water mixtures oxidize and degrade rapidly above 150°C. Therefore, an HTF other than water and glycol/water is normally utilized at temperatures higher than these. The HTFs used in these applications are normally referred to as high-temperature fluids. Table 2 provides a list of popular HTFs used in a variety of applications. This table also shows the manufacturers of these fluids along with some properties. It is seen that some fluids can be used at high as well as low temperatures because of their wide temperature range.

The most important property for a high-temperature HTF is its thermal stability at exceptionally high temperatures. These HTFs are normally used above their flash and fire points in closed and airtight systems. In many applications, an inert gas such as nitrogen is utilized in the head space of the holding/expansion tank.

There are two mechanisms by which the high-temperature fluids degrade, i.e., 1) thermal degradation and 2) oxidative degradation.

Thermal Degradation

A heating fluid reaches its highest temperature at the surface of the heating equipment such as electric heater, fired furnace, or vaporizer. At this surface, a stagnant film known as boundary layer develops creating an additional resistance for heat transfer. Temperature in this film region can be much higher compared to the bulk fluid temperature. This results in severe degradation of the fluid near the heat source. Fluid can also degrade outside the film depending on the bulk temperature.

There are two types of thermal degradation observed in high-temperature systems. In one type, the fluid molecules break down into low molecular weight products. Compounds with a large number of single bonds (i.e., aliphatics) are more susceptible to this type of degradation compared to compounds with double bonds (aromatics). A compound with both single and double bonds (alkylated aromatics) has better thermal stability than a pure aliphatic compound and worse than a pure aromatic compound.

The other important property of a high-temperature HTF is its boiling point. Because most of the HTFs are

Table 2 A list of widely used HTFs with some properties

Brand name	Manufacturer	Temperature range (°C)	Boiling point (°C)	Flash point (°C)	Autoignition temp (°C)	Freezing point (°C)

blends, the most volatile component boils first followed by the next and so on. So the boiling point of a blend is tricky and in many cases referred to as the initial boiling point, i.e., the temperature at which the first component boils. However, this does not give a true picture of the boiling point of the entire blend. So the HTF manufacturers provide a boiling point range (starting from when 10% of the fluid boiled to end at 90% of the fluid boiled).

High-Temperature Fluids

Normally, organic fluids (hydrocarbons and silicones) are used to attain a temperature between 200°C and 400°C. A great degree of information can be obtained from the fluid manufacturers as well as other published literature. Different chemistries that are utilized for these applications are discussed below.[5–10,13–20]

Petroleum Oils

Also known as mineral oils and hot oils, these petroleum-derived fluids are mostly aliphatic in nature. They are inexpensive, mostly nontoxic, and noncorrosive. Higher molecular weight oils have a high flash point but also have high viscosity. At higher temperatures, their decomposition rate is much more severe than that of the synthetic fluids. Exposure to air at high temperatures results in oxidation of the molecules. Subsequently, the oxidized fluid can react with moisture to form acids that can lead to corrosion of system components. The maximum operating temperature for petroleum oils is about 315°C. These fluids are used in applications where a nontoxic, less odor, economical fluid is desired.

Synthetic Fluids

Synthetic HTFs were developed to provide more thermal stability. These fluids are predominantly aromatic in nature, and can be used at lower and higher temperatures than their petroleum oil counterparts.

One popular synthetic fluid is a eutectic mixture containing 73.5% of diphenyl oxide and 26.5% of biphenyl. This is one of the oldest and most widely used synthetic HTFs. This fluid can be used in both liquid and vapor phase systems. Because of its high freezing point (12°C), it often requires protection against freezing. This fluid has exceptionally high thermal stability. The recommended maximum service temperature is 400°C at a pressure of 16 mPa (150 psia). However, because of the toxicity and odor problems, this fluid has lost popularity over the years.

Other popular synthetic fluids are alkylated aromatics, di- and triaryl compounds, mixture of diphenyl oxide and methylated biphenyl, partially hydrogenated terphenyls, mixture of isomeric dibenzyl toluene, polyalkylene glycol, synthetic paraffins, and silicone oils.

Dealing with High-Temperature HTFs

Similar to the low-temperature HTFs, engineers routinely deal with certain issues and problems with high-temperature fluids. They include 1) fluid expansion; 2) inert gas blanket; 3) draining and flushing; 4) venting; 5) heaters; 6) insulation; 7) filters; and 8) heat tracing.

Fluid expansion

High-temperature fluids usually go through a larger temperature change than the low-temperature fluids. These fluids can expand up to 30% when heated from ambient to operating temperatures. The reservoir or expansion tank must be sized to accommodate the increase in volume. The expansion tank should be at a higher level than and removed from the rest of the system so that the contained fluid exerts a positive pressure on the rest of the system. This arrangement also cools the vapors before venting.

Inert gas blanket

Organic HTFs oxidize when heated in the presence of air. This starts at about 150°C and the rate increases with temperature. Heat transfer fluid manufacturers usually recommend a blanket of an inert gas such as nitrogen or argon on the expansion tank to prevent oxidation. This inert gas can also be utilized to pressurize the system in case the fluid will be utilized above its boiling point or the net positive suction head (NPSH) of the pump needs to be elevated.

Draining and flushing

Draining and system flushing is required when the fluid needs to be changed. It is very difficult to effectively drain the entire system because of the presence of low-lying areas. Draining is enhanced by sloping the pipelines and including drain valves at all the low points during the initial installation. After draining is completed, a good flushing fluid can be used to clean the system of all the sludge deposits. Most HTF manufacturers carry a flushing fluid in their product line.

Venting

Flow of the HTF through the expansion tank during start-up is recommended because it facilitates venting

of vapors that result from residual water and any low boiling components in the fluid. The fluid, however, is seldom circulated through the expansion tank during normal operation. This allows the fluid in the tank to cool, which is necessary if there is no inert gas blanket.

At high temperatures, HTFs break down into low-boiling compounds. Vapor of these compounds needs to be vented from time to time to prevent pump cavitation, reduced fluid flow rate, lower fluid flash point, and reduction in safety because of continuously increasing pressure.

Heaters

As with all heat transfer equipment, there are trade-offs between the capital cost of equipment and the savings in operating cost. A good temperature control system is essential to obtain a long fluid life and limit unscheduled shutdowns. Gas-fired heating units usually have a single flow path heating coil. This eliminates zones with low fluid velocity and pockets of stagnant vapor. The heat flux stays around $20\,W/in.^2$ Hence, there is little danger of overheating the fluid. On the other hand, electric heaters consist of a bundle of elements surrounded by a cylinder filled with the fluid. Even with baffles to control the fluid flow pattern, it is impossible to completely eliminate zones with low fluid flow and collected vapor. The heat flux can reach $45\,W/in.^2$, which may cause degradation of the fluid at the heater surface.

Insulation

Insulation should be covered with an aluminum jacket, and the joints should be caulked. This protects the insulation from fluid leaks and accidental spills. It also prevents accumulation of the hot fluid in the porous insulation, which is very dangerous. Likely sources of leaks such as flanges, pump seals, and valve stems should not be insulated because exposure facilitates the early detection of leaks.

Filters

Most HTF systems do not have filters to remove coke, sludge, and other solids. One reason is that particulate filters are not very effective in removing the very fine solids formed when fluids degrade. Also, operators do not want to change filter cartridges containing hot fluids, especially when the fluids are toxic or have disagreeable odors. Filters containing high-temperature fiberglass and fine mesh stainless steel cartridges are very effective for removing particles. However, the filter should be installed in a sidestream where it does not interfere with the operation.

Heat tracing

Systems filled with biphenyl–diphenyl oxide mixtures or inorganic salt should be heat traced to avoid freezing during cool down to ambient temperature. This is very important because severe pump failure can occur and restarting of the system will be extremely difficult.

ULTRA-HIGH-TEMPERATURE FLUIDS

At temperatures above 400°C, organic compounds degrade so rapidly that their use becomes uneconomical. Under these conditions only inorganic salt mixtures and liquid metals have been employed.

Heat Transfer Salts

The most common salt mixture used is a eutectic blend of 40% sodium nitrite, 7% sodium nitrate, and 53% potassium nitrate.[21] Its temperature range is from 150°C to 540°C. The melting point of a fresh mixture of this salt composition is 142°C. However, sodium nitrite slowly undergoes endothermic breakdown to form sodium nitrate, sodium oxide, and nitrogen. Nitrite can also undergo oxidation to form nitrate. This process results in the increase of its melting point. It can react with carbon dioxide to form carbonates and with water to form hydroxides.

The salt is a strong oxidizing agent, hence should not be brought in contact with flammable or combustible materials. Even use of carbon steel is recommended up to 450°C. Above this temperature, low-alloy or austenitic stainless steel is recommended.

Liquid Metals

Liquid metals are used when temperature requirement is so high that even the nitrate/nitrite salt mixture becomes unsuitable. The most commonly used liquid metal is a eutectic mixture of sodium and potassium (44%). This has a very broad temperature range (40–760°C) and very high thermal conductivity. Lead and lead–bismuth eutectic can be used up to 900°C. There are several disadvantages with the use of liquid metals. Special precautions must be taken while using alkali metals because they react violently with water and burn in air. Mercury, lead, and bismuth-based mixtures are highly toxic, hence their applications are restricted. One common use of liquid metals is in the cooling of nuclear reactors.

CONCLUSIONS

In summary, several factors can affect the decision making process while choosing an HTF for a new system or for retrofitting a fluid in an existing system. Proper selection of the fluid can reduce the overall cost of a process in the long run.

Heat transfer fluids can be divided into various categories based on the lowest or highest temperature of operation. An operator or an engineer has to deal with different issues and problems with both low-temperature and high-temperature fluids.

The new frontiers in HTF research include nanofluids, phase change materials, fluids for specialty applications such as fuel cells, electronic cooling, thermal storage, etc., and environment friendly high-temperature fluids with excellent thermal stability.

Heavy Water (Deuterium Oxide)

Sharad M. Dave
Bhabha Atomic Research Center, Mumbai, India

INTRODUCTION

Use of heavy water both as a neutron moderator and as a coolant in fission reactors has resulted in its worldwide demand and many heavy water plants (HWPs) have been constructed. This interest in heavy water, both scientific and technological, has been responsible for the generation of immense information regarding its various aspects. In this article, the nuclear and other properties of heavy water, its production from natural abundance, upgrading and detritiation of downgraded and irradiated water in the reactor are reviewed and an attempt is made to present an overview of the major aspects of heavy water management in nuclear power generation.

ISOTOPE OF HYDROGEN

Unambiguous identification of the isotope of hydrogen, having mass 2, was made by Urey, Brickwedde, and Murphy.[1] Urey received the Nobel prize for the discovery and named it deuterium and symbol D was used to designate it. Deuterium has a peculiar property of efficiently slowing down thermal neutrons, without absorbing them. Because of this very property, deuterium oxide, also known as heavy water, finds profound application in the nuclear industry. Tritium is another isotope of hydrogen having mass 3. It is radioactive, emits low-energy β-particles and has a half-life of 12.26 yr. Isotopes having mass 3 and 4 are unstable and have short half-lives.[2]

PROPERTIES OF HEAVY WATER

Although hydrogen and deuterium have similar physical properties, their nuclear properties are markedly different.

Neutron Moderation

D_2O is the best moderator of thermal neutrons. D_2O absorbs far less neutrons than H_2O and heavy water-moderated reactors can operate with less reactive fissile material. Different moderators are compared in Table 1. A very large moderating ratio for D_2O has led to the construction of reactors that can use a very low concentration of fissile material such as natural uranium (0.7% U^{235}).[2]

This neutron economy leads to low fuelling costs. Also, the production of about 3 g plutonium per kilogram of the fuel at the end of the cycle is an added advantage.[2]

D_2O is also an excellent coolant and as both moderator and coolant, it is not consumed, but does get downgraded and leaks out of the system. Fortunately, these losses are manageable. A few neutrons, captured by D_2O in the reactor, result in the formation of tritium, which exists in the form of DTO and presents hazards in the handling irradiated heavy water.[2]

Physical Properties of Heavy Water

The difference in molecular composition and weight of the isotopic water molecules gives rise to slight differences in their chemical and physical properties. These differences, even though very small, are not insignificant and provide the basis for their separation and analysis. They are also useful for investigation of chemical and biological isotope effects and the structure of molecules. Important properties of H_2O, D_2O, and T_2O are compiled in Table 2.

D_2O has higher density, higher freezing and boiling points, and lower vapor pressure and refractive index as compared to H_2O. The ionization constant for D_2O at 298°K is 1.95×10^{-15}, about one-fifth that for H_2O. Hence, the usual pH meter cannot be directly used as a pD meter. Neutrality is expected at 7.363.[1,2]

D_2O is a poorer solvent than H_2O. The difference in solubility decreases as temperature increases. Substances, in general, are about 16% more soluble in H_2O as compared to D_2O.[1,2]

Thermophysical Properties of Heavy Water

While standardizing the values for the thermophysical properties of water and steam, also known as water substance, the International Association for the Properties of Steam (IAPS) has established formulations for various properties.[3]

Ghosh and Dave have compiled the internationally accepted formulations for various thermophysical

properties of heavy water substance and have calculated thermodynamic and transport properties of D_2O for the temperature and pressure ranges of 3.8–800°C and 0.01–100 MPa.[4]

NATURAL ABUNDANCE OF DEUTERIUM

The accepted abundances of hydrogen and deuterium are 99.9844% and 0.0156%. Because of the largest relative mass differences, the hydrogen isotopes show the largest variations in the abundance ratio. The major reasons for variations are differences in vapor pressures, equilibrium and kinetic isotope effects, hydration and ultrafiltration.

Deuterium contents of seawaters from major oceans, rivers, lakes, and different water sources in North America and the Indian subcontinent have been surveyed.[2] These studies show that water from the ocean depth has an average D-content of 156 ± 1 ppm, with little variation, whereas the same for surface water is lower. D-content of tropical seawaters is around 160 ± 1 ppm. Freshwater samples show large variations due to isotopic fractionation, which occur when water evaporates from land or sea and is condensed from air. Various factors such as local weather conditions, altitude, latitude, mean air temperature, drainage pattern, distance from the ocean, average precipitation, etc. are responsible for these variations.

Industrial Sources of Deuterium

To qualify for a feed for a HWP, the compound should be available in a very large quantity, with reasonable purity, and at a cheap rate.

A large quantity of feed is required to recover a rather small amount of heavy water. Hence, plants have to handle large flows. Only water, hydrogen, and natural gas fulfill the above conditions. Feed requirement for a 100 Mg D_2O plant are given in Table 3.

Both seawater and freshwater can be a source of deuterium. But freshwater is preferred because corrosion and other problems are less severe with it. Natural gas is available in large quantities, but there is no process available for extracting deuterium from hydrocarbons. Synthesis gas (abbreviated as syngas—a mixture of 75% hydrogen and 25% nitrogen by volume), used for producing ammonia, is a major source of hydrogen. Electrolytic hydrogen is very pure but is excessively expensive.

GENERAL PROCESS CHARACTERISTICS

Problems that are common to all heavy water processes are a very dilute feed, a large overall concentration ratio, and low recovery. Thus, irrespective of process, the ratio of feed to product is 8000 : 1 for 100% and 40,000 : 1 for 20% recovery.[5]

Rae compared different cascades for the H_2O–H_2S process.[6] For a two-stage cascade, the first stage gave a 10-fold enrichment, for a three-stage cascade, the first stage gave fourfold enrichment, whereas the second stage provided sixfold enrichment. Relative tower volumes showed a hefty 30% decrease for the two-stage arrangement and an additional 10% decrease for a three-stage cascade. For a single-stage cascade, the inventory of heavy water approaches the annual production capacity. For a two-stage case, the inventory is reduced by an order of magnitude. For a three-stage cascade, the inventory is further reduced by a factor of 2. Adding more stages increases plant complexity and capital cost. The first stage dominates the plant costs and hence, while comparing different multistage processes, only the first-stage figures are compared.

PARAMETERS FOR PROCESS EVALUATION

The separation factors and energy cost are the most important criteria for the commercial acceptance of any process.[7] The separation factor α denotes the degree of enrichment obtainable in a single equilibrium contact and is defined as

$$\alpha = [D/H + D]_A/[D/H + D]_B \quad (1)$$

where A and B are enriched and depleted streams in equilibrium, respectively. α Ranges from unity (no

separation) to about 30. Parameters, such as flows, plant volume, and recovery depend directly on α, whereas the dependence of energy consumption on α is indirect. This interdependence of process parameters is schematically illustrated in Fig. 1. Certain parameters such as reaction rate, energy consumption, etc. often outweigh α.[2]

PROCESSES FOR HEAVY WATER ENRICHMENT

Separation processes can be broadly classified according to thermodynamic reversibility:

Irreversible processes: Diffusion, thermal diffusion, gravitational, crystallization, adsorption, biological, laser-based photochemical, electrolysis.

Reversible processes: Distillation, chemical exchange.

Irreversible processes require a continuous supply of work and use energy inefficiently. Among irreversible processes, electrolysis and laser-photochemical methods are important.

Electrolysis

During electrolysis, hydrogen is discharged more rapidly than deuterium, so that the electrolyte becomes enriched in D_2O.

Separation factor, α, is defined as the ratio of the relative abundance of deuterium in water to that in the evolved hydrogen gas.

In alkaline solutions, α ranging from 5.3 to 7.6 was observed for electrodes of iron, nickel, cobalt, silver, and lead, while values ranging from 3.4 to 6.5 were obtained for acid electrolytes. α values as high as 13.9 in alkali solutions and 14.7 in acid solutions were found for anode-polarized platinum cathodes. A similar gold electrode gave α as high as 17.6.[2] α increases with decreasing temperature. Current density is indirectly related to α. At higher current densities, the temperature of the cathode increases, which leads to lowering of α. The condition of the electrode surface and electrolytes has a marked effect on the separation.

The following relationship exists between the initial and final deuterium concentrations and their volumes:

$$[H_0/H][D/D_0]^0 = [V/V_0]^{\alpha-1} \quad (2)$$

Thus, the initial concentration is of vital importance for the economic performance of the electrolytic process.

For the electrolytic separation of heavy water, two different flow sheets are used, viz., electrolytic cascades with and without recycle. The former is used for primary while the latter is used for the final enrichment.[2]

Prior to 1943, all the heavy water was produced by electrolysis. Analysis of a typical electrolytic cascade (without recycle) showed that when the number of stages was 15, the maximum amount of D_2O produced in such a cascade was 0.224 g, with a by-product of about 10,000 g/mol of hydrogen. Consumption of electric power was 4836 kW hr/g D_2O.This enormous consumption of pure electrical energy makes this process unviable.[2,5]

However, for the final enrichment and upgrading of heavy water, electrolysis provides an efficient and economically viable route.

Table 3 Feed requirement of a 100 Mg D_2O/yr plant

Feed material	Deuterium concentration (ppm)	Deuterium recovery (%)	Feed rate (nm^3/day)
Water	145–155	20	8.85×10^3
Syngas	110–130	80	3.95×10^3
Hydrogen	90–145	80	2.95×10^6
Natural gas	110–134	50	2.30×10^6
Calculated values			

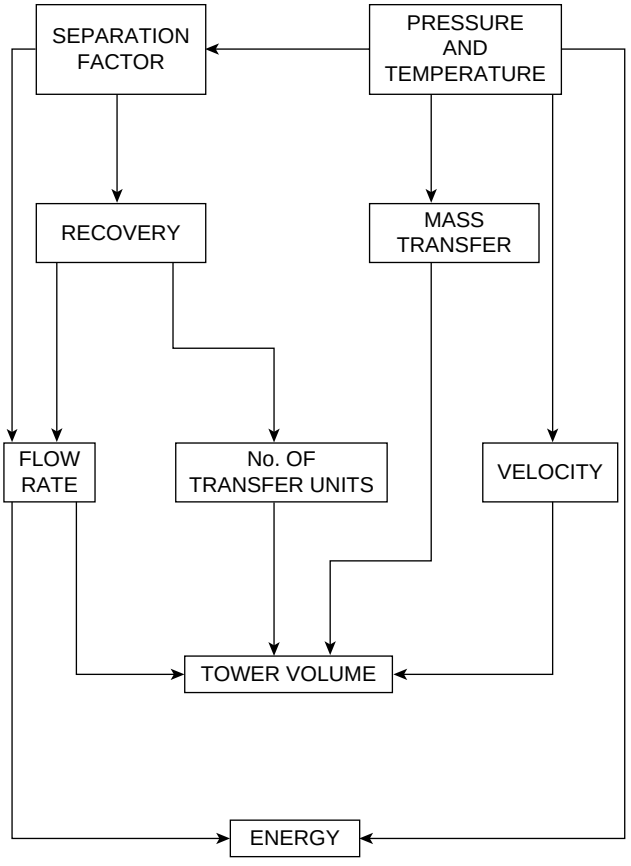

Fig. 1 Interdependence of process parameters.

Distillation

The distillation process utilizes the difference in vapor pressures of isotopic species. Because these differences are small, the process has to be repeated many times in a fractionating column, resulting in a cascade of several stages. Liquid is boiled at the bottom and vapor is condensed at the top, so that a continuous countercurrent contact is established.

Vapor pressures and separation factors

For a mixture of isotopic compounds such as XH_n, XH_{n-1}, $XH_{n-2}D_2$, XD_n, the separation factor, α, can be expressed as

$$\alpha_D = [p_{XH_n}/p_{XD_n}]^{1/n} \quad (3)$$

α is large for compounds having low molecular weight and increases as the temperature is lowered.

Salient features of distillation columns

Distillation columns consist of cylindrical vessels, arranged vertically, within which countercurrent contact between liquid and vapor is established. The less volatile isotope concentrates in liquid phase and is withdrawn from the bottom. A schematic representation of a distillation column is shown in Fig. 2.

Distillation columns can be broadly classified into two types, plate columns and packed columns. In plate columns, there is repeated contact between two phases, as in a bubble-cap column. Plate columns are generally used for primary enrichment. Random packings are used for small-diameter columns, whereas ordered packings are used in large-diameter towers. Packed columns are used for the final enrichment.

A process unit that separates an entering stream into two exit streams of different compositions is known as a stage. For a packed column, the height equivalent to a theoretical plate (HETP) signifies that height of a packed column that achieves the same separation as a theoretical plate. For a plate column, plate efficiency should be as high as possible, whereas in packed columns HETP should be as small as possible.[5] For such an arrangement, the plant volume is proportional to $1/(\alpha - 1)^2$. The effect of this term is overwhelming!

Distillation processes for separation of deuterium

Characteristics of distillation processes based on the above working materials are compiled in Table 4.

Three HWPs with a combined capacity of 1.15 Mg D_2O/mo were built in the United States in 1943 at Morgantown, Childsberg, and Dana but were shut down in the 1950s.[2]

Hydrogen distillation

Because of high separation factors, low-temperature distillation of hydrogen offers a viable route to D_2O production.

This process requires highly pure and a parasitic source of hydrogen. The bottom product gets enriched in deuterium, which is burnt in a stream of pure O_2 to give 99.8% D_2O.

Hydrogen distillation plants were built in France, Germany, Switzerland, Russia, and India. These plants were shut down in the late 1960s, with the exception of an Indian plant at Nangal, which has been operational for more than three decades, producing 14 Mg D_2O/yr.[2]

CHEMICAL EXCHANGE PROCESSES

Chemical exchange processes are characterized by large α, high recovery, and low energy requirement,

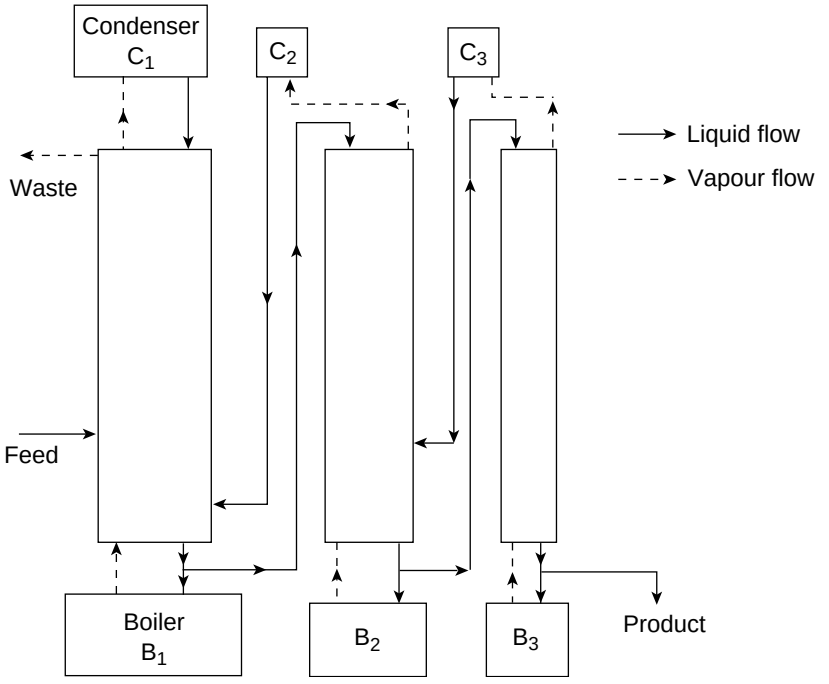

Fig. 2 Schematic diagram of a distillation column.

resulting in lower capital and operational costs. Commercially important exchange processes are:

- Water-fed hydrogen sulfide and hydrogen process.
- Hydrogen-fed ammonia and amine process.

The H_2O–H_2S process, being ionic, requires no catalyst. The remaining three require catalysts.

In large-scale separation, it is economical to combine chemical exchange for primary enrichment (10–25%) with either vacuum distillation or electrolysis for the final enrichment (99.8%).

There are two flow sheets available for achieving countercurrent gas–liquid exchange—monothermal and bithermal (dual temperature), as shown in Figs. 3A–C.

In a monothermal process the gas–liquid contact occurs at a single temperature and the reflux is provided by the conversion of liquid to gas by physical or chemical means in the equipment outside the exchange tower. This process is not suitable for H_2S–H_2O but is successfully used for NH_3–H_2 and H_2O–H_2 exchanges. In the former, ammonia is converted into hydrogen by cracking, whereas in the latter, water is electrolyzed to obtain hydrogen. This phase conversion is always expensive.

To circumvent the high cost of chemical reflux, Geib and Spevack suggested a dual-temperature process, which provides reflux by purely physical means.[5] The cold tower in bithermal operation performs the same function as monothermal tower and enriches deuterium by exchanging deuterium from the ascending gas stream to the descending liquid stream. The hot tower provides the reflux. Both flow sheets are used for producing heavy water.

Water–Hydrogen Sulfide Exchange Process

The first dual-temperature plant for the Manhattan District Heavy Water program was built at Dana and the second at Savannah River. The process was known as GS process (Girdler-Sulfide or Girdler-Spevack). A very simplified flow sheet of this process resembles Fig. 3C.

Table 4 Comparison of different distillation processes

Substance distilled	Temperature (K)	Pressure (kPa)	Separation factors, α	Number of stages, N_{min}	Boil-up rate, $(GlW)_{min}$
Hydrogen	24	250	1.5	37	2.08×10^4
Methane	112	100	0.9965	4373	1.99×10^6
Ammonia	235	100	1.036	431	1.99×10^5
Water	378	120	1.024	643	2.96×10^5

(From Ref.[6].)

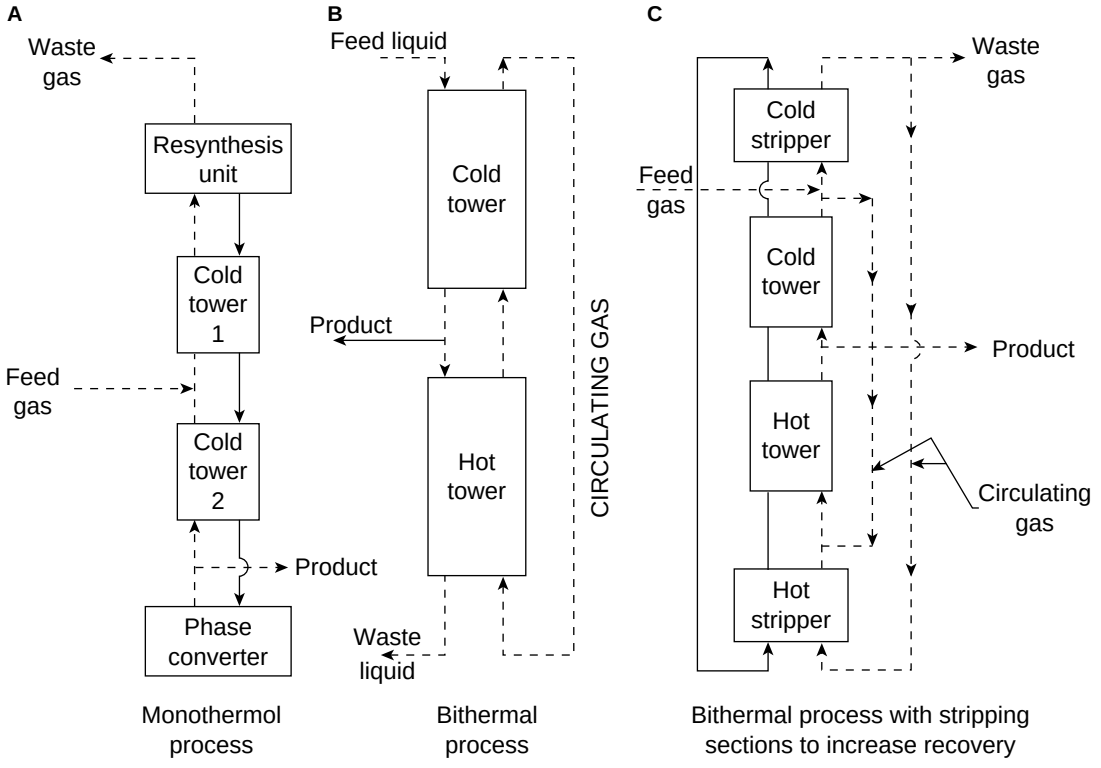

Fig. 3 Chemical exchange processes: (A) monothermal, (B) bithermal, and (C) bithermal process with stripping sections.

General process characteristics

The deuterium exchange reaction between water and hydrogen sulfide

$$H_2O(l) + HDS(g) = HDO(l) + H_2S(g) \quad (4)$$

proceeds rapidly and has an equilibrium constant of 2.32 at 32°C.

Temperature dependence of liquid–gas separation factors, β, is given by

$$\beta = -0.00736T + 4.534 \quad (5)$$

β decreases with increasing temperatures.[8] When a process is carried out at dual temperatures,

$$\beta_{\text{effective}} = \beta_{\text{cold}}/\beta_{\text{hot}} \quad (6)$$

Lower cold tower temperatures would be preferable. Unfortunately, below 28°C, H_2S forms solid hydrate.[5] This limits the cold tower temperature to 30°C. The higher hot tower temperatures are preferred for better recovery. But operating hot tower beyond 130°C is uneconomical, as this leads to increase in hot tower diameter and steam consumption, offsetting the marginal gain in recovery.

At 20 atm (2 MPa), the minimum safe cold tower temperature is around 30°C, below which hydrate formation occurs. The rapid increase in the condensation temperature above 20 atm is another reason for this being the optimum pressure.

Benedict, Pigford, and Levi have carried out mathematical analysis of the GS process.[5] An exhaustive treatment of the process, including calculations for flow rates, dependence of composition on number of stages, effect of solubility and humidity on process analysis, temperature profile in cold towers, simultaneous heat and mass transfer in heat transfer section, concentration reversal in heat transfer section, corrosion, materials of construction, feed purification, and safety, etc. have been reviewed by Dave, Sadhukhan and Novaro.[2]

The main drawback of the GS process is the highly corrosive nature of its aqueous solutions. A 400 Mg/yr GS plant requires an inventory of 800 Mg of H_2S, which is an extremely toxic, flammable, and corrosive gas with a distinct, disagreeable smell even at low concentrations. Hence, adequate measures must be taken for material selection, fabrication, feed purification, feed and waste discharges in water and the atmosphere, safety of staff, the surrounding population, and environment.[2]

Heavy water plants

Plants in the United States. Two plants, one at Dana, IN, and the other at Savannah River, SC, were built in 1952. The first plant at Dana was shut down in 1957

because of lack of demand. The Savannah plant was operating with one-third of its capacity, producing about 150 Mg D_2O/yr, and the plant began to be dismantled in 1994.

Canadian HWPs. The design concepts of Proctor and Thayer were incorporated in the CGE/Lummus process for large plants in Canada, viz., the Port Hawkesbury plant in Nova Scotia and the Bruce near Douglas Point in Ontario.[9]

In 1966, a plant with a capacity of 380 Mg D_2O/yr was commissioned at Port Hawkesbury, Nova Scotia, and production started in 1970. The plant at Glace Bay, Nova Scotia, built in 1963, faced numerous problems caused by seawater feed. The plant was rehabilitated in 1976. The Bruce HWP (BHW-A) at the Bruce site on Lake Huron was built in 1971. Two identical enriching units in parallel were used to double the plant capacity. The final enrichment was achieved by vacuum distillation. Three additional identical plants (BHWP-B, BHWP-C, and BHWP-D) were constructed at Bruce, Ontario, and at Le Prade in Quebec. BHWP-B was commissioned in 1979. Owing to lack of demand, the remaining plants were cancelled.[2,10]

Indian HWPs. Two plants, one at Kota, Rajasthan, and the other at Manuguru, Andhra Pradesh, are in operation. The Kota plant has a capacity of 85 Mg/yr of 99.8% D_2O. It uses GS process for primary enrichment (15%) and vacuum distillation for the final enrichment. The plant was commissioned in 1982.

The second plant, at Manuguru, was commissioned in 1991. The plant, with its own captive power station, has a capacity of 185 Mg/yr of 99.8% D_2O.[2]

The economics of the GS process

The construction and production costs of the Savannah River HWP, have been estimated as[5]

Investment: \$148/kg of D_2O/yr

Operating: \$17.60/kg D_2O/yr

Towers and piping account for almost 50% of equipment costs.

In 1972, it was estimated that a plant with a capacity of 400 Mg of D_2O/yr and a power plant would cost about \$115 million. This corresponds to a specific investment of \$290/kg of D_2O/yr. Thus, the H_2O–H_2S process is both capital and energy intensive.

Hydrogen–Water Exchange

Hydrogen–steam exchange was selected for the Manhattan District project and a 6 Mg/yr plant was built at Trail, Canada.[5]

This process has high separation factors, no corrosion, and large capacity, but all these advantages are nullified by the need for a catalyst. Separation factors have been calculated as function of temperature and deuterium concentrations in water.[11]

Catalysts and their performance

Carbon supported platinum catalysts catalyze this exchange in the gas phase, but they rapidly lose activity on contact with liquid water. For liquid–gas exchange, hydrophobic catalysts were developed by depositing platinum on porous polytetrafluoroethylene (PTFE, Teflon). Teflon provides a water-repellent environment to the platinum crystallite.[12] In a more successful approach, platinized carbon was prepared and bonded to a variety of column packings, using Teflon both as a bonding and as a waterproofing material. Butler has evaluated the performance of different types of Teflon-coated catalysts for water–hydrogen exchange.[12] He found that the reaction is fast and the catalyst stable. Impurities in feed, however, poisoned the catalysts. Many homogenous catalysts have been studied, but so far no suitable catalyst has been found for H_2O–H_2 exchange.

Monothermal hydrogen–water exchange

When hydrophobic catalysts were used for monothermal operation and reflux was provided by electrolysis, the process was termed combined electrolysis and catalytic exchange (CECE).

Because water can be used directly in the liquid form, there is a considerable saving in capital and operating costs. Because of combination with electrolysis, α is large, which bestows many advantages.[13]

But CECE involves production of a huge amount of electrolytic hydrogen and unless there is a direct market for this hydrogen, the process remains uneconomical for primary enrichment.

Dual-temperature H_2O–H_2 process

This process has been explored by many workers.[2] In most cases the cold and hot tower temperatures were at 100°C and 500–600°C. At high temperatures and high pressures, catalysts lose activity, making the process economically unviable.

Ammonia–Hydrogen Exchange Process

The ammonia–hydrogen process is represented by:

$$NH_3(l) + HD(g) = NH_2D(1) + H_2(g) \qquad (7)$$

Both monothermal and bithermal versions are feasible. For cold and hot tower temperatures of −40°C and +70°C, effective α is 2.03. For this exchange, α and its temperature coefficient are large, resulting in large recovery and small plant volume and low energy requirement. Corrosion and operational problems are manageable.

The ammonia–hydrogen plant requires a large source of ammonia or hydrogen. Synthesis gas, used for producing ammonia on an industrial scale, is an ideal source. But this limits the production capacity of HWP to about 100 Mg D_2O/yr corresponding to 1500 Mg NH_3/day in the ammonia plant.

Separation factors

The separation factors increase with decreasing temperature and follow the relationship

$$\ln \alpha = A/T + B \quad (8)$$

where A and B are constants. A corresponds to the heat of exchange reaction and was found to be 4.38 kJ/mol.[2] α increases with decreasing deuterium concentration of the system.[2]

Kinetics and the role of catalyst

Deuterium exchange between ammonia and hydrogen does not proceed spontaneously. Wilmarth, Dayton, and Flournoy found that potassium amide catalyzed this exchange.[14] Further studies showed that the rate of exchange is proportional to solubility of both hydrogen and catalyst in ammonia, which can be increased by intimate mixing of the liquid and gas phases.[2,14]

While high temperatures favor rapid mass transfer, low temperatures are desirable for higher α. NH_3 freezes at −78°C and slow kinetics at lower temperatures suggests a lower limit of temperature of −40°C for the cold tower.[2]

Properties of amide–ammonia solutions

The solubility of amides in liquid ammonia differs appreciably and increases from lithium to rubidium. Because of the high reactivity of amides and the excellent solvent properties of liquid ammonia, amide–ammonia solutions are highly reactive and react with most substances.[15]

The alkali amides react spontaneously with water and oxygen to form hydroxides; with CO they form formamide (HCONHK) and formate (HCOOK) and with CO_2 they form ammonium carbamate (NH_4CONH_2), which reacts with KNH_2 to yield stable potassium carbamate ($KCONH_2$). These reaction products are highly insoluble in liq. NH_3 and cause serious operational problems. Hence, it is imperative to have feed gas absolutely free from oxygenous impurities.[2]

Monothermal ammonia–hydrogen exchange process

The monothermal NH_3–H_2 process was developed in France. Deuterium exchange takes place between liquid NH_3 and gaseous H_2. KNH_2 is the catalyst, obtained by dissolving potassium metal in liquid ammonia. A schematic diagram of the process is given in Fig. 4.

The important steps in the process are:

Purification of feed gas: Stripping of syngas by molecular sieves and liq. NH_3 + KNH_2 wash to remove impurities.

The exchange process: To achieve reasonable mass transfer rates, an ejector contactor was developed by M/s Sulzer Brothers.[5] The plate consists of a ring of nozzles in which syngas breaks up and scatters the liquid in tiny droplets. At each stage, gas is expanded through nozzles and liquid is sucked into the high-velocity gas stream, giving a very intimate gas–liquid mixture.[2,5]

Catalyst recovery and recycle: Amide also gets enriched in its deuterium content. This deuterium and amide must be recovered by evaporating ammonia and stripping off deuterium by scrubbing.

Cracking of ammonia (ND_3): Complete dissociation of ammonia is achieved by heating it with catalyst at 550–580°C at 55–60 atm pressure. The product syngas can be burnt in air or oxygen to produce D_2O.

Integration of HWP with the ammonia synthesis plant: Purified synthesis gas after the pressure adjustment is sent to HWP, which acts as a by-pass to the ammonia synthesis unit.[2]

Plants based on the monothermal process

The monothermal ammonia–hydrogen exchange process was developed in France. The first plant was built at Mazingarbe and five plants have been built in India.

Mazingarbe HWP. The Mazingarbe plant was started in 1968. The basic design described above was followed. The final concentration of 99.8% was achieved by ammonia distillation. The Mazingarbe plant was shut down in 1972 because of an explosion in the ammonia synthesis plant.[2,5]

Indian HWPs. Four plants, based on the monothermal process, have been constructed at Baroda and Hazira in Gujarat, Tuticorin in Tamilnadu, and Thal in Maharashtra in India.[2]

The Baroda plant utilizes syngas from the Gujarat State Fertilizer Corporation plant at a pressure of

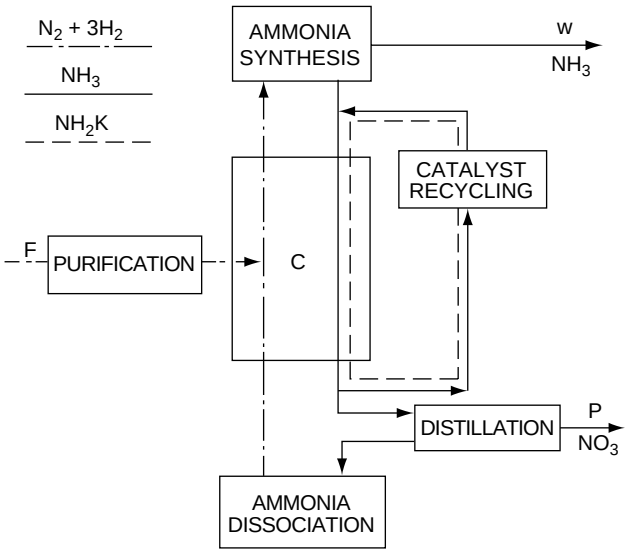

Fig. 4 Schematic monothermal ammonia–hydrogen process.

about 650 atm. It was started in 1983. The plants at Baroda and Tuticorin were built by Gelpara consortium for the Department of Atomic Energy, India. The final enrichment was carried out by distillation. Two more Indian HWPs, one at Thal and the other at Hazira, were designed and fabricated by the Department of Atomic Energy and were commissioned in 1986 and 1990, respectively. The Thal plant draws its requirement of syngas from two fertilizer plants, having a combined capacity of 1050 Mg of NH_3/day. Because of the larger capacity of the ammonia plant, two prototype HWPs, each having a capacity of 65 Mg D_2O/yr, have been set up. These plants are in operation.[2]

Despite the relatively low heat of decomposition of ammonia, 3×10^{-6} J/kg, cracking of ammonia represents the costliest operation.[2] Hence, bithermal process for the ammonia–hydrogen exchange was proposed.

Dual-temperature NH_3–H_2 process

A bithermal ammonia–hydrogen HWP has been constructed for the Government of India at Talcher by Uhde, GmBH of Germany.

The Talcher HWP is coupled with a 900 Mg/day ammonia synthesis plant of the Fertilizer Corporation of India to produce 62.5 Mg D_2O/yr. After purification, syngas enters the enrichment section, which consists of a three-stage cascade. The first stage is superimposed by two cold- and hot-stripping columns. Each stage consists of one pair of cold and hot columns. Deuterium concentration in ammonia is high at the base of the cold tower and in synthesis gas at the top of the hot column. Deuterium is transferred to water by ammonia–water exchange. The final enrichment is achieved by distillation.

A detailed analysis of this flow sheet is given by Benedict, Pigford, and Levi.[5] The Talcher plant, which was to be commissioned by the end of 1975, had a series of problems. The plant was commissioned in 1979 but it could never achieve sustained production and has become uneconomical to operate.

Large hot and cold tower volumes due to large flows and complex heat exchanger systems are the major drawbacks of the bithermal process.

Problems in the ammonia–hydrogen exchange process

1. The capacity of HWP is limited by the ammonia synthesis plant.
2. The deuterium content of syngas is low (110–120 ppm).
3. Interruptions in the ammonia plant lead to serious disruptions in the working of HWP.

These limitations can be removed by linking syngas feed of HWP with water. This can be achieved by:

1. Equilibration of depleted hydrogen with water.
2. Isotopic exchange of ammonia with water.

Amine–Hydrogen Exchange Process

Replacing ammonia by methylamine in the exchange

$$CH_3NH_2(l) + HD(g) = CH_3NHD(l) + H_2(g) \quad (9)$$

was first suggested by Bar-Eli and Klein.[16] Further studies have shown that monomethylamine (MMA) is a better substitute for ammonia and offers the following advantages:[17]

1. Larger separation factors, better kinetics, lower cold tower temperature.
2. Lower vapor pressure of MMA, low capital cost, low energy requirement.

Process characteristics

Separation factors for this process have been measured by Dave, Ghosh, and Sadhukhan and the temperature

dependence of the equilibrium constant can be expressed as[17]

$$\ln K = A/T + B \quad (10)$$

where A and B are constants. The gradient A corresponds to the enthalpy of reaction. ΔH was found to be 4.61 kJ/mol.[17]

Amide–amine solutions react vigorously with water and oxygenous impurities in syngas and form insoluble products. Hence, scrupulous purification of feed gas becomes inevitable.[2] At high pressures, hydrogen reacts with methylamide catalyst [potassium methylamide (PMA)] to form potassium hydride (KH), which is insoluble in amine. To circumvent this hydride precipitation and obtain a reasonable rate, an equimolar mixture of lithium methylamide (LMA) and PMA, called PLMA, was developed by Canadian workers.[6,18]

As conversion of methylamine to hydrogen is difficult, only bithermal operation is possible. The cold tower temperature is fixed at 223°K where the rate is fast and α is 7.9, the highest known for any practical exchange reaction. The optimum hot tower temperature is limited to 313 K, a limit set by the decomposition of the catalysis. Sulzer, GmBH and Atomic Energy Canada Limited have given a flow sheet for 65 tons/yr HWP.[6,18]

LASER SEPARATION OF ISOTOPES OF HYDROGEN

Laser isotope separation (LIS) utilizes small differences in the spectroscopic properties of isotopic substances. Each isotope-bearing substance absorbs a radiation of a particular wavelength. Separation of the excited species can be achieved by multiple-photon absorption or photopredissociation of molecules or chemical scavenging.

For laser separation of heavy water, the working material must be cheap, nontoxic, volatile, and easily redeuterable. It must have acceptable photon utilization and high optical selectivity for multiphoton absorption. Photoproducts must be stable and separable.

Concepts in Large-Scale Separation of Deuterium

A basic flow sheet containing common features of an LIS plant is schematically shown in Fig. 5. The two major components in a deuterium LIS plant are the laser isotopic separator and chemical exchange reactor.

The feed gas, entering the separator, is exposed to laser and is separated into enriched product stream and depleted stream.

The chemical exchange reactor replenishes the depleted stream by chemical exchange reaction with an abundant source of deuterium.[19]

Promising Deuterium Laser Separation Processes

Photopredissociation of formaldehyde and the consequent enrichment of deuterium were reported by Yeung and Moore.[20] When an equimolar mixture of H_2CO and D_2CO was irradiated with a ruby laser, the D_2CO molecules were excited and dissociated into $D_2 + CO$ and sixfold enrichment was obtained. Better enrichments were obtained by subsequent workers by using narrower wavelengths. Letokhov and Vanderleeden have given the mathematical analysis of the process.[21–26] Redeuteration of formaldehyde was studied by Vanderleeden and Dave and Ghosh.[2,25,26]

Multiphoton Dissociation

Marling and Herman investigated CF_3CDCl_2, known as Freon-123 (2,2-dichloro-1-1-1-trifluoroethane).[27] This compound absorbs selectively near 10.2 and 10.6 μm, accessible with CO_2 TEA laser, and undergoes dissociation to give stable CF=CFD as the main product. The selectivity for this process was as high as 1400. The depleted working material can be redeuterated by chemical exchange with water in the presence of NaOH catalyst.[27]

Another starting material, fluoroform-d, was reported by Tuccio and Harford.[28] This molecule undergoes multiphoton dissociation when irradiated with a pulsed CO_2 laser and dissociates to yield DF. An enrichment factor of greater than 5000 was obtained. Based on these studies, Marling, Herman, and Thomas have proposed a 100 Mg/yr deuterium separation plant using trifluoromethane as the working material.[29]

Formidable engineering and technological problems have to be solved before deuterium LIS can compete with other established processes.

FINAL ENRICHMENT AND UPGRADING OF HEAVY WATER

The primary enrichment processes discussed above give enrichment of 10–25% depending on the design. Further concentration of up to 99.8% is achieved by the final enrichment step. The final enrichment involves only a fraction of the total outlay and is a part of the heavy water program. Feed has more or less constant concentration.

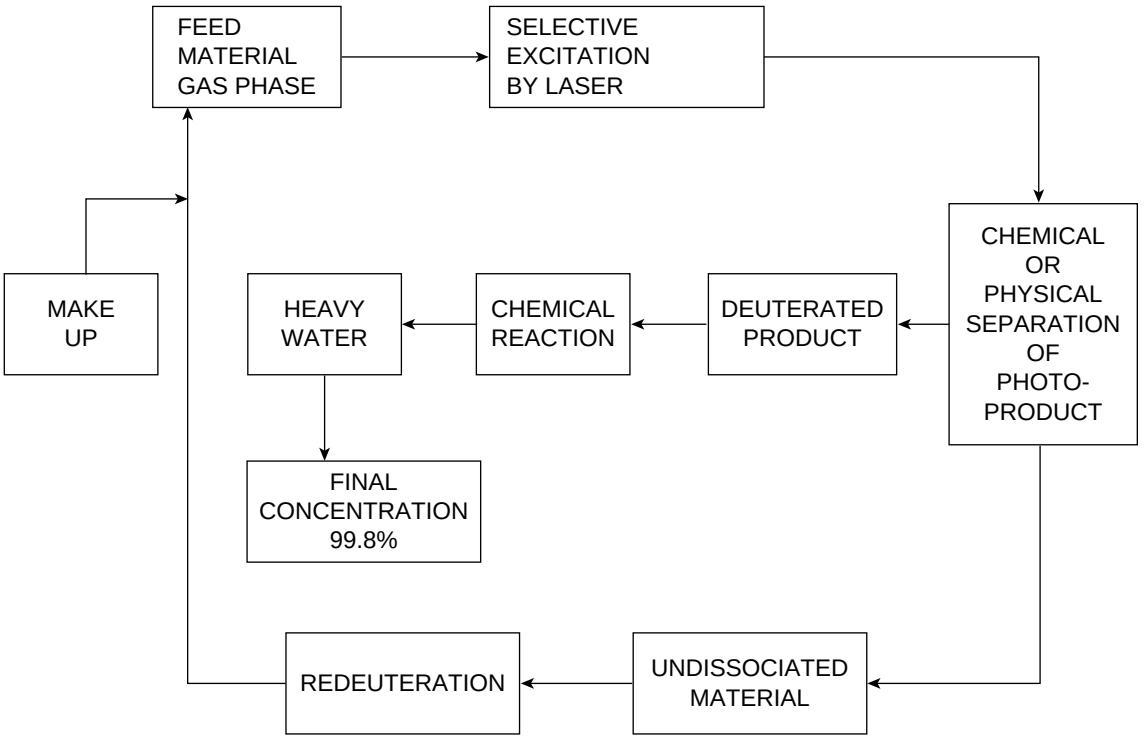

Fig. 5 Simplified flow sheet of an LIS plant for production of heavy water.

Heavy water reactors have a huge inventory of heavy water (0.9 tons/MWe), which leaks out. Yearly leakages amount to about 50%. Purity of recovered heavy water, which varies from 5% to 98% is radioactive. Hence, the upgrading facility should be near the reactor site.

Any process that is suitable for the final enrichment can be employed for upgrading also. The criteria for selecting a process are reliability, simplicity, and conservation of costly feed. Distillation and electrolysis fulfill these requirements.[2]

Distillation can be used for the final enrichment, or upgrading, or extracting of light water from the moderator heavy water.

As the capacity of the primary plant is large, the distillation columns for the final enrichment are large. For smaller-diameter columns, dixon rings are used. For large-diameter columns, ordered packings, developed by Sulzer Brothers, having a high surface area (therefore, low HETP), less pressure drop, and high wettability are used. The column and associated equipment should be leak-tight to prevent loss of costly D_2O.

For upgrading plants, the equipment must be leakproof and under vacuum to prevent tritium from escaping. There is a cleanup unit to avoid contamination. The electrolysis employed for the final enrichment or upgrading is a batch process and is carried out in a tank-type cell. The anode is usually made of nickel, while low-carbon steel is used as a cathode. The process temperature should be maintained as low as possible, for high separation factors. Basically, an electrolytic plant consists of an electrolytic section, a purification section, and a storage section. The separation factors for HTO/H_2O being much higher for electrolysis than for distillation, the tritium content in the reject in an electrolytic plant can be controlled effectively.

DETRITIATION OF HEAVY WATER

Tritium is produced by ternary fission and resides in the moderator. It is a soft β-emitter and is responsible for about 40% of man-rems exposure in the reactor.[2]

Processes for Detritiation

Distillation, electrolysis, chemical exchange, and laser-based photochemical methods are employed for separating tritium. In the detritiation process, tritium should concentrate in the gas phase as DT or T_2 and not in the aqueous phase. The permissible limit for tritium in air is 25,000 times larger than that for aqueous tritium.

Water distillation and electrolysis are not suitable because of high energy costs and tritium gets enriched

in the aqueous phase. Cryogenic distillation in combination with chemical exchange is used for detritiation as well as in tritium production. Tritium concentrates in the gas phase.

D_2O–DT exchange can be used for transferring tritium from heavy water to deuterium. Further enrichment is achieved by cryogenic distillation. Because of the similarity between deuterium and tritium, platinum on charcoal is the catalyst for vapor phase exchange, whereas hydrophobic catalyst is used for liquid–gas exchange.

Two basic schemes are available:

Vapor phase catalytic exchange (*VPCE*), *followed by cryogenic distillation*: Platinum on charcoal catalyst is used for the exchange. The heavy water has to be converted into steam. The exchange is, therefore, carried out at 200°C.

Liquid phase catalytic exchange (*LPCE*), *followed by cryogenic distillation*: Hydrophobic catalyst is used. Exchange is carried out between 50°C and 70°C. Commercial detritiation plants are based on VPCE.[2]

CONCLUSIONS

Heavy water is not only the most important component, but also the major cost contributor to the nuclear power program, which utilizes pressurized heavy water reactors.

The GS process has the advantage of unlimited feed but has serious limitations also. The prospects of sizeable cost improvement look bleak. Nevertheless, this proven process reigns supreme and is a major producer of heavy water. The ammonia–hydrogen process has emerged as a serious alternative. There is scope for improvement and its reliability is improving. The hydrogen–water process has the potential to become a major process, provided existing constraints are removed. In spite of many advantages, commercial exploitation of the amine–hydrogen process has to await solution of critical process chemistry problems. Laser separation of heavy water exhibits some potential, but it will take great effort and investment to remove existing limitations. Because of the dwindling demand for heavy water at present, serious R&D efforts to develop more efficient and cheaper processes are lacking and we will have to rely on the proven processes.

Heterogeneous Catalysis

Richard W. Rice
James G. Goodwin, Jr.
Department of Chemical Engineering, Clemson University, Clemson, South Carolina, U.S.A.

INTRODUCTION

Catalysts are materials that speed up a reaction by orders of magnitude without being consumed by the reaction. For example, iron (Fe) catalysts increase the rate of ammonia synthesis from nitrogen and hydrogen by a factor of roughly 10^{40}. Basically, catalysts provide an alternate mechanism for the reaction that involves at least one reactant chemically bonded to the catalyst. This alternative mechanism provides a lower energy barrier for reaction to occur, resulting in a lower ''apparent'' activation energy for reaction, but does not alter the thermodynamic features, i.e., heat of reaction or equilibrium constant. There are three classes of catalysts: heterogeneous (or solid inorganic catalysts), homogeneous (typically organometallic compounds, metal compounds, or liquid acids/bases), and enzymes (or biological catalysts). This entry focuses on only one of these classes, i.e., heterogeneous catalysts, but it is useful to briefly point out the main distinguishing features of all three.

As the name implies, a heterogeneous catalyst differs in phase from the reactants and products involved in the process. In general, heterogeneous catalysts are finely divided or porous solids that provide a large active surface area for reaction. They are the preferred catalysts for industrial use because they tend to be stable at higher temperatures, have high rates of reaction, and are easy to separate from the reaction media (gas or liquid) because of their phase difference. However, it is hard to achieve 100% selectivity to desired products. Homogeneous catalysts have higher selectivities, but are limited to lower temperatures because of their thermal stabilities. In addition, because they are in the same phase as the reaction mixture, expensive separation is usually required to recover the catalyst. In some cases, e.g., polymerizations, catalyst recovery is impracticable/impossible. Many homogeneously catalyzed reactions utilize liquid acids such as H_2SO_4 and HF. These strong liquid acids bring problems of process unit corrosion, catalyst separation, and, most importantly, disposal of the acid. With stricter environmental regulations being imposed on the chemical processing industry, processes using liquid acids have become less desirable.

Biocatalysts or enzymes are very interesting because of their extremely high selectivities (near 100%) at close to ambient temperature. For example, methane monooxygenase enzyme, which can be extracted from several bacteria, is able to oxidize methane directly at ambient temperature and pressure with a 100% yield of methanol. However, biocatalysts cannot be used much above 70°C and tend to prefer aqueous environments. Consequently, high rates cannot typically be obtained for industrial applications because of the temperature restriction. Immobilization of enzymes by tethering them to inert solids has been investigated with limited success. Such catalysts have features common to both heterogeneous and homogeneous catalysts.

HISTORY

Although scientific historians often cite Berzelius (1835) as the first to use the term ''catalysis,'' it is probably more meaningful to say that the science and technology of heterogeneous catalysis as we now know it began with Ostwald, who received the Nobel Prize in 1909 for his pioneering work. One of the earliest large-scale commercial uses of heterogeneous catalysis was in an ammonia synthesis plant commissioned by BASF in 1913. Industrial production of methanol from carbon monoxide and hydrogen via catalyzed processes began in the mid-1920s and the Fischer–Tropsch process for hydrocarbon synthesis from CO and H_2 was developed shortly thereafter. Conceptual/theoretical advances were also achieved in the 1920s with H.S. Taylor's hypothesis concerning active centers and Irving Langmuir's work on adsorption.[1] From these beginnings the development of both scientific and technological insight concerning catalysis has continually increased, thereby making possible enormous growth in many industries central to our economy. These include not only petroleum refining and the ''conventional'' chemical industry, but also pharmaceuticals, environmental protection, etc.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120018066

DEFINITION OF IMPORTANT TERMS

Active Site(s)

For most catalysts the accessible surface is nonuniform and typically only a small percentage of sites, i.e., individual atoms or small clusters of atoms, have the ability to cause rapid conversion of adsorbed reactant molecules to the desired product(s).[1] Although research has revealed the nature of such sites for some specific combinations of reaction and catalyst, there is no universally accepted description of what makes a site "active." One school of thought avers that an active site is a location where highly reactive intermediates (chemisorbed species) are stabilized long enough to undergo chemical transformation. For crystal surfaces it has been found for some reactions that only one of various exposed planes has the necessary features, i.e., atomic spacing and/or coordinative unsaturation, for causing a high rate of reaction.[2,3]

Activity

The rigorous definition of activity is the ratio of the rate of reaction (or rate constant) on a catalyst after some time, t, to the rate (or rate constant) on a fresh catalyst at the same conditions.[4] Thus, the loss of catalytic ability with time in use is called "deactivation." However, the term "activity" is also often used to merely refer to the rate constant, k, or to the intrinsic ability of a catalyst to carry out a reaction.

Reaction Rate

Because heterogeneously catalyzed reactions occur exclusively on the catalyst surface, the relevant normalizing quantity (basis) chosen for the rate is usually either the mass of the catalyst, the surface area, or something directly related to these. Thus, for a reaction such as $aA + bB \leftrightarrow mM + sS$, a commonly employed expression for calculating the rate based on mass (or weight) of catalyst is:

$$\begin{aligned}\text{Rate} &= \frac{\text{Moles A reacted}}{\text{Weight of catalyst} \times \text{Time}} \\ &= -\frac{1}{W}\frac{dN_A}{dt} \text{ for a batch reactor} \\ &= \frac{F_{A_0}X_A}{W} \text{ for a flow reactor}\end{aligned}$$

Here, N_A = moles of A, W = weight of catalyst, t = time, F_{A_0} = molar flow rate of A, and X_A = fractional conversion of A. For a given catalyst the rate is dependent on temperature and the concentration(s) of participating species. Often this relation is approximated as a simple power law expression, e.g., rate $\approx kC_A^{\alpha}C_B^{\beta}$, where C_A and C_B are the respective fluid phase concentrations of A and B, α and β are the respective orders of reaction, and k is referred to as the "rate constant" even though it generally is highly dependent on temperature. Typically, an Arrhenius expression is used for k, i.e., $k = k_0\, e^{-E/RT}$, where k_0 is a constant, E is the apparent activation energy, R is the gas constant, and T is the absolute temperature. The orders of reaction (α and β) are not necessarily equal to the reaction stoichiometric coefficients.

Turnover Frequency

The rate of reaction expressed as molecules reacted (or formed) per unit time per catalytic site (or per exposed atom of active metal for metal catalysts) is called the turnover frequency. For supported metal catalysts the calculation requires knowledge of the "dispersion," i.e., the fraction of the active metal available for adsorption of reactants. Boudart coined the term "demanding" (structure-sensitive) for catalyzed reactions for which the turnover frequency varies with the dispersion.[5] Related to this is the "ensemble effect," where the active site requires a specific multiatom grouping.[3]

Selectivity

For cases in which multiple reactions occur, e.g., parallel reactions such as $A + B \rightarrow M$ and $A + B \rightarrow P$, selectivity is the ratio of the rate of formation of one product relative to the other.

Carrier (or Support)

A solid, typically a highly porous metal oxide, which provides an appreciable surface area upon which the active component(s) is (are) dispersed.

Promoter

A substance that has little or no activity itself, but which imparts to the catalyst improved activity, selectivity, or stability.

CATALYST TYPES

The main types of heterogeneous catalysts are as follows.

Metal(s)

A wide variety of metals are used in the reduced (zero-valent) state as catalysts. Most often the metal is

dispersed within the pores of a support, but there are several bulk (unsupported) metal catalysts of commercial interest, e.g., bulk Fe ammonia synthesis catalysts, Pt/Rh wire gauzes, Raney Ni or Co.[6] The most commonly used supports are γ-Al_2O_3, SiO_2, and carbon, and the metal loading may vary from <1 wt% to, say, 40 wt%, depending on the application, support characteristics, and the relative cost of the metal.[7] Supported transition metals, particularly Group VIII metals such as Pt, Ni, and Fe, are frequently used as catalysts. Platinum is an excellent catalyst for many reactions, e.g., hydrogenation, dehydrogenation, oxidation, but is only used when its superior performance offsets its high cost. Often Pt is used in combination with other metals, e.g., Re for naphtha reforming and Pd and/or Rh for automotive catalytic converters.[8,9] Nickel is an active catalyst for hydrogenation and is often used for methanation, i.e., $CO + 3H_2 \rightarrow CH_4 + H_2O$.[6,10,11] Iron and cobalt have been used for Fischer–Tropsch synthesis of hydrocarbon oligomers.[10,12,13]

Metal Oxides and Sulfides

In addition to serving as supports, metal oxides are widely employed as catalysts themselves or as a ''co-catalyst'' with a metal in multifunctional catalysts for reactions involving two or more types of sites, e.g., dehydrogenation/hydrogenation on a metal and isomerization on an acid (oxide or hydroxyl) site. As discussed in the next section, metal oxides catalyze many reactions based on acid–base chemistry, utilizing either Lewis acid sites or Brönsted (proton donating) surface OH groups.[14] For example, γ-Al_2O_3 has been used industrially for alcohol dehydration.[3] The use of zeolites, i.e., crystalline aluminosilicates, as catalysts has continued to grow since their first major application in catalytic cracking of petroleum. The well-defined microporous structure of zeolites has been exploited to improve selectivity for several reactions by allowing only molecules of a restricted range of sizes/shapes to reach the active sites. In addition, by varying the Si/Al ratio and/or the exchangeable cation, the distribution and strength of acid sites can be varied considerably.[3] Metal oxides are also widely used as oxidation catalysts.[15] Usually, the catalyst and conditions are chosen to achieve selective partial oxidation, e.g., V_2O_5, Cr_2O_3, MoO_3, and WO_3 catalyze conversion of hydrocarbons to aldehydes, ketones, and acids. These metal oxides are often used in combination, e.g., as the catalyst used along with NH_3 in the selective catalytic reduction of NO and NO_2 to N_2, a redox reaction for pollution abatement.[9] Although often referred to as metal oxide catalysts, many petroleum hydrodesulfurization catalysts, e.g., alumina-supported cobalt-molybdate or nickel–molybdate, are actually closer to metal sulfide or hybrid oxide–sulfide catalysts because they are active only when properly sulfided.[11]

Acid–Base Catalysts

As mentioned in the preceding section, some zeolites exhibit appreciable surface acidity, which makes them useful for reactions involving carbonium (or carbenium) ions, e.g., cracking, isomerization, and alkylation. The widely used low Al content zeolite HZSM-5 has sites with very high proton donor strength at high temperature. Other solid very strong acid catalysts include sulfated zirconia and SbF_5 adsorbed on silica–alumina.[3] Chlorinated or fluorinated alumina, H_3PO_4-treated clays, and certain polymers, e.g., porous cross-linked poly(styrenesulfonic acid), are examples of more conventional solid acid catalysts.

The essential feature of base catalysis is formation of carbanions. Compared to acid catalysts, solid base catalysts are not as widely used commercially, but can be active for alkylation, condensation (oligomerization), isomerization, and dehydrohalogenation.[12] Common base catalysts are alkali metal oxides, carbonates, and hydroxides, as well as alkaline earth metal oxides.

CATALYSIS FUNDAMENTALS

Pore Structure and Surface Area

Although there are a few processes utilizing nonporous catalysts, e.g., ammonia oxidation over platinum wire gauze, most solid-catalyzed reactions are conducted over porous catalysts because such catalysts provide high surface area per unit mass (or volume). The latter usually consist of a porous support upon which is dispersed the catalytically active material. Such supported catalysts are especially used when the active material is very expensive, e.g., platinum, and a high dispersion is desired or when it would be hard to prepare a stable, high surface area unsupported version of the active material, i.e., most metals. Porous catalysts are often semiamorphous and have a rigid sponge-like structure with a complex network of interconnecting pores of various shapes and sizes. However, for simplicity, such pores are often modeled as being long cylinders of uniform diameter, $\bar{d}$, which can be roughly related to surface area, S_A, and pore volume, V_P, via $\bar{d} = 4V_P/S_A$. In reality, there is generally a distribution of pore sizes consisting of macropores ($\bar{d} > 50$ nm), mesopores (2–50 nm), and micropores (<2 nm). Some porous catalysts may be crystalline, e.g., zeolites, with well-defined micro- or mesopore structures.[16] Typical values for pore volume and surface area are 0.2–0.6 cm^3/g

and 25–300 m^2/g, respectively, but zeolites and activated carbons can have measured surface areas exceeding 1000 m^2/g.

Adsorption Isotherms

Unlike in the bulk of a solid, there is a lack of balance in the attractive forces at the surface. The unbalance can be relieved by attachment of molecules from a contacting fluid, i.e., by adsorption. ''Physical adsorption'' involves weak, e.g., van der Waals, interactions and resembles condensation. In contrast, ''chemisorption'' involves the formation of a chemical bond between the solid and the adsorbing molecule and generally occurs only at specific sites.[17] The equation relating the equilibrium extent of adsorption to the adsorbate partial pressure at constant temperature is called an ''adsorption isotherm.'' One of the simplest is the Langmuir isotherm, which attempts to describe single-layer physical adsorption on an assumed uniform surface.[3] It has the following general form: $\theta = K_A P_A/(1 + K_A P_A)$, where θ is the fractional surface coverage, P_A is the pressure of A, and K_A is the adsorption equilibrium constant. The latter is related to absolute temperature T via $K_A = K_0 e^{Q_{ads}/RT}$, where K_0 is a constant and Q_{ads} $(= -\Delta H_{ads})$ is the ''heat of adsorption.'' For chemisorption, θ is replaced by $C_{A,ads}/C_t$, where $C_{A,ads}$ is the surface concentration of adsorbed species A and C_t is the total concentration of potential sites.

The Coupling of Transport Phenomena and Surface Reaction

For a heterogeneously catalyzed reaction to take place the following sequence of events must occur:

1. Transport of reactant(s) through the bulk fluid phase to the exterior of the catalyst pellet.
2. Transport (diffusion) of reactants through the pores to an active site.
3. Adsorption of reactants at the active site.
4. Surface reaction at the active site (sometimes involving several steps and/or multiple sites).
5. Desorption of product(s) from the active site.
6. Transport (diffusion) of products through the pores to the catalyst's exterior.
7. Transport of product(s) into the bulk fluid phase from the exterior of the catalyst pellet.

This sequence is illustrated in Fig. 1. Steps 1 and 7 are typically complicated by the presence of a thin stagnant (laminar flow) fluid layer between the pellet exterior surface and the bulk fluid.

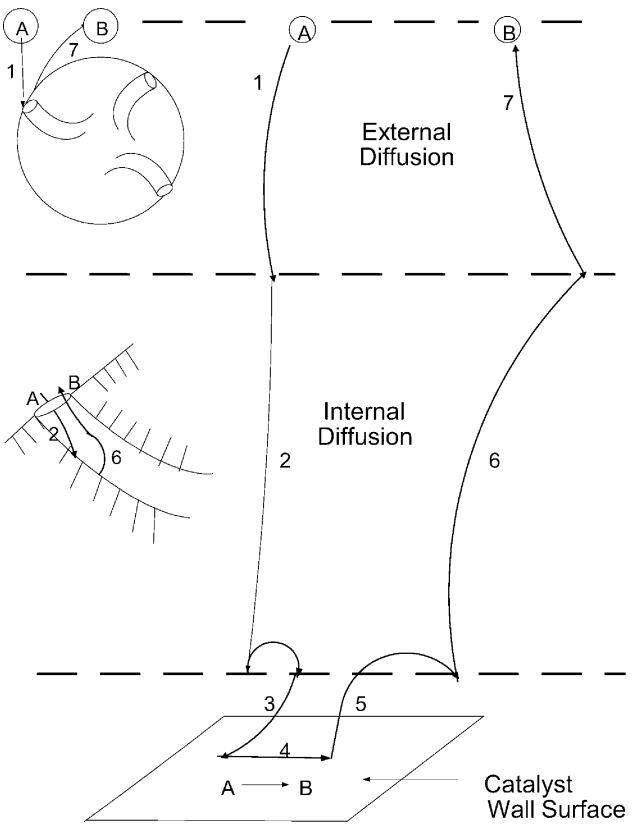

Fig. 1 Overall sequence of steps in a heterogeneously catalyzed reaction. (From Ref.[4].)

An extremely important concept in catalysis is that of the ''rate-limiting step,'' which is analogous to the idea that a chain is no stronger than its weakest link. At steady state the rate of each of the seven steps outlined above must be the same and will be equal to the rate of the slowest step. If external and internal (pore) mass transfer, as well as adsorption and desorption, are rapid enough that surface reaction is rate limiting, the observed rate will be the intrinsic rate, i.e., what the catalytic sites are capable of achieving under the existing conditions. However, if the sites are sufficiently active such that reactants cannot be supplied to them nearly as quickly as the sites could potentially process them, the system is said to be ''mass transfer-limited.'' Because the temperature dependence of surface reaction rate constants (exponential) is much greater than that of mass transfer coefficients or diffusivities (power law), the probability of mass transfer becoming rate limiting increases with increasing temperature. Similarly, it increases with decreasing average pore size and increasing particle size. As a system shifts from surface reaction limited to mass transfer limited, the apparent activation energy decreases appreciably and the apparent reaction order shifts toward first order.[4] When external mass transfer is limiting, the apparent activation energy can be very small, e.g., <8 kJ/mol.

Effectiveness Factor

A measure of the absence of internal (pore diffusion) mass transfer limitations is provided by the ''internal effectiveness factor,'' η, which is defined as the ratio of the actual overall rate of reaction to the rate that would be observed if the entire interior surface were exposed to the reactant concentration and temperature existing at the exterior of the catalyst pellet. A value of 1 for η implies that all of the sites are being utilized to their potential, while a value below, say, 0.5, signals that mass transfer is limiting performance. The value of η can be related to that of the Thiele modulus, ϕ, which is an important dimensionless parameter that roughly expresses a ratio of surface reaction rate to diffusion rate.[4] For the specific case of an nth order irreversible reaction occurring in a porous sphere, $\phi = \sqrt{k' R^2 \rho_c C_{AS}^{n-1} / D_e}$, where k' is the true reaction rate constant based on catalyst mass, R is the sphere radius, ρ_c is the sphere density, C_{AS} is the concentration of reactant A at the exterior, and D_e is the effective pore diffusivity. Figs. 2 and 3 show how ϕ influences the concentration profile within the pellet and η, respectively. Note that when pore diffusion is limiting, η is roughly inversely proportional to ϕ. An ''overall effectiveness factor,'' Ω, that also takes into account external mass transfer may also be calculated.[4]

Although this discussion has focused on mass transfer, heat transfer is also an important consideration, particularly for highly exothermic reactions. In such cases, significant intraparticle and interparticle temperature gradients can occur, with potentially strong effects on rate, selectivity, and stability.[10,18] Criteria have been published for estimating whether mass and/or heat transfer effects can be neglected.[4]

Catalytic Mechanisms and Kinetics

The mechanism of a catalyzed reaction such as A(g) ↔ B(g) + M(g) is the detailed set of elementary steps that show how the reaction is believed to occur on a molecular level, including specifying the rate-limiting step. Various mechanisms may be hypothesized, each generally leading to a different rate expression; thus, only those mechanisms that predict behavior that agrees with experimental results can be considered to be possible true explanations. It is virtually impossible to obtain absolute proof that a given mechanism uniquely describes what actually occurs at the molecular level. The procedure for obtaining a rate equation from a proposed mechanism was first proposed by Hinshelwood based on Langmuir's ideas concerning adsorption; thus, the resulting equation is referred to as reflecting Langmuir–Hinshelwood kinetics.[3] To implement this approach, one must write a rate equation for each of the elementary steps, then use the equations for the non-rate-limiting steps to express surface concentrations, e.g., C_{A^*S}, in terms of more readily measurable fluid phase concentrations, e.g., C_A. The results are then inserted into the rate equation for the rate-limiting step. In effect, the non-rate limiting steps are approximated as being at

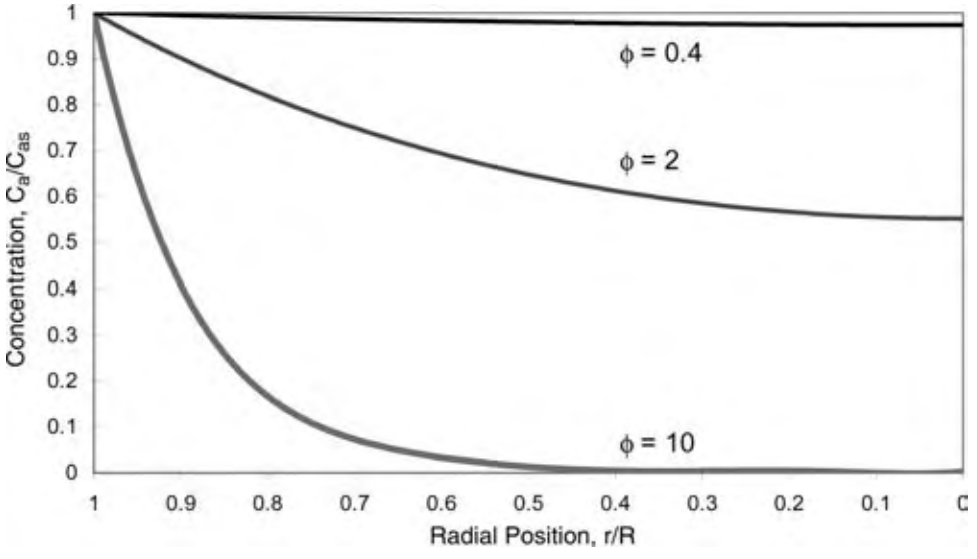

Fig. 2 Concentration profile within a porous catalyst for a first-order reaction. (Cas = concentration of reactant A at exterior surface, R = catalyst pellet radius, ϕ = Thiele modulus.)

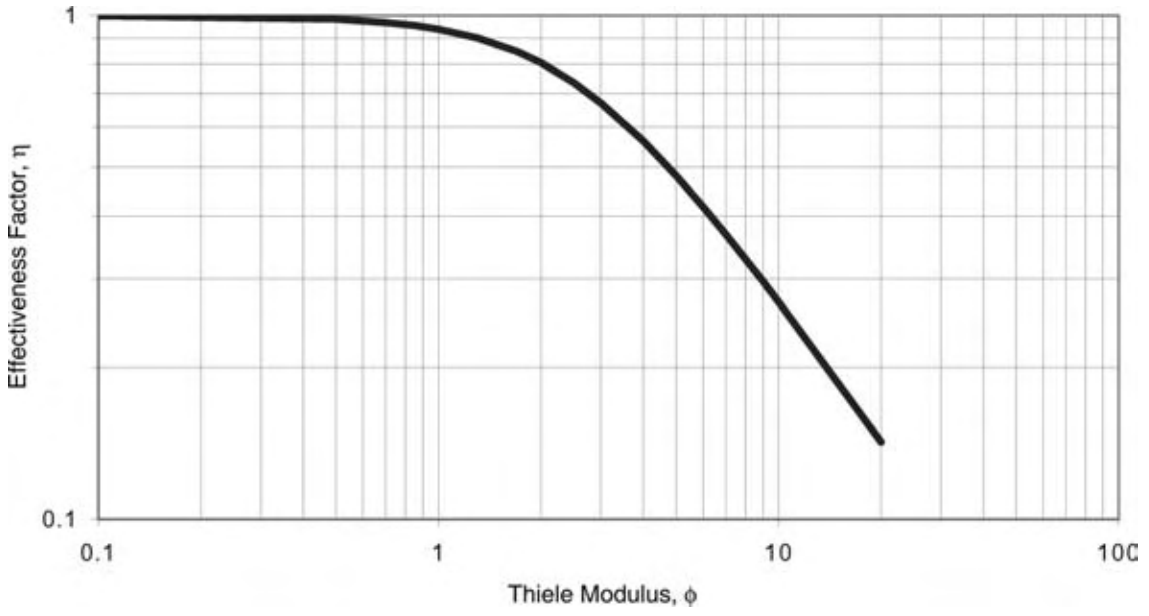

Fig. 3 Effectiveness factor vs. Thiele modulus for a first-order reaction in a spherical catalyst.

equilibrium. As an illustration, consider the following steps where A(g) = gaseous A, S = a vacant site, A*S = adsorbed A, etc.:

1. $A(g) + S \leftrightarrow A^*S$ Adsorption of reactant(s)
2. $A^*S \leftrightarrow B^*S + M(g)$ Surface reaction
3. $B^*S \leftrightarrow B(g) + S$ Desorption of product(s)

If surface reaction is assumed to be rate limiting and irreversible (and no adsorbed inerts are involved), the overall rate expression for consumption of A becomes $-r_A = kK_AC_A/(1 + K_AC_A + K_BC_B)$, where k is the surface reaction rate constant and K_A and K_B are adsorption equilibrium constants. If the surface is only sparsely covered, i.e., $K_AC_A + K_BC_B \ll 1$, this can be approximated as simply $-r_A \approx kK_AC_A = k'C_A$. This illustrates how a simple power law rate expression can apply, under some circumstances, for what is actually a relatively complex mechanism.

Deactivation

Ideally, a catalyst would remain unchanged regardless of time of use, but real catalysts undergo changes that lead to decreased activity and/or selectivity. There are three general categories (causes) of catalyst deactivation.

The first is ''poisoning'' in which small concentrations of impurities in the feed stream strongly adsorb on previously active sites, making these sites inactive. Usually, poisoning is irreversible, e.g., traces of heavy metals such as lead permanently deactivate supported noble metal catalysts used for many processes. In some cases a limited extent of poisoning is intentionally performed to optimize the selectivity of a catalyst for a particular product or reaction. One example of this is the presulfiding of petroleum reforming catalysts using H_2S to suppress undesired hydrogenolysis while only marginally affecting the desired dehydrodecyclization and isomerization reactions.

The second mode of deactivation is ''sintering,'' which denotes loss of surface area owing to crystallite growth. One type of sintering that often occurs for catalysts used at very high temperatures involves collapse of pores. Another type involves agglomeration of the original highly dispersed small clusters of active metal into a smaller number of larger clusters of lower dispersion. This can occur during regeneration of coke-deactivated catalysts if the burning of coke is not carefully controlled. In some cases, in situ methods have been developed to redisperse large clusters, but often extreme sintering requires replacement of the catalyst.

The third form of deactivation is called ''fouling'' or ''coking'' and refers to the formation of high molecular weight carbonaceous species (residues) that cover active sites. Depending on the hydrocarbon feedstock, catalyst, and conditions involved, the ''coke'' may range from graphitic to tar-like. The most common method for regeneration of coked catalysts is controlled combustion, but in some cases high-temperature steam or H_2 treatments have been used.

Various attempts have been made to mathematically model deactivation in a manner similar to that used for reaction kinetics, i.e., to express the rate of change in activity in terms of factors such as temperature, activity,

and concentration of relevant species.[4,19] These models are usually totally empirical, but are useful in predicting the decline in activity with time on stream. Such information can be used to guide the changes in operation, e.g., gradual raising of temperature, needed to compensate for deactivation if a fixed production rate is to be maintained.

CATALYST PREPARATION

Although both the number of applications for heterogeneous catalysis and the body of fundamental knowledge concerning catalysts have increased considerably over time, catalyst preparation still involves a major element of ''art'' (as opposed to ''science''). Because of the sensitivity of catalyst performance to subtle differences in preparation and/or pretreatment, achieving reproducible results for successive batches of catalyst, i.e., good quality control, can be a major challenge, requiring extreme attention to detail. Among the numerous techniques for making solid catalysts, some of the most common are briefly described below. Details concerning these and other methods can be found elsewhere.[6,10,16,20]

Impregnation

This involves first contacting the preformed support (carrier) with a solution, usually aqueous, containing the active metal(s) in the form of a readily decomposable salt, e.g., $Fe(NO_3)_3$, H_2PtCl_6, etc., then performing a series of additional steps. These include: 1) removing excess impregnating solution by filtration; 2) drying in air at, say, 120°C to remove solvent from the pores; 3) calcination (sometimes in an inert atmosphere, sometimes in air) at a sufficiently high temperature, e.g., 500°C, to complete removal of the solvent and to decompose the salt, and, in some cases; 4) pretreatment of the calcined catalyst, e.g., reduction using H_2 to ''activate'' the catalyst. ''Incipient wetness'' is a special form of impregnation in which only just enough solution is used to completely fill the pores. Usually, a nearly uniform distribution of the active component(s) within the porous support is desired and achieving this often requires not only allowing sufficient time for complete penetration by the solution, but also adjusting factors such as pH to avoid preferential deposition near the pellet exterior. Likewise, drying must be gradual to avoid unwanted redistribution (migration) of the active species. Because of the nature of certain reactions, some catalysts are prepared with the active phase intentionally nonuniformly distributed, e.g., ''egg-shell'' structured catalysts that have nearly all of the catalytic metal sites in the outer region of a porous support granule.[10]

Coprecipitation

In this method, the active component(s) and the support are made together by rapidly mixing concentrated solutions of the appropriate salts (plus an agent such as NH_4OH to induce precipitation), followed by filtration/centrifugation, drying, calcining, etc., as described above. Control of pH and agitation during precipitation is important for producing a relatively uniform particle size. This method can generally produce a catalyst with a higher ''loading,'' i.e., surface concentration, of active sites than can impregnation. Sol–gel processing is a technique that may be considered a special case of coprecipitation. Here, typically, a metal alkoxide undergoes hydrolysis/condensation to form a colloidal suspension (sol), which next undergoes further condensation to a wet gel, then conversion to a dry porous solid by extraction/evaporation of solvent.

Catalyst Forming

Most commercial catalysts are used in the form of either spheres or cylindrical pellets of 1–6 mm diameter, with the cylinders typically having a length to diameter ratio ≤ 3. There are three main methods that are used to form such shaped pellets from the irregularly shaped catalyst particles obtained via precipitation or from the powdered alumina, silica, etc. used in making the support for an impregnated catalyst.[6,12]

The first method is tableting (or pelletization), in which powder is mixed with plasticizing agents and die lubricants, e.g., stearic acid, and compressed in a die. A second method is extrusion, where a thick paste of powder and liquid is extruded through a die with many holes, yielding spaghetti-like strands that are subsequently cut into short cylinders, then dried, calcined, etc. Small amounts of clay, stearates, etc., are often added to facilitate extrusion and/or add strength to the formed pellet. The third method is granulation (or tumbling), which is usually used to obtain spheres. Most lubricating agents used in any of these methods are removed by calcination.

The conditions used for pellet forming can have a major influence on several important catalyst properties, including pore size distribution, pellet strength, and abrasion resistance. Both the size and shape of catalyst pellets affect the pressure drop across a packed bed reactor and also, as indicated earlier, affect the Thiele modulus and thus the effectiveness factor. Recently, monolith catalysts have begun to be used in circumstances where low-pressure drop and/or

enhanced heat transfer are important. One example is the use of monolith versions of the ''three-way'' catalyst used in automobile catalytic converters.[4,10] Monolith catalysts generally consist of an inert preformed ''honeycomb'' with many parallel channels that have had a washcoat of active powdered catalyst deposited via contacting with a slurry.

CATALYST CHARACTERIZATION

There are numerous properties that can affect the overall performance, i.e., activity, selectivity, deactivation, and durability, of a catalyst. As a result, full characterization of a catalyst requires using a wide variety of analytical/testing techniques.[21] These can be roughly sorted into three categories, corresponding to the general type of property studied. The following listing is not an exhaustive one, but includes most of the commonly used methods. More detailed information is available in the literature.[6,10,12,22]

Bulk (Nonsurface) Chemical Properties

1. Atomic absorption spectroscopy and inductively coupled plasma can be used for analysis of elemental composition.
2. Infrared, visible, and ultraviolet spectroscopy can determine bonding features, and thus structure.
3. X-ray diffraction can determine the crystal phases present and their average size.
4. Electron dispersive spectroscopic analysis can be used to determine the variation of composition over a cross section of a pellet.
5. X-ray fluorescence and electron diffraction (during electron microscopy) can determine particle composition and structure.
6. Nuclear magnetic resonance can determine the chemical environment of some elements.
7. Temperature-programmed reduction can determine the oxidation state of reducible species.
8. Extended x-ray fine structure analysis can determine the identity, coordination number, and distance of atoms surrounding a given element.

Surface Properties

1. X-ray photoelectron spectroscopy, Auger spectroscopy, and secondary ion mass spectroscopy are sophisticated techniques for determining the chemical nature of surface and ''near-surface'' layers.
3. Fourier transform infrared spectroscopy (FTIR) and attenuated total reflectance spectroscopy can give information on adsorbed species.
4. Physisorption of gases, e.g., N_2 or Ar, commonly referred to as the BET (Brunauer–Emmettt–Teller) method, can determine the total surface area.
5. Chemisorption of gases such as H_2 and CO can determine the surface area of specific reduced metal surface species (and thus the dispersion and average cluster size).
6. Temperature-programmed desorption (TPD) can determine the identity of adsorbed species.
7. Chemisorption of gaseous bases, e.g., ammonia or pyridine, followed by adsorption microcalorimetry, FTIR, and/or TPD, can determine the concentration, ''strength,'' and type of surface acid sites.
8. Steady-state isotopic transient kinetic analysis can determine the concentration and ''relative strength distribution'' of active sites.
9. Electron microscopy can reveal surface topography and structure.

Bulk Physical Properties

1. Mercury porosimetry (for macropores) and BET N_2 physisorption (for micro- and mesopores) can determine both the total pore volume and the pore size distribution.
2. Pellet crushing tests can determine compression strength.
3. Pellet tumbling tests can determine attrition loss, related to abrasion resistance.
4. ASTM fluidized bed and jet cup attrition tests can determine the attrition properties of powdered/pelleted catalysts.

IMPORTANT CATALYTIC PROCESSES

Because of page constraints, this section must be limited to only a handful of the many important processes in which heterogeneous catalysis plays an indispensable role. The coverage is merely intended as an introduction to the general features, e.g., feedstock(s), product(s), catalyst(s), and operating conditions. In addition to references cited under specific topics, Pines' book deals with a wide variety of reactions.[23]

Catalytic Cracking

In terms of throughput, catalytic cracking is the largest industrial catalytic process. Because the catalyst rapidly deactivates owing to coke formation, either

fluidized or moving bed reactors are used. These allow continuous regeneration by tightly controlled burning of coke off the catalyst (in a separate reactor). The feedstock is typically gas–oil (230–540°C boiling range) and the products are high-octane gasoline, middle distillate, and lower molecular weight olefins and paraffins. A typical catalyst used is a rare earth-stabilized Y zeolite imbedded in an amorphous silica–alumina binder. Operation is essentially at atmospheric pressure and the temperature range is normally 480–540°C.[3,10–12]

Reforming

As the name implies, the main purpose of reforming is to rearrange the molecular structure of naphtha to convert it to high-octane number gasoline. Secondarily, it also is a net producer of aromatics and hydrogen for use elsewhere in the refinery. The usual feed is heavy naphtha (95–205°C) consisting primarily of C_6–C_{11} paraffins and naphthenes. The increase in octane number results from isomerization of *n*-paraffins to branched paraffins, dehydrocyclization of paraffins to naphthenes and aromatics, and dehydrogenation of naphthenes to aromatics. The complex network of reactions involved requires that the catalyst be bifunctional, with the supported metal sites that are active for hydrogenation/dehydrogenation acting in concert with the acidic chlorinated alumina sites that are active for isomerization. The most commonly used catalyst is bimetallic Pt–Re/Al_2O_3 with 0.3–0.6 wt% of each metal and 0.7–1 wt% Cl.[8] Presulfiding fresh catalyst with H_2S is performed to add a trace surface concentration of S that suppresses undesired hydrogenolysis, but afterward the S content in the feed must be kept quite low, e.g., 1 ppm. Usually, several fixed bed adiabatic reactors are used in series, with interreactor heating to maintain temperature in the 480–520°C range. Pressure is typically 1–2 MPa and H_2 is introduced with the feed to minimize coking.[3,7,10–12]

Steam Reforming of Hydrocarbons

Steam reforming is a process in which either natural gas or naphtha is reacted with steam to produce H_2, CH_4, CO, and CO_2. After the initial formation of CO and H_2 from naphtha and steam, the primary reactions are the same as for natural gas feed, i.e., $CH_4 + H_2O \leftrightarrow CO + 3H_2$ and $CO + H_2O \leftrightarrow CO_2 + H_2$. The latter reaction is the water-gas shift. The conditions used depend on both the feed and the intended primary product, e.g., H_2 vs. "synthesis gas" (a mix of CO and H_2) vs. CH_4 (from naphtha).[6,11,12] For hydrogen production from methane the typical conditions are 800–850°C, 1–4 MPa, 5 mol H_2O/1 mol C in the feed. The catalyst used is normally Ni/NiO on a CaO–Al_2O_3 support. This is the main process for hydrogen production and will become even more important as H_2 usage grows for applications such as fuel cells and desulfurization.

Ammonia Synthesis

Because of the use of NH_3 in the production of fertilizer and explosives, ammonia synthesis is one of the most important large-scale catalytic processes. The reaction, $N_2 + 3H_2 \leftrightarrow 2NH_3$, is catalyzed using a magnetite, Fe_3O_4, catalyst with several promoters added, e.g., Al_2O_3, K_2O, CaO, MgO. Under the conditions normally used, i.e., 430–480°C, 15–30 MPa, conversion per pass through the catalyst bed is generally less than 80% of the equilibrium value, thus NH_3 is condensed downstream and unreacted H_2 and N_2 are recycled.[6,11,12]

Ethylene Epoxidation

Direct partial oxidation of ethylene over a supported silver catalyst accounts for essentially all of the very large quantity of ethylene oxide produced for subsequent use in making ethylene glycol (antifreeze), polyester fibers, polymers, and various chemicals. In addition to being industrially important, it is one of the most interesting reaction/catalyst systems because no other metal is even remotely comparable to Ag in terms of selectivity and because no other olefins appear to undergo similar reactions on any metal, including Ag.[3,10] The catalyst used is 10–15 wt% Ag on a low-area ($<1\,m^2/g$) α-Al_2O_3, the temperature is 230–280°C, and the pressure is 1–3 MPa. The reaction is believed to occur via a Rideal mechanism in which $C_2H_4(g)$ reacts with a previously adsorbed diatomic oxygen ion to form an activated complex, which subsequently splits at the O–O bond to give $C_2H_4O(g)$ and an oxygen atom adsorbed on Ag.

CONCLUSIONS

For at least the first half of the 21st century the world will continue to rely heavily on petroleum and coal as fuels and as hydrocarbon sources for use in making polymers, etc. Improved versions of existing catalysts, as well as new catalysts/processes, will be vital in making an orderly transition from reliance on nonrenewable resources. Included in this will be the continued development of practicable fuel cell technology and processes for synthesizing clean fuels from coal, tar sands, etc. Catalysis will play a role in the shift toward increased use of renewable/recycled materials and in efforts to minimize air pollution. Catalysts that mimic

biological systems will be developed for use in the pharmaceutical industry and elsewhere.[24] As in the past, improved instrumentation and fundamental understanding will undoubtedly evolve as catalysis meets the challenges of the future.

High-Pressure Reactor Design

Joseph M. Lambert, Jr.
Steven C. Hukvari
Parr Instrument Company, Moline, Illinois, U.S.A.

INTRODUCTION

Specific design criteria allow for the manufacturing of vessels and reactors that can be used safely at elevated temperature and pressure. The design criteria and testing of these vessels and reactors are governed by the American Society of Mechanical Engineers (ASME) code. Allowances need to be made for corrosion, welding efficiency, and connections. Complete designs also include provisions for agitation, heating, cooling, and control of the high-pressure reactor.

Many chemical processes are conducted at elevated pressures, particularly those processes that involve a reduction in the number of moles present as the reaction proceeds (e.g., hydrogenation) and those that benefit from increased solvent effects (e.g., supercritical processing). The safe application of these processes requires adequately designed pressure vessels. Vessels intended for use at elevated pressure need to have sufficient strength to safely contain the pressure. This is achieved by the careful selection of material and providing adequate wall thickness to support the intended pressure at the temperature of application. Numerous bodies of experts have developed such design criteria. The criteria discussed below are primarily that of the ASME.

To achieve the desired pressure containment at elevated temperatures, most pressure vessels are made of metal or metal alloys. Suitable materials must be ductile; that is, the material must expand (strain) with applied pressure (stress). It is important to select a material of construction that is in its ''proportional range'' such that the strain is linear, or proportional, to the stress. In this region, the proportionality is called Young's modulus. At sufficiently high stress (the proportional limit), the strain will be more than that predicted by the linear ratio. Up to this point, the material will return to its original dimensions when the stress is removed. Above the proportional limit, permanent deformation will occur and the material will not completely return to its original dimension when the stress is removed. The yield point of many materials is defined as the stress at which a permanent deformation of 0.2% is measured.

The classic approach to pressure vessel design differentiates between a thin-walled and a thick-walled vessel. The formulas for thin-walled pressure vessels are first-order equations and are easier to rearrange and solve for minimum thickness and maximum stress values. The thick-walled vessel formulas provide the most accurate value for the stresses in the pressure vessel wall, but solving the thin-walled equations provides comparatively accurate results and is, therefore, quite useful for preliminary design estimates.

THIN-WALLED PRESSURE VESSEL CALCULATIONS

The cylindrical shell is frequently used in pressure vessel design. For initial designs, it is useful to calculate the stresses in a thin-walled cylindrical shell that is uniformly loaded with internal pressure. For thin-walled pressure vessel calculations to be valid, the radial stresses in the shell need to be negligible. This is usually taken to be a valid assumption when the ratio of the vessel inner radius to the wall thickness (R/t) is greater than 10.[1]

The stresses in a thin-walled cylinder are divided into longitudinal and tangential components. The longitudinal stress that would tend to make a cylinder longer is generally expressed as one-half the tangential stress. The larger, and therefore more significant, is the tangential stress, the stress that attempts to widen or bulge the cylinder. As might be expected, the stress on a pressure vessel wall, expressed in pounds per square inch (psi), is proportional to the applied pressure and to the size of the vessel, while being inversely proportional to the wall thickness. The tangential stress is expressed as $\sigma_T = PR/t$, where P is the internal pressure (in psi); R is the inside radius of the cylinder in (in.), and t is the wall thickness (in.). For metric calculations, N/mm^2 and mm may be substituted for the English units.

A first level of improved results can be obtained by using the mean radius of the vessel ($R + 0.5t$) in these calculations.[1] Making this substitution leads to the following formula for the tangential stress: $\sigma_T = P(R + 0.5t)/t$. Values obtained from the use of this form of the equation provide stress values within 2% of the values calculated using the more exact thick-walled pressure vessel formulas.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007802

THICK-WALLED PRESSURE VESSEL CALCULATIONS

Generally referred to as the Lamé equations, the equations for a thick-walled cylinder are a continuation of the theory of thin-walled pressure vessels.[2] The thick-walled cylinder is viewed as a collection of thin laminar rings. A series of equations can be derived to find the stresses in a thick-walled cylinder, if the strain variation through the wall is such that all of the rings are in equilibrium and the stresses and deformations are consistent at the boundaries between the rings. This is likely a valid assumption for vessels that are not scaling apart or cracking from the applied stress.

For internally pressurized cylinders, the tangential stress on the outside cylinder wall is $2r_i^2p/(r_o + r_i)t$ and the tangential stress on the inside cylinder wall is $(r_o^2 + r_i^2)p/(r_o + r_i)t$, where r_i is the internal radius, r_o is the external radius, p is the internal pressure, and t is the wall thickness. Because r_o is always greater that r_i, the $(r_o^2 + r_i^2)$ term is always greater than $2r_i^2$. Therefore, the stress on the inside wall is always found to be greater than the stress on the outside wall. For this reason, it is the stress on the inside wall that is used for design calculations.

ASME CODE STANDARDS

A standard is a set of technical definitions and guidelines for designers and manufacturers. A code is a standard that has been adopted by one or more governmental bodies or has been incorporated into a business contract. ASME publishes its standards; accredits users of standards to ensure that they are capable of manufacturing products that meet those standards; and provides stamps that accredited manufacturers place on their products to indicate that a product was manufactured according to the ASME code.

A third-party inspector may be called upon to verify that a pressure vessel has been designed and manufactured according to the requirements set forth in a particular standard. Documentation from these inspections is often required for purchasing or installing a pressure vessel.

ASME PRESSURE VESSEL CALCULATIONS

The ASME code formula for the thickness of a cylindrical shell is listed in UG-27, as $t = PR/(SE - 0.6P)$.[3] In this formula, t is the minimum thickness of the shell (in.), P is the maximum allowable working pressure (MAWP) (psi), R is the internal radius of the vessel (in.), S is the allowable stress in the material listed in ASME Section II, and E is the weld joint efficiency. The allowable stress, S, includes a variety of factors including ultimate tensile strength of the material, the yield values of the material, and a safety factor to prohibit the possibility of underdesigning. ASME code permits the use of this formula until t exceeds $0.5R$.

The structure of this formula can quickly be related to the thin-walled pressure vessel cylinder equation. Using the equation that calculates the stress at the center of the vessel wall, $\sigma_T = P(R + 0.5t)/t$, and rearranging to solve for the thickness, results in $t = PR/\sigma_T - 0.5P$. The addition of the weld joint efficiency, E, and changing the coefficient before P to 0.6 results in the ASME code formula, $t = PR/(SE - 0.6P)$, which they feel best represents the minimum wall thickness required to contain an internal pressure, P, in a cylindrical vessel having a radius, R, and made of a material with an allowable stress, S.

A comparison of the equations developed above is shown in Fig. 1. Each of the four formulas, referred to as Thin-1, Thin-2, ASME, and Thick-walled, were used to evaluate the stress on the walls of the same hypothetical pressure vessel (with a radius of 2 in. and a pressure of 1000 psi) at various wall thicknesses between 1/8 and 7/8 in. The resultant stresses for the first three formulas were then normalized to the calculated thick-walled vessel stress and plotted to demonstrate the relative accuracy of the various methods.

ASME FORMULA FOR ELLIPSOIDAL HEADS

The ASME design formula from UG-32 for ellipsoidal heads having a major-to-minor axis ratio of 2 : 1 and being subjected to pressure on the concave side is $t = PD/(2SE - 0.2P)$, where t is the minimum thickness of the head (in.), P is the MAWP (psi), D is the internal diameter of the major diameter of the ellipsoid (in.) (and equal to the inside diameter of the vessel), S is the allowable stress of the material, as listed in ASME Section II, and E is the weld joint efficiency.[3]

ASME FORMULA FOR CIRCULAR FLAT HEADS

The ASME design formula from UG-34 for circular flat heads subjected to internal pressure is $t = d(CP/SE)^{1/2}$, where t is the minimum thickness of the head (in.), d is the internal diameter of the vessel (in.), P is the MAWP (psi), S is the allowable stress in the material listed in ASME Section II, and E is the weld joint efficiency.[3] The value of C ranges from 0.10 to 0.75 depending on the method of attachment of the head and the shell dimensions. For preliminary designs, a value of 0.33 for C will lead to a good approximation of the required head thickness.

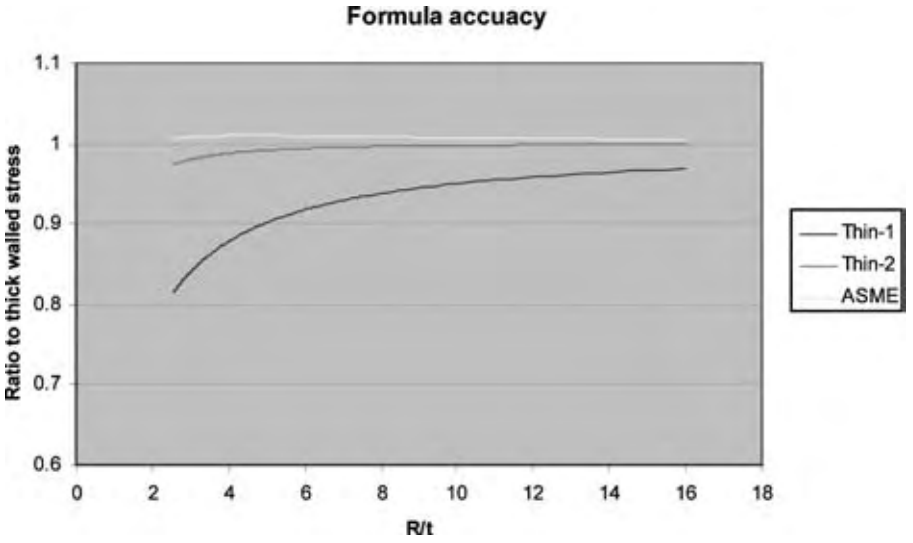

Fig. 1 Comparison of pressure vessel design formulas. (Equation Thin-1 is $\sigma_T = PR/t$; Equation Thin-2 is $\sigma_T = P(R + 0.5t)/t$; ASME equation is $\sigma_T = P(R + 0.6t)/t$, assuming a weld efficiency of 1). *(View this art in color at www.dekker.com.)*

Closures between heads and cylinders, often taking the form of clamps, split rings, or bolts, are also an important consideration in the proper design of the pressure vessel, for it is these components that must hold the vessel head to the cylinder. It is important to recognize the force that is exerted on the closure. For example, in a 1000 psi vessel, a circular head with a diameter of 12 in. will have over 110,000 lb of force pushing on it. This force must be evenly divided between bolts or spread out over the clamp or split ring closure.

ASME VALUES FOR ALLOWABLE STRESS

ASME publishes allowable stress values for materials in Section II, part D. Values for all ASME approved materials are listed in tabular form for operating temperatures ranging from −20°F to the maximum allowable working temperature of that material. These values are constantly under review and periodically change when better information is available. The basis for determining the tabulated stress values at a specific temperature is using the lesser of the tensile strength of the material divided by 3.5 or the yield strength divided by 1.5. Additional factors such as creep strength are considered by ASME materials committees and are factored into the final published values in the tables. The exact values of these derating factors used to calculate the final stress values are proprietary to ASME. Examples of allowable stress values are shown in Table 1.

Prior to the publication of the 1999 addenda to the ASME Boiler and Pressure Vessel Code, the criteria for determining the tabulated stress values at a specific temperature was based on the lesser of the tensile strength of the material divided by 4 or the yield strength divided by 1.5, commonly stated as the lesser of one-fourth the tensile or two-thirds the yield. The minimum value for the hydrostatic test pressure was 1.5 times the MAWP, corrected for temperature. In 1999, an increased confidence in material manufacturers and their testing programs prompted the ASME Materials Committee to rework all of the published allowable stress values based on the tensile strength of the material divided by 3.5 rather than 4. A consequence of this change was the reduction of the hydrostatic test multiplier from 1.5 to 1.3.

It is now common to hear it expressed that the "ASME code imparts a $3\frac{1}{2}$-to-1 safety factor." It is often common, in addition, that users of pressure reactors tend to impart their own safety factor of 2 or 3, so that the resultant vessel is designed with an overall safety factor of 10. Not only is such a vessel overdesigned, but it leads to operational difficulties such as excessive weight, high closure torque requirements, increased number of bolts, and poor heat transfer rates through the unnecessarily thick walls.

Table 1 Allowable stress values for selected materials

	Allowable stress (psi)		
Temperature (°C)	T316 SS	Alloy C-276	Titanium (Gr2)
0	20,000	27,300	14,300
100	20,000	27,300	12,136
200	19,412	27,300	8,912
300	17,280	25,676	6,780
400	16,092	23,484	316°C max.
500	15,472	22,472	

(From Ref.[3].)

STANDARD HYDROSTATIC PROOF TEST

The ASME code (UG 99) requires a hydrostatic test of each pressure vessel to validate the design, materials, and construction before that vessel is put into service. The minimum value for the test pressure is 1.3 times the MAWP, corrected for the temperature at which the test is conducted. This temperature correction is the ratio of the stress value at the hydrostatic test temperature (usually room temperature) to the stress value of the material used in the design formulas, usually at the maximum allowable working temperature of the pressure vessel. To conduct the test, water is pumped into the vessel to increase the internal pressure to the level of the test value and then released.

For example, a T316 stainless steel vessel designed for use at up to 1000 psi at 300°C needs to be hydrostatically tested at room temperature to a pressure of (1000) (1.3) (20000/17280) or 1505 psi. The room temperature and 300°C stress values of 20,000 and 17,280 psi, respectively, are found in Table 1.

ALTERNATIVE PROOF TESTS TO ESTABLISH MAWP

Recognizing that some reactor designs may be impractical or very difficult to completely validate with design formulas, ASME UG-101 offers alternative methods, such as using strain gages, deflection measurements, or pressurizing a vessel to failure, to determine the MAWP.

The strain gage and deflection methods require the vessel to be pressurized and then released at successively higher pressures until a permanent deflection of 2% is measured. The MAWP of the vessel is established by dividing this test pressure by 2.5.

In another type of deflection testing, the vessel is pressurized with water to the test pressure and then released. This procedure is repeated three times. The outside diameter of the vessel is measured and recorded at each successive increase and release of pressure. A vessel is considered to have passed the test if it expands to the same dimension each time it is pressurized and contracts to the same original dimension each time the pressure is released.

Another acceptable method of establishing the MAWP for a vessel is to pressurize it until it bursts. This burst pressure is divided by 5 to calculate the MAWP of the design.

The permanent deflection and burst methods of these alternative testing procedures are typically conducted at room temperature and, hence, provide maximum allowable pressure ratings for a vessel when used at room temperature. The corresponding pressure rating at an elevated temperature may be established by multiplying the calculated room temperature rating by the ratio of the stress value of the material at the maximum allowable working temperature of the pressure vessel divided by the stress value at room temperature. A vessel rating established by this method is only applicable for that specific design. Any alteration or subsequent changes to the design would require repeating the pressure tests to validate the new design.

WELD JOINT EFFICIENCY

Welding may be required on pressure vessels to construct seams or attach heads, nozzles, and flanges. External jackets for heating and cooling may also be welded to the main chamber of a pressure vessel. The value of the weld joint efficiency, E, is governed by the type of weld and the extent of radiographic examination of the weld. Radiography is a nondestructive examination of welds using x-rays to discover discontinuities or defects within the weld. Double-welded butt joints, for example, have an efficiency of 1.0 when they are fully radiographed but an efficiency of only 0.7 when no radiography is done.

Vessels can be designed with thinner walls when full radiography is performed to give a weld joint efficiency of 1.0. Conversely, the cost of radiographic examination can be traded for the increased cost and weight of a thicker vessel having a weld joint efficiency of 0.7. Such trade-offs need to be considered early in the design process. Welds that fail the examination must be reworked and retested.

The weld joint efficiency values of various types of welds are tabulated in ASME UW-12. The design of welded vessels should also take into account the capability of the prospective welders as well as the limitations of the existing welding procedures. New material combinations or variations in material thickness may require welding procedures to be revised and requalified. The person performing the welding needs to be certified for each material and procedure. Welding processes used for pressure vessel fabrication are usually gas tungsten arc welding (GTAW) and submerged metal arc welding (SMAW). Both of these processes are compatible with a wide variety of metals.

CRYOGENIC APPLICATIONS

Materials such as austenitic stainless steels, nickel-based alloys, and titanium alloys can be used as materials for pressure vessel components in cryogenic applications at temperatures as low as −200°C. Alloy steels have brittle transition points making their impact properties at low temperatures unsuitable for pressure applications. Closures and bolts must also be made of materials that remain ductile at low temperatures.

Gaskets made of polytetrafluoroethylene (PTFE) or silicone are commonly used in cryogenic applications.

TYPES OF LOADING TO CONSIDER, ASME UG-22

The design of laboratory reactors and similarly small vessels can be completed with consideration of only the effects of internal pressure. As vessels and tanks get larger for full-scale operations, the design must also consider the effects of additional external loads. Typically, these factors need to be included in vessels larger than 40 L. These loadings include:

1. The weight of the vessel and its contents.
2. Static loading from attached piping, insulation, internals, or external supports.
3. Dynamic loading due to pressure or thermal variations.
4. Wind, snow, and seismic loading.
5. Impact from water hammer shock during filling or draining.
6. Stresses induced by thermal gradients and differential thermal expansion.

SEALING

Three types of seals are commonly used to attach heads and wide ports to pressure vessels: flat gaskets, O-rings, and angled metal gasket seals. Flat gasket sealing surfaces are easy to machine and can be used with a variety of sealing materials. Lower-temperature flat gasket seals are often made of PTFE. Higher-temperature seals can be made of flexible graphite and can be used for temperatures in excess of 600°C. Both PTFE and flexible graphite have excellent chemical resistance properties. Soft metals, such as copper, nickel, or silver, can also be used in flat gasket designs.

Flat gasket seals must be preloaded with a force equivalent to the force that will be exerted by the pressure within the vessel. A flanged bolt closure or split ring bolt closure design can be used to achieve this preload. Closure bolts should be evenly tightened to a specified torque that will provide the proper closing force.

Grooves for O-ring seals can be machined into the head and cylinder walls of a pressure vessel to produce a gland type of seal arrangement. O-ring seals such as this do not require a preload on the closure parts, thus making assembly and disassembly of the vessel quicker. The elastomers used in O-ring seals introduce temperature and chemical compatibility restrictions. Practical temperature limits for O-ring seals are 150°C for NBR (Buna-N) and 225°C with FKM (fluorocarbon) material. Perfluoroelastomer (FFKM) material may not only increase the temperature limit to about 275°C, but also significantly increase the cost of the seal. The chemical compatibility of specific O-ring compounds should be checked against the reactants, intermediates, products, and by-products expected for each vessel application.

High-temperature reactions, incompatible with flexible graphite seals, may be sealed with angled metal gaskets. The preloading forces needed to deform and seal this type of gasket are significantly higher. These gaskets are best applied to smaller-diameter vessels where they are easier to install, tighten, and seal.

INTERNAL STIRRING

Internal stirring enhances many reactions.[4] Flat or pitched blade turbine impellers are typically used for good general mixing. Multiple turbine impellers are often employed, positioning one near the bottom of the vessel and the other at the vortex of the mixing liquid. Turbine impellers are typically sized to have a diameter of 30–60% of the diameter of the vessel in which they are used. Fluids with a high viscosity, above 50,000 cP, could benefit from anchor-type stirrers that slowly mix the vessel contents from the walls inward. Spiral stirrers are often used to keep heavy suspensions properly mixed. Gas entrainment impellers with hollow shafts are used in systems where high revolutions per minute can be obtained and there is a need for recirculating headspace gas into the liquid. Gas dispersion impellers are used to prevent gases introduced through a bottom sparge ring from traveling up the center shaft and avoiding contact with the bulk liquid.

Internal baffles are used to improve mixing in fluids that tend to rotate along with the impeller rather than being mixed. Baffles reduce the flow of fluids to speeds much lesser than that of the impeller. This increase in shear provides additional turbulence leading to improved mixing of the fluids. Baffles are typically designed to have a width of 1/12 to 1/10 of the vessel diameter and are located slightly off of the internal vessel wall to prevent accumulation of the material.

To prevent leakage and loss of pressure, a seal must be made between the vessel and the rotating agitator shaft. This seal can be made either with a magnetic coupling or with a mechanical seal.

Magnetically coupled drive mechanisms have a set of inner magnets located atop the impeller shaft that extends down into the pressure vessel. This inner magnet assembly is positioned so that it can be rotated within and be encapsulated by a small pressure vessel chamber. This chamber is made of nonmagnetic material and is attached and sealed to the head of the reactor vessel. This chamber is then surrounded by another set of matching magnets located in an

assembly that is supported in such a way as to permit its rotation with an attached motor. Rotation of the outer magnets will cause the inner magnets also to rotate, thereby providing a rotating shaft sealed to prevent leaking.

Mechanical seals are of two different types: single and double. Single mechanical seals are available in a variety of styles that provide a means of pressing a seal or set of seals against the shaft. Such a seal will ultimately wear off because of friction and high temperature. A means is usually provided to permit continuous or periodic tightening of the seal, such as spring loading or compression loading with a packing nut.

A double mechanical seal employs two seal arrangements, each similar to the single mechanical seal. A fluid, typically oil, is pumped through the region between the two seals. This oil serves the purpose of removing the heat of friction to add life to the seal ring and to create a liquid film to aid in sealing. The oil is pumped into the space between the two seal rings at a pressure slightly higher than the operating pressure of the vessel. This allows the lower seal to function as the primary pressure containment seal. The oil can be monitored for the presence of leaking material and provide early warning of failure. The upper seal prevents the escape of oil and vessel contents to the atmosphere.

ASPECT RATIO

The aspect ratio of a pressure vessel, defined as the ratio of the internal length to the internal diameter, is also important for improved mixing and heat transfer. As important as these factors may be, they must often be balanced with the cost of the pressure vessel. As the diameter of a vessel increases, the thickness of the wall must increase proportionally for safe operation at the same pressure. The heat transfer rate can become limited because of the thicker wall and because of the decreased surface to volume ratio of vessels with larger diameters.

SURFACE FINISH

The inside finish of a pressure reactor is an important physical attribute that can affect its functionality. A smoother surface finish is less conducive to corrosion and is easier to clean. The smoothness of a surface finish is expressed as the roughness average (R_a) of a surface. This is the average of the absolute values of the surface deviations from a centerline of these deviations. The values are typically stated in microinches or micrometers. The roughness is measured with instruments or prefinished sample blocks can be used for comparison. Typical machined finishes can range from 50 to 100 μin. R_a depending on the machining process and tooling used. Mechanical polishing can further smooth the finish to an R_a value of approximately 20 μin. Mechanical polishing may be followed by electropolishing to achieve extremely smooth ($R_a < 20$ μin.) finishes on stainless steel surfaces.[5]

Electropolishing cleans and polishes metals in an electrochemical bath. An electric current passing through the bath dissolves a small amount of metal from the surface of the part being polished, leaving a smooth, highly reflective surface. Electropolishing removes surface impurities and leaves the part passivated. Care should be taken to minimize mechanical scratches and polishing striations before a part is electropolished. These markings become accentuated rather than removed by electropolishing. Metals other than stainless steel may be electropolished, but the special techniques required are not commonly available with most vendors.

Abrasive blasting techniques can be used for large or irregular surfaces provided the abrasive medium is free of contaminants that could become embedded into the metal surface. Internally welded vessels should be finished according to prescribed welding procedures. Wire brushing or grinding should be done with materials compatible to the welded material, and at speeds that will not embed material into the weld.

CORROSION ALLOWANCE, ASME UG-25

Pressure vessels are subject to thinning by corrosion, erosion, or mechanical abrasion. To increase the desired useful life of the vessel, the design should include a suitable increase in wall thickness over the minimum design thickness required for safe pressure containment. In most cases, there is no specific code requirement for how much corrosion allowance a vessel requires. Vessels subject to corrosion should have provisions for complete draining as well as openings to allow for the inspection of internal surfaces.

Corrosion is generally considered to be in one of two forms: uniform or localized. Uniform corrosion occurs evenly on all surface areas of a pressure vessel. Such corrosion occurring at slow rates is quite typical and can be planned for by increasing the original wall thickness design. For vessel systems with a predictable corrosion rate, allowances can be calculated for vessel life spans of 2–20 yr.[6]

Localized corrosion occurs at a particular site, typically because of a breakdown of the passivation protection layer. This can often occur because of anionic attack from chlorides and similarly aggressive components in the vessel. Such localized corrosion is manifested as pitting at various sites across the surface or as crevice corrosion within the material extending beneath the surface.

Additionally, material can lose its alloying, such as when high temperature carbide formation leaches chromium out of stainless steel. This can lead to intergranular corrosion at grain boundaries and to stress corrosion cracking. One means of eliminating or greatly reducing this possibility is to use alloys that are low in carbon content as the material of construction.

Proper selection of the material of construction can avoid many catastrophic corrosion problems. Stainless steel is an excellent choice for many organic acids, but is rapidly attacked by halogen acids. Although readily attacked at elevated temperature, pressure, and concentration, stainless steel offers some protection against sulfuric, nitric, and phosphoric acid at low concentration and ambient temperature.

Sodium hydroxide, even at low concentrations, will cause stress corrosion cracking in stainless steel when subjected to temperatures above 100°C. Caustic solutions are much better handled in alloys with high concentrations of nickel, such as Alloy 400 or Alloy 600. Alloy 400 has also found success in applications involving fluoride, hydrogen fluoride, and hydrofluoric acid.[7]

Alloys rich in nickel, chromium, and molybdenum, such as C-22, C-276, and C-2000, offer the broadest range of corrosion inhibition. The high molybdenum content assists in diminishing corrosion by reducing acids, while the high chromium content assists in diminishing corrosion by oxidizing acids.[8]

Alloy B-3 can tolerate quite high concentrations of hydrochloric acid without severe corrosion, provided the solution is free of oxidizing ions such as Fe^{+3}, Cu^{+2}, Ni^{+2}, Mo^{+6}, and Ti^{+4}.[8] In contrast, hydrochloric acid solutions containing these ions can be easily handled in vessels made of titanium, which would quickly corrode in pure hydrochloric acid. Even low concentrations (<30 ppm) of ferric ion in hydrochloric acid have been demonstrated to greatly reduce the corrosion rate of titanium.[9]

PROCESS CONNECTIONS

Pressure vessels are usually designed with a variety of process connections. Ports for the attachment of valves are included for gas and liquid reagent addition, as well as product sampling and removal. Ports on top of a vessel can also be equipped with dip-tubes to permit access to the bottom of the vessel. Similarly, vessel bottoms can be ported for drain valves or equipped with inverted dip-tubes, usually to act as overflow weirs. Ports are also often provided for the installation of internal cooling coils.

Most pressure vessels are also equipped with a Bourdon-tube, analog pressure gage to indicate the internal pressure of the vessel at all times. This gage can also be used to verify any electronic readings taken by attached electronic pressure transducers. A proper pressure gage would have a usable range of about 1.5 to 2 times the maximum working pressure of the vessel.

Heated or chilled vessels require provisions for measuring the temperature of the vessel contents. Cooling coils, internal or external, can be used in conjunction with heaters to help control and stabilize process temperatures.

A relief valve or burst disk with a rating equivalent to or less than the rating of the vessel is not only a prudent accessory, but is also required by most safety codes. ASME recommends that the burst rating of a safety rupture should not exceed 110% of the MAWP. Rupture disks may be of a prebulged or scored type. Prebulged disks can be operated repeatedly to pressures up to 70% of their rating. Scored disks can be used repeatedly to pressures up to 90% of their rating.

In some cases, the pressure rating of various accessories that might be added to a pressure vessel may be lower than that of the vessel to which they are attached. In such cases, it is common to rate the overall system with a maximum operating pressure that is lower than the vessel's MAWP.

HEATERS

The contents of a pressure vessel are most commonly heated with external heaters. A variety of heater types, watt densities, and mounting techniques are available to the pressure vessel designer.

Clamp-on band heaters, for use up to 700°C, are specified when high-watt densities are required or the external vessel area is limited. Heating elements can be woven into a quartz fabric to permit flexibility and ease of removal. These heaters are typically specified for lower-temperature demands because of their lower watt density. More rigid heater designs employ fully exposed, radiant heating elements or heating elements embedded within a ceramic fiber matrix. The latter are the heater of choice for high-temperature applications.

Electric heating elements can be sealed within aluminum blocks to provide a more uniform heat distribution and a protective measure of safety in hazardous, explosive environments. Cooling channels can also be designed into the aluminum blocks to provide external cooling for the vessel.

External chambers, such as welded jackets, can provide a means for both heating and cooling from external sources such as steam generators or circulating baths. These jackets are themselves pressure vessels and have the same design considerations as the inner vessel.

CONTROL SYSTEMS

Control systems are used to monitor and regulate temperature, pressure, flow rates, stirring speeds, and compositional characteristics in a pressure reactor. Commercially available process controllers can sense and display temperatures and regulate heaters for temperature control. Controllers may also be specified to sense pressure and operate control valves for pressure control, adding reagents or relieving contents. Motor controllers are available for both AC and DC motors. They can vary from those with simple manual adjustment of speed settings to closed loop controllers that will maintain constant revolutions per minute, torque, or power to the motor.

Various types of probes are employed to monitor compositional changes. Among these are pH probes, dissolved oxygen probes, and high-pressure infrared probes. Such probes can be off-line, on-line, or in-line. Off-line probes require that samples be withdrawn from the reactor for analysis. In-line probes are typically installed on a slipstream that can be diverted from the reactor. In-line probes are installed directly into the reactor for real-time monitoring. Signals from the probes are interpreted by probe-specific electronics that, in turn, send a signal to the process controller for possible action.

Integrated microprocessor-based and PC-based control systems require correctly specified and programmed software, as well as an interface system between the process and the computer. Most commercially available control systems are user-configured with appropriate signal conditioning modules that convert the analog process signals into the digital signals acceptable to a computer. Most modules are multichannel boards designed to handle analog inputs, analog outputs, digital inputs, or digital outputs.

CONCLUSIONS

The safe design of a pressure vessel takes into account the strength of the material and the stresses that are imposed on it by internal pressure and exterior forces. The approach to satisfactory design can be best understood with an appreciation of the equations of a thin-walled vessel. Expansion of these concepts to the implications of a thick-walled vessel will lead to the code rules written by the ASME.

This governing body has published proper design equations and assigns allowable stress for each of a variety of materials of construction as a function of temperature. In addition to published formulas for common shapes of pressure vessels, the ASME code also provides methodologies to test irregular shapes by evaluating their point of permanent deformation or their bursting pressure.

The design of pressure vessels must also take into consideration weld efficiency, number and size of openings, and also add additional thickness to allow for controlled corrosion over time and use.

The complete design will also incorporate the aspect ratio needed for stirring or other desired flow paths, special finish as required by the process, and control of the vessel heating and cooling.

Hollow Fiber Technology

Vicki Chen
Pierre Le-Clech
UNESCO Centre for Membrane Science and Technology, School of Chemical Engineering, University of New South Wales, Sydney, New South Wales, Australia

INTRODUCTION

Hollow Fiber technology has transformed the membrane separation processes for over 40 years. By utilizing analogous fabrication techniques to textile fiber spinning, hollow fibers allows extremely large surface areas to be generated for heat and mass transfer within a compact module. The surface of the hollow fiber can be used as a contactor between different phases as well as a selective separation layer for diffusive, adsorptive, reactive, or convective processes. The commercial importance of hollow fiber technology is particularly evident in biomedical, filtration, and gas separation applications. This entry gives an overview of widely used hollow fiber materials, fabrication, modules, and applications. Operational and design issues inherent to hollow fiber modules are identified. New and potential hybrid processes and fiber materials/fabrication are also briefly discussed.

MATERIALS AND FABRICATION

Materials

As shown in Table 1, hollow fiber membranes can be synthetically manufactured from a large number of materials, which are generally classified into two groups, i.e., organic (polymeric) or inorganic (mainly glass or ceramic). The most important class of membrane material, especially for hollow fiber technology, remains the organic polymers. Because of their high impact on the market, polypropylene (PP), polyethylene (PE), polyethersulfone (PES), polyvinyl pyrrolidone (PVP), and polyvinylidene fluoride (PVDF) are the most common materials used for the fabrication of hollow fiber membranes. Supplied by leading membrane companies like Memcor, Mitsubishi Rayon, Asahi, Zenon, and X-Flow, these materials are easily spun and configured into dense and porous hollow fiber formats and are applied in a large range of applications (described in detail in ''Hollow Fiber Applications''). Other organic materials used in the fabrication of hollow fiber include compounds based on cellulose [cellulose acetate (-CA-) and triacetate (-CTA-), regenerated cellulose (-RC-)] and nitrogen [polyamide (-PA-), polyacrylonitrile (-PAN-)]. More recently, some hollow fibers based on material alloys (PES/PVP) and more complex organics (like polyetherimide, polybenzimidazole) are also commercially available or have been studied experimentally.

Although they provide higher chemical and temperature stability, inorganic-based hollow fibers are not as common as organics. Because of their higher production cost, lower permeability, and their tendency to break easily, only few companies, like CEPAration and Schott/Bioran, propose inorganic hollow fiber membrane systems, based on ceramic (aluminum oxide) and glass hollow fiber, respectively. Still, research for new inorganic materials is being carried out; Liu and coworkers[1] worked on the fabrication of orthorhombic perovskite hollow fiber, while Ismail and David[2] recently reviewed carbon-based hollow fiber technology.

Properties

Membrane morphology

Membrane could be configured into two types of geometry. While flat sheet membranes are generally assembled into plate and frame or spiral wound modules, tubular membranes can be externally or self-supported and are subdivided into different categories based on their bore diameter. Different terms and diameter thresholds could be found in the literature.[3,4] However, tubular membranes with a maximum external diameter of around 2 mm and that are self-supporting are generally considered as hollow fibers. Further discussion and comparison based on fouling, cleaning, packing, and capital investment is given for the different membrane configurations in Refs.[4,5].

Membrane morphology (or structure) is generally classified into two groups: porous and dense. Dense fibers utilize the chemical and the physical characteristics of their structure to provide separation depending on the diffusivity or solubility of the solute species. In the case of porous membranes (Fig. 1), internal structure could be symmetric, asymmetric, or composite. Asymmetric membranes feature a very thin active layer, responsible for the separation process, supported

by a highly permeable, nonselective, and porous structure. In the case of composite membranes, those two layers are made from different materials (Fig. 2). For composite membrane, the active skin is usually a very thin (0.1–1 μm) dense layer, which could be located on either the inner or the outer fiber surface, or somewhere in between.[6] Dual layer spinneret could be used; but even if the compounds used in the active layer cannot be extruded into a hollow fiber shape, they are deposited (or chemically cross-linked) on the surface of the support fiber in a post-treatment stage. This process generally results in higher transport rates and lower hydraulic resistances, and therefore to lower operating costs, compared to those of symmetric membrane systems of similar nominal pore size. As a result, most of the academic and industrial research now concentrates on asymmetric or composite structures for hollow fiber materials. Based on a PES support matrix, dual layer asymmetric hollow fibers (Fig. 2) have been fabricated for gas separation with fluoropolyimide, matrimid, and polyimide.[1,7,8]

Thermal and chemical properties

For separation applications using porous membranes like microfiltration and ultrafiltration, the choice of polymeric material does not influence significantly the removal efficiency. However, because some membrane processes are required to operate under extreme conditions (temperature, pH, pressure), the chemical and thermal properties of the polymer must be adapted to a given application. Other important membrane properties like hydrophobicity, wettability, and adsorption are directly dependent on its material. While hydrophilic materials are used for aqueous feeds, hydrophobic polymers are required when gases and organic solvents are separated. For the treatment of aqueous feeds, naturally hydrophobic polymeric materials such as PE, PP, and PVDF are surface modified with some hydrophilic functional groups. The selection of the cleaning agent for a given hollow fiber membrane is also a delicate step in the process design. For example, polyamide (PA) membranes cannot be cleaned with chlorine-based agents, as chemical degradation would occur.

Mechanical properties

As a self-supported cylinder, hollow fiber membrane is required to withstand high transmembrane pressure without collapsing. Modulus of elasticity is a crucial parameter for the calculation of the collapse pressure of a given fiber. With a much more porous overall structure, asymmetric hollow fibers specifically require a high modulus of elasticity to avoid collapse of the

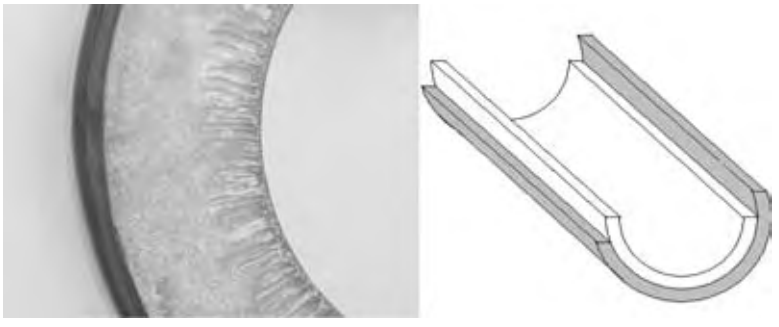

Fig. 2 Fluoropolyimide/polyethersulfone dual layer HF used for gas separation. (Courtesy of T.S. Chung, National University of Singapore.)

filament. For high pressure-driven processes like reverse osmosis, it is recommended to keep the internal diameter of the fibers at the order of magnitude of the fiber wall thickness. However, for microfiltration and uitrafiltration systems, where the transmembrane pressure is much less, the internal diameter can be significantly larger than the fiber wall. This allows for inside-out filtration (without the risk of lumen clogging) and generally reduces the hydraulic resistance offered by the membrane.

Fabrication

Hollow fibers membranes can be fabricated from most of the spinnable materials. Because of their self-supported properties, the dimensions and morphologies of hollow fiber are to be optimized and carefully assessed during the fabrication process. Three preparation methods based on spinning technology could be applied—wet (or dry–wet), melt, and dry spinning. While melt and wet spinning are generally used to obtain dense isotropic morphologies, the dry–wet method (Fig. 3) is the most widely used one as it leads to the formation of almost all membrane morphologies.

During the dry–wet spinning process (Fig. 3), a viscous, degassed, and filtered polymer solution (20–40% w/w polymer) is pumped through the outer bore of the spinneret. A nonsolvent fluid (also called bore injection fluid) is delivered through the inner part of the spinneret to maintain the annular structure and/or to control coagulation of the fiber bore. The newly formed thread spends a short time in the air before being immersed in a nonsolvent bath where coagulation occurs. The length of the air gap located between the spinneret and the coagulation bath is one of the main parameters determining the membrane dimension. Other important parameters affecting hollow fiber morphology are numerous and include dope composition and viscosity, spinning temperature, pumping rates, composition of coagulants, and the spinneret dimensions. Finally, residual liquid and solvent are removed during a washing step before the hollow fiber being collected on a spool. Depending on its desired functionality, other post-treatments could be applied to the hollow fiber such as (photo) chemical cross-linking, addition of antiplasticizers, and fluorination. For example, cellulose and polyamide-based hollow fiber often need to be kept wet (or plasticized) in order to maintain their morphology and properties. These fibers could be plasticised on-line or the hollow fiber collection spool could be directly immersed in a plasticizing medium. Final agents' addition to the storage solution could include formaldehyde (to avoid biological fouling) or magnesium ions (to increase fiber stability). Nonporous polymer hollow fibers have also been spun to provide polyester heat transfer surfaces for temperature in blood oxygenators, while others have been used for crystallization surfaces.[9]

HOLLOW FIBER MODULES

The small size of hollow fiber allows high surface area to volume ratios in hollow fiber modules ranging from 500 to 10,000 m^2/m^3 in comparison with 500 and 1000 m^2/m^3 for plate and frame and spiral wound modules, respectively. The majority of hollow fiber modules are assembled as shell and tube heat exchanger (Fig. 4). Flow can occur in the exterior (shell side) or the interior (lumen) of the fibers in a countercurrent or cocurrent manner. Shell-side flow can be introduced or collected using side ports in the external casing (Fig. 4A) or a central tube in the middle of the module to create radial flow across the fiber bundle

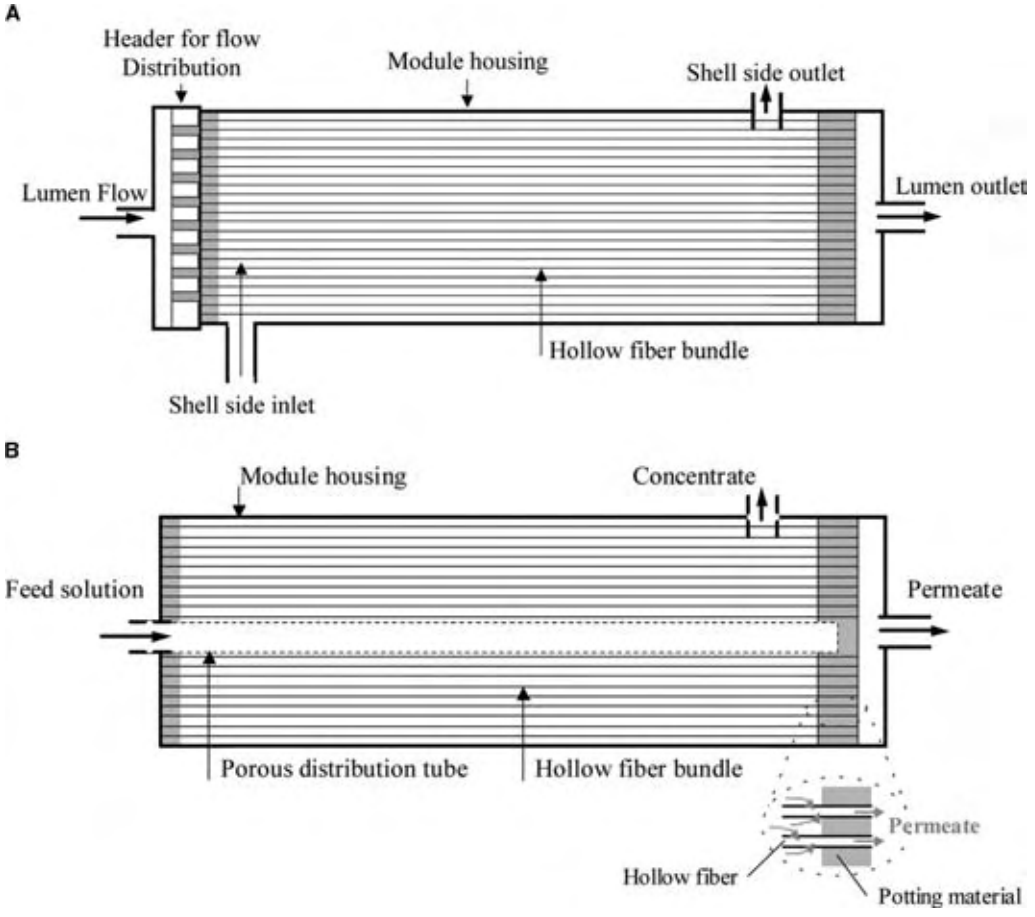

Fig. 4 Schematic of the axial view of a hollow fiber module featuring (A) shell-side ports and (B) operating from out-to-in the fiber with central feed tube. *(View this art in color at www.dekker.com.)*

(Fig. 4B). Typically for liquid–gas contactor applications, the gas flows in the lumen, while the liquid is fed in the shell to provide more mixing in the liquid side where mass transfer is more likely to be high.

Hollow fiber bundles, which can exceed 10,000 fibers, are rarely ordered arrays like heat exchangers. Most fiber modules consist of randomly packed fibers, closely packed (packing density of approximately 50%), with both ends of the fiber potted into a tubesheet with epoxy, silicone, or urethane resin (Fig. 5). The tubesheets are then cut to expose the fiber lumen. Headers on the potted ends are used to distribute or collect flow in the lumen while ports on the external casing perform the same purpose on the shell side. Metal casings are required for high pressure operations such as reverse osmosis and gas separation. The external casing is not required where the transmembrane pressure or the suction is applied solely via the lumen side. In these submerged membrane systems, fibers can be directly immersed in liquid to carry out filtration (Figs. 6 and 7) or serve as contactors. These modules can be, in the forms of bundles or sheets, potted into collection tubes. Fibers may also be potted only in one end and allowed to fluidize freely to reduce concentration polarization and improve mass transfer.[10] Unlike spiral wound modules that often exist in 4 and 8 in. diameter modules, hollow fiber modules are not as standardized and can vary significantly in length and diameter even for the same applications.

Flow maldistribution through these fiber bundles leading to low mass transfer and stagnant regions for fouling is a significant concern, particularly when liquids and shell-side feed are used. Woven or helically wound fiber packing has been used to overcome channeling of fluids between axial bundles of fibers and reduce concentration polarization in reverse osmosis and gas–liquid contactors and enhance heat transfer in oxygenators. Baffling and strategic location of the collection tube have been used in improving mass transfer for liquid contactors for the Liqui-Cel™ from Celgard shown in Fig. 8. Other strategies for generating transverse flow or turbulence in the module include crimping fibers to disrupt the axial flow, gas injection on shell or lumen side, and small amplitude oscillations.[11]

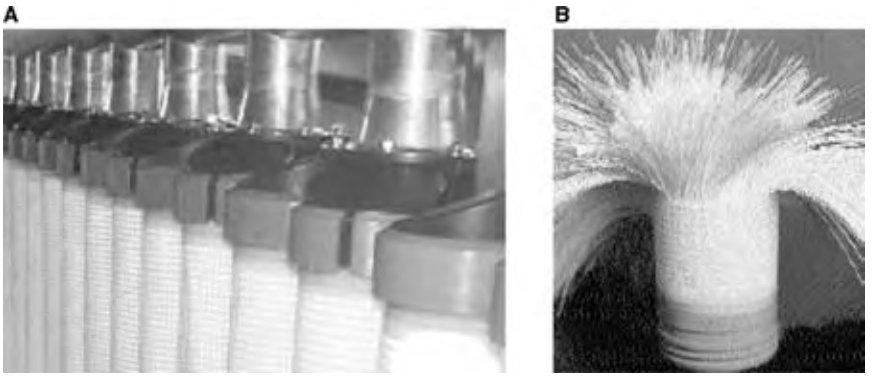

Fig. 5 Conventional (A) hollow fiber module assembly and (B) cutaway. (Courtesy of Memcor.) *(View this art in color at www.dekker.com.)*

Careful design of the headers and shell-side ports must be considered as they can be a source of significant flow maldistribution.[12]

To avoid major fouling and clogging problems, the nature of the feed to be treated has to be considered when hollow fiber modules are used. In the case of lumen to shell filtration, the inside diameter of the fiber is supposed to be at least 10 times the diameter of the largest species present in the feed.[13] However, when the permeate flows from shell to lumen, concentration and viscosity of the feed and the density of hollow fiber membrane per module may be critical parameters in the design process. Specific aeration or mixing requirements are necessary to keep the feed particles in suspension, and to avoid the clogging of the membrane module.

Where porous hollow fibers are used as contactors between phases, the pressure differential along the module needs to be lower than the critical breakthrough pressure determined by the surface tensions between the phases and the membrane pore size. High pressure differential between the entrance and exit of hollow fiber modules should be limited for filtration as it can promote excessive flux and fouling on one end of the module. Recirculation of permeate flow back into the feed size due to Starling flow can even occur during filtration if the pressure drop on the feed side drops below the permeate side as it flows through the module.[14] As lumen sizes decrease and hollow fiber lengthens, the pressure drop on both the lumen and the shell-side can become excessive.

A wide range of mass transfer correlations based on Reynold and Graetz numbers have been used to characterize the performance of hollow fiber module contactors. The variation of mass transfer correlations has been attributed to the nonideality in flow distribution, deviation from simple axial flow, and fiber inhomogeneity.[15,16] Modeling for concentration polarization build-up and two phase flow on the lumen side has also been developed for hollow fiber modules used in filtration.[17] Flow distribution in modules has also been characterized using residence time distribution

measurements, nuclear magnetic resonance imaging, and x-ray computed tomography.[18] The hydrodynamics of shell-side flow and two phase flow around submerged hollow fiber systems however remains a challenge to fully characterize and model. Assembly of the modules into arrays allows easy scale-up and compact footprint of many hollow fiber processes. The modular nature of these arrays allows easy replacement and localized integrity testing when fiber breaks (Fig. 5).

HOLLOW FIBER APPLICATIONS

Filtration

With a nominal pore size ranging from 0.01 to few microns, microfiltration is generally used for the removal of colloidal, fine particles and bacteria, while ultrafiltration membranes and their molecular weight cutoff from 200 to 500,000 Da retain polymers, sugars, and viruses. Because of the relative ease of producing microporous, polymeric hollow fibers, the use of this membrane configuration for ultrafiltration and microfiltration treatments also varies widely. Only specific process requirements, like high chemical and thermal resistance of polymeric filters, have limited the application of hollow fiber microporous membranes; the development of ceramic or metal membranes (in a flat sheet or a tubular configuration) offers means to overcome these limitations. Hollow fiber microporous membranes could be used for concentration, purification, and fractionation in the following main industries:

- Food
- Medical, pharmaceutical, and biotechnological
- Water treatment and reuse
- Industrial wastewater treatment
- Air filtration

Clarification of rough beer, vinegar and pasteurization of clarified beer by cross-flow ultrafiltration are also very common processes utilizing hollow fiber ultrafiltration. As seen in Table 1, an important number of membrane manufacturers specialize in medical and pharmaceutical applications. In pharmaceutical and biotechnology industries, hollow fiber membranes are used for the concentration, separation, and purification of physiological activators such as antibiotics, vaccines, enzymes, proteins and peptides, as well as blood purification (hemofiltration). As a physical barrier for bacteria and viruses, membranes are also a popular option for the production of purified water for hospitals and pharmacies.

A growing application of hollow fiber technology is in the areas of water and wastewater treatment. Recent issues related to water shortage in many parts of the globe had forced the development of the number of potable water treatment .plants. Surface water sources can be very efficiently treated by hollow fiber membrane (sometimes coupled with coagulation) process. Based on the Asahi Kasei's Microza membrane, Pall Corporate commissioned 45 facilities, while US Filter/Memcor are responsible for 36 on-line plants and 11 under construction. Zenon Environment is probably the leader in the market with 68 plants on-line and 19 under construction. The biggest of these plants is located in Mery sur Oise (France) and reaches 44.4 mega-gallon per day (Pall Corporation). In many of these plants, hollow fiber microporous technology is used as a pretreatment, generally before nanofiltration or reverse osmosis membrane process. Because of their relatively small footprint and high reliability, these dual membrane systems are becoming more and more popular. The cost of treating sewage to indirect potable water reuse standards (i.e., by ultxafiltration followed by reverse osmosis processes) is only 39% of the cost of seawater desalination.[19] Hollow fiber membrane

technology is also increasingly used for industrial wastewater recovery and reuse.[20] Only limited usage of hollow fibers has occurred in reverse osmosis modules. The most common hollow fiber reverse osmosis membranes that attained the stage of economic application in desalination plants are generally made of polyamide (DuPont and Toyoto). Application of hollow fiber for nanofiltration has been explored by Akzo Nobel and others but are not yet commercially available.[21] By using 0.1 μm (or lower) pore size hollow fibers, compressed gases can also be sterilized as bacteria and viruses are removed.

Gas Separation and Pervaporation

Since its inception in 1979, gas separation using membranes has developed into an industry worth over $150 million worldwide, with the bulk being in hollow fiber modules.[22,23] The current major applications include air separation into nitrogen and oxygen, hydrogen separation from ammonia purge gas streams, and natural gas treatment.[24] The first two are relatively clean feed streams and thus are relatively straightforward processes, limited only by the maximum purity that can be produced commercially (approximately 99.9–99.99% nitrogen for air separation).[6] However natural gas treatment (CO_2, H_2S, and H_2O removal) and other potential petrochemical applications may have substantial foulants, including particulates, plasticizing, and condensable vapors. As transport of gas solutes through dense membrane requires high pressures (up to 70+ bars) and ultrathin selective layers, hollow fibers must be defect free, and the fibers and the potting material sufficiently robust to withstand solvent vapors commonly present in such feeds. The basis of the separation mechanisms is the ''solution–diffusion mechanisms'' of the solute through the free volume of the membrane material, typically polymeric thin films on a porous support layer. While the tradeoff between selectivity and permeability tradeoff with a common separation polymer is well known, current research has focused on a combination of short flexible molecules between bulky, rigid segments to enhance selectivity.[24,25] Other developments include using facilitated transport membranes where the complexing ligand is used to shuttle desired species across the membrane. Dense hollow fibers can also provide contact area for gas stripping or oxygenation using oxygen selective polymer such as polymethylpentene in low pressure applications, for instance blood oxygenators.

With respect to gas separation hollow fiber modules, the chemical compatibility and the mechanical stability of the fibers and potting are paramount. High pressure modules use shell-side feed while low pressure modules use lumen side feed when fouling is not an issue.[24] While flow maldistribution may not be as severe as liquid flow in hollow fiber modules, modeling suggests that at high purities or recoveries, it may become a significant limiting factor.[6]

In contrast to gas separation, pervaporation involves the solubilization and the diffusion of species from liquid feed and transport through membrane into a vapor phase, removed by vacuum or sweep gas. Instead of high pressure, temperature and the chemical potential of the species drive the separation, mainly dehydration of organic liquids and removal of organic species from water. Despite the larger surface area provided by hollow fiber modules, they are not as prevalent as plate and frame and spiral wound modules as the small channels contribute to resistance to permeate flow. This results in vapor pressure buildup in the permeate-side (typically the fiber lumen as the separation layer is often on the shell side), reducing driving force. Thus optimization of fiber length and fiber productivity for pervaporation are discussed in the literature.[26] Porous hollow fibers can be used for air purification, but only few companies (such as Parker-Finite and Praxair Inc.) have proposed using hollow fiber membranes permeable to water vapor to dry compressed air.

Hollow Fiber Contactors

Hollow fiber contactors use membranes to separate two phases and transport is due to diffusion, chemical reaction, or chemical potential rather than pressure. The main examples of hollow fiber contactors are found in dialysis, gas adsorption/deadsorption, and solvent extraction. Use of hydrophilic and hydrophobic fiber materials controls the wetting of the pores. Typically, the phase that has higher mass transfer is allowed to wet the pores in order to minimize overall mass transfer resistance.

In dialysis, size exclusion is the main separation mechanism, while osmotic pressure and concentration difference drive the transport across two typically aqueous phases. While dialysis is used in some analytical separations,[27] dialysis for the removal of toxins from blood (hemodialysis) is the most prominent application for hollow fiber technology in the biomedical field. The hemodialyzers are used to treat over one million people a year and have become a mass produced, disposable medical commodity.[28] While the first hemodialyzers were developed from cellulosic material (Cuprophane, RC, etc.), synthetic polymers such as polyacrylonitrile, poly(ether) sulfone, and polyvinyl pyrrolidone are increasingly used to improve blood compatibility and flux. Hemodialyzer modules consist of thousands of extremely fine hollow fibers

(approximately 250 μ with wall thicknesses of 5–10 μ) in a short casing (approximately 30 cm) to minimize fluid holdup. Dialysate flows in the shell side while blood flows in the lumen. As mass transfer can be severely compromised by flow maldistribution in the liquid phase, modules such as those by Membrana GmbH have incorporated wavelike undulations in the fiber and spacer fibers on the shell size to improve fluid distribution. Control of flux through the hollow fiber is also crucial as the pressure drop along hollow fiber modules can result in back-transport from the dialysate of endotoxins removed from the blood. Current research in hemodialysis is focused on better blood compatibility, low flux membranes, and adsorptive membranes that bind endotoxins.[28]

Hollow fibers can separate not just two liquid aqueous phases as in dialysis but also organic and aqueous phases. Liquid–liquid separation using porous hollow fibers to control the interfacial area has been proven successful for using organic solvent to strip organic solutes from the aqueous phase or aqueous phase to strip water soluble solutes from organic phase. So far, only small liquid–liquid extraction units have been used industrially.[29] Significant problems exist in controlling pressure fluctuations within the module and fouling of membrane surfaces, which cause fluids to breakthrough the pores of the fiber, resulting in emulsification or contamination of the feed or the stripping streams. The critical breakthrough pressure is governed by the Laplace equation relating minimum pressure to force liquid into a pore to surface tension of the liquid, surface energy of the material, and pores size. With hollow fibers, the pressure drop in lumen or shell can be significant thus making pressure control crucial to avoid undesired wetting and breakthrough of the fibers.

The application of hollow fibers for gas stripping and gas transfer into liquids has been commercialized successfully. As with liquid–liquid contactors, undesired fluid breakthrough can be reduced with careful pressure control to the shell and lumen side of the fiber throughout the module. Typically, the hydrophobic fibers are used to reduce mass transfer resistance from the stagnant liquid in the pores; thus the deposition of hydrophilic foulants on the membrane surface can provide an undesired conduit for liquid penetration into the hollow fiber. The use of nonporous, gas selective hollow fibers avoids some of these wetting problems.

Aside from blood oxygenators, the major applications include degassing (O_2 and CO_2 removal) for ultrapure water production (Membrana GmbH, W.L. Gore & Associates), bubble-less aeration (Membrana GmbH) and carbonation, and CO_2 removal from natural gas and exhaust gases (Kvaerner, W.L. Gore & Associates). The Kvaerner process involves using porous hollow fibers (polytetrafluoroethylene) to contact gases with an amine stripping solution to achieve CO_2 removal. Originally developed for off-shore natural gas processing, there are very few examples of large scale gas processing using hollow fiber membranes. However, as CO_2 removal has gained new importance, there are new efforts to expand hollow fiber contactors to flue gas and other large scale applications using cheaper polypropylene and alternative absorbants to the alkanolamines used in the original Kvaerner processes.

Other potential uses for hollow fiber contactors include membrane distillation where microporous membranes form a barrier to liquid water but allow vapor to pass. Studies of these modules have been so far limited to laboratory scale investigations. Extensive reviews of the mass transfer correlations and applications for hollow fiber contactors are given in the literature.[15]

Hybrid Processes

In hybrid processes, membranes are used to remove end-product from the reactor, allowing a chemical or a biochemical reaction to carry on. Hybrid membrane

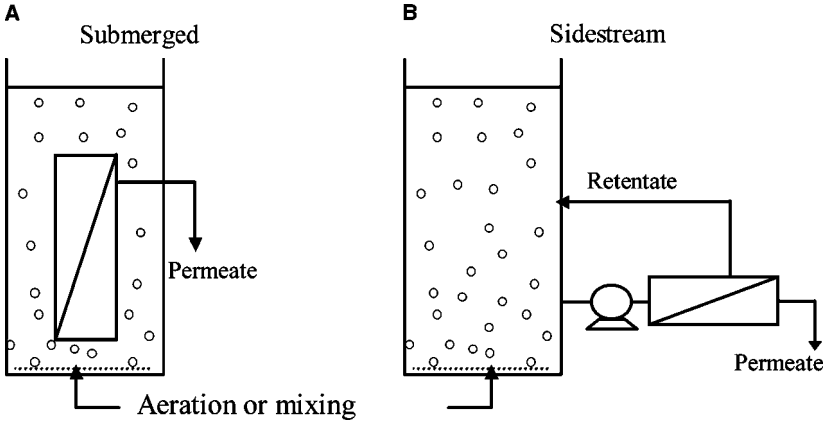

Fig. 9 Two operating configurations for hollow fiber membranes: (A) submerged (or immersed) and (B) sidestream (or cross-flow) *(View this art in color at www.dekker.com.)*

processes could be configured into two different designs. In a submerged configuration, the membrane is directly submerged in the reactor, while a sidestream membrane reactor features an external loop where the membrane separation unit is located outside the reactor (Fig. 9). Originally, most of research based on membrane reactors was carried out on gas phase reactions (catalysis-based dehydrogenation, hydrogenation, and oxidation), while studies on coagulant and adsorbent hybrid hollow fiber membrane processes for treatment of water and wastewater have been more recently reported.

The most remarkable development in membrane process is probably due to the exponentially increasing number and size of membrane bioreactor (MBR) treatment plants for municipal and industrial wastewaters.[30] Advantages of MBR over conventional process comprise higher process intensity and effluent quality, and reduction of footprint and sludge volumes. The process could be designed both in submerged or sidestream configurations (Fig. 9) with flat sheet or hollow fiber membranes. Although the relative merits of those designs are subject to discussion, a majority of contractors and users tend to choose the submerged hollow fiber technology, probably because of the backwashing option offered by the hollow fiber membrane.

Currently, three submerged hollow fiber MBR designs are commercially available. Mitsubishi Rayon, Zenon, and Memcor offer hollow fiber membrane specifically designed for MBR applications. Zenon, the market leader in terms of global capacity, has increased its MBR capacity from less than $1000\,m^3$/day in 1993 to almost $1.5\,Mm^3$/day currently. However, MBR could still be considered too costly, and issues related to membrane fouling and clogging are the main reasons limiting an even more widespread large-scale application. Membrane suppliers generally guarantee the integrity of the hollow fiber membrane for 3 to 5 years when they are used under normal conditions. A comparison between MBR and membrane used for tertiary filtration of effluents from conventional activated sludge process (both based on hollow fiber technology) showed that integrated MBR was the least expensive.[19] Proper hollow fiber module design is crucial in MBR where a high concentration (around 20 g/L) of active biomass is filtered. Aeration devices are generally located below the HF module to ensure good circulation of the biomass, promote membrane movement, both phenomena limiting clogging and fouling. In that same effort, recent optimization of the aeration of hollow fiber MBR has been recently developed by experimenting intermittent aeration and coarse bubbling. Fig. 7 shows one such wastewater treatment plant based on MBR—submerged hollow fiber technology in the Westview wastewater treatment plant in Canada.

CONCLUSIONS

Hollow fiber technology has allowed high surface area for mass and heat transfer to be generated relatively cheaply. However, the module design and the operational mode are crucial as the majority of capital or operating costs in chemical processing is often in achieving the pressure, flowrates, or turbulence in hollow fiber modules rather than the cost of the fibers itself. The advent of submerged hollow fiber systems has made a significant impact in the water and wastewater treatment areas, and new innovative module designs and operation modes are quickly developing. For gas separation and other dense membrane applications, sophisticated material science for developing more selective and robust fibers and potting materials will dictate the further penetration of hollow fiber modules into large scale petrochemical separations.

INTRODUCTION

Hybrid inorganic–organic materials can be broadly defined as synthetic materials with organic and inorganic components, intimately mixed, either homogenous systems derived from monomers and miscible organic and inorganic components or heterogenous and phase-separated systems where at least one of the components' domains has a dimension ranging from some angstroms to several nanometers. Hybrid nanocomposites had an explosive development since the 1980s, with the expansion of soft inorganic chemistry processes.[1–4] The mild synthetic conditions provided by the sol–gel process such as metallo-organic precursors, low processing temperatures and the versatility of the colloidal state allow for the mixing of the organic and inorganic components at the nanometer scale in virtually any ratio. These features, and the advancement of organometallic chemistry, and polymer and sol–gel processing, permit a high degree of control over both composition and structure (including nanostructure) of these materials, which present tunable structure–property relationships. This, in turn, permits tailoring and fine tuning of properties (mechanical, optical, electronic, thermal, chemical) in very broad ranges, and designing of specific systems for applications. Hybrid materials can be processed as gels, monoliths, thin films, fibers, particles, or powders. The seemingly unlimited variety, unique structure–property control, and the compositional and shaping flexibility give these materials a high potential for applications.

GENERAL REFERENCES AND APPLICATIONS

The subject of hybrid materials has been extensively reviewed in different fields, such as synthesis, properties and applications, textured hybrids, and biohybrids.[5–11] Therefore, in this entry we will mainly refer to those comprehensive reviews, to encourage the interested reader to explore into them for more specific sources.

Some hybrid materials have already entered the market. Commercial examples include materials from electronics to automotive coatings with varied mechanical and optical properties, adhesives, and composites, to cite a few.[12–14] Recent examples include the indigo dyes embedded in a silica/zirconia matrix (Toshiba TV screens), organically doped sol–gel glassware (Spiegelau), and sol–gel entrapped enzymes (Fluka).

CLASSIFICATION

A distinct characteristic of hybrid materials is that not only are their properties related to the chemical nature of the inorganic and organic components, but they also rely heavily on their synergy. Therefore, the interface between inorganic and organic domains is of paramount importance. Indeed, one key point is the control of this interface, the hybrid interface.

Hybrid materials can thus be broadly classified into two main classes, depending on the nature of the links and interactions existing at the hybrid interface (Fig. 1):[15] Class I hybrids include all systems where there are no covalent or iono-covalent bonds between the organic and inorganic components. Thus, only van der Waals, hydrogen bonding, or electrostatic forces are present. On the contrary, in Class II hybrids, at least parts of the inorganic and organic components are linked through strong covalent or iono-covalent bonds. Hybrids can also be characterized by the type and size of the organic or the inorganic precursors. Precursors can be two separate monomers or polymers, or they can be covalently linked. Generally, phase separation between the organic and the inorganic components will occur, owing to mutual insolubility. However, it is possible to obtain homogenous or single-phased hybrids by choosing bifunctional monomers presenting organic and inorganic components, or by combining both types of components in phases where one of them is in large excess.

Brief Sol–Gel Concepts

Sol–gel processes, based on the controlled polymerization of inorganic molecular precursors in mild temperature conditions, organic solvents, and controlled water quantities are central in the development of hybrid materials. Typically, MX_n precursors are used, where M represents a metal center, n is its oxidation state, and X is a group such as alkoxy, RO–, which represents a deprotonated alcohol. X can also represent a halogen anion, as in metal chlorides. The sol–gel process implies connecting the metal centers with oxo- or hydroxo- bridges, therefore generating metal-oxo or metal-hydroxopolymers in solution. Hydrolysis and condensation reactions are activation and propagation steps. Hydrolysis of an alkoxy group

attached to a metal center leads to hydroxyl-metal species (Reaction 1).

$$M - OR + H_2O \longrightarrow M - OH + ROH \quad (1)$$

The hydroxylated metal species can react with other metal centers leading to condensation reactions, where an oligomer is formed by bridging two metal centers. In the case of oxolation, condensation leads to an oxo bridge, and water or alcohol is eliminated (Reaction 2).

$$M - OH + XO - M \longrightarrow M - O - M + X - OH$$
$$X = H \text{ or } R \quad (2)$$

In the case of olation, an addition reaction takes place, and a hydroxo bridge is formed. This reaction takes place when metal centers may have coordination higher than their valence, as in the case of Ti(IV), Zr(IV), or related cations (Reaction 3).

$$M - OH + M - OX \longrightarrow M - (OH) - M - OX$$
$$X = H \text{ or } R \quad (3)$$

In most sol–gel processing, the inorganic framework is built by successive hydrolysis and condensation reactions.[1] The structure, connectivity, and morphology of the final inorganic network depend strongly on the relative contribution of reactions 1–3.[16,17] Depending on intrinsic (i.e., metal center features such as coordination, acidity, lability, etc.) or extrinsic (i.e., tunable reaction conditions such as solvent, water contents, pH, catalyzers, reaction time, etc.) conditions, the hydroxo-oxo-polymers thus formed can exhibit a variety of structures, from branched arrangements to compact clusters. The growth of these structures can be arrested (for example, by poisoning or by limiting aggregations), and thus, sols made of suspended colloidal size entities are obtained. Some of these structures may grow extensively or aggregate until they reach macroscopic dimensions, trapping solvent and smaller monomers; a gel is thus obtained. Precipitates can also be obtained when extended growth of oxo-polymers leads to their insolubility. Drying of gels in ordinary or supercritical conditions leads to dried gels (xerogels) or high-surface aerogels, respectively. Solvent removal is a crucial step to control surface area, porosity, integrity, morphology, and eventual segregation.[16]

[1]While most sol–gel chemistry depends on the use of controlled water quantities to yield metal-oxo polymers, there is an alternative method to generate metal-oxo polymers in nonhydrolytic conditions, see, eg., Bourget, L.; Corriu, R.J.P.; Leclercq, D.; Mutin, P.H.; Vioux, A. J. Non-Cryst. Solids **1998**, *242*, 81 (and references therein).

Chemical control of activation/polymerization reactions [Eqs. (1)–(3)] permits tailoring of the size and shape of the inorganic polymers or colloids, as well as their and miscibility (i.e., the interactions, for example, hydrophobic/hydrophilic) with the organic counterparts. Functional precursors can also be used to cocondense with MX_4 precursors, or to modify the surface of inorganic entities, therefore enhancing the compatibility with organic monomers or polymers. The following sections will show general synthesis routes and some examples.

General Routes Toward Hybrid Materials

Fig. 2 shows the general chemical pathways used to obtain hybrid materials, from mutual dispersions of polymer domains attainable by the relatively simple combination of sol–gel techniques and polymerization (Route A), to the assembly of well-defined nanobuilding blocks (NBB), by using separators, or polymerization of functional NBB (Route B), to organized pore systems, obtained by the combination of sol–gel and self-assembly techniques (Route C). Materials with hierarchical structures and complex forms can also be obtained by ''integrative pathways,'' i.e., by combining controlled phase segregation, selective interactions, and morphosynthesis to the sol–gel/self-assembly tandem (Route D). Novel phases, composites, or dispersions bearing original properties (chemical storage, sensors, controlled delivery, etc.) can be created, which will have a deep impact on the technology of the 21st century. The chemical construction and patterning of materials with long-range order architectures (beyond nanometer size) remains an important challenge in the new field of ''organized matter chemistry.''[18]

Conventional Routes

Class I hybrid materials

The main strategies toward Class I hybrid materials encompass: 1) embedding small organic molecules in inorganic gels; 2) embedding preformed organic polymers in inorganic gels; 3) impregnation of previously formed porous inorganic matrices (glasses) by organic molecules; or 4) simultaneous formation of both polymer networks (organic and inorganic).

Organic molecules can be readily mixed with $M(OR)_4$ alkoxide precursors. Upon precursor hydrolysis, dye molecules, such as coumarines, rhodamines, pyranines, or others with nonlinear optical properties have been entrapped into silica, aluminosilica, or transition metal oxide matrices.[19] Alkoxides can also be mixed with polymers dissolved in alcohols or

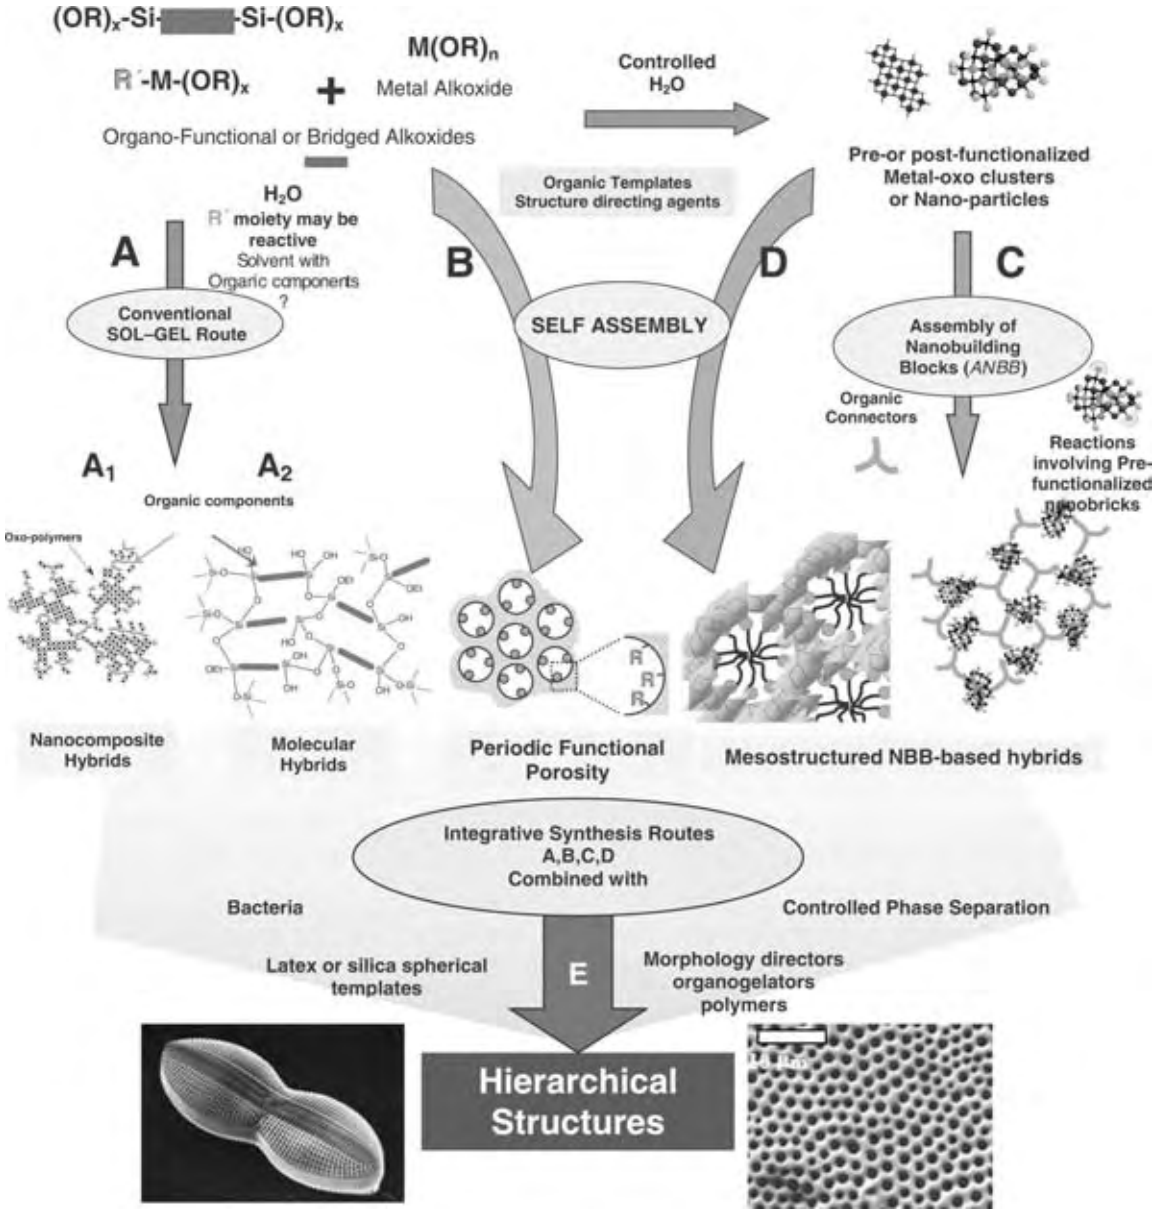

Fig. 2 Different paths to obtain hybrid materials from molecular sources. Path A: Sol–gel routes (A1: conventional route for hybrid nanocomposites, A2: molecularly homogenous hybrids). Path B: Assembly of nanobuilding blocks (ANBB), of prefunctionalized or postfunctionalized clusters or nanoparticles. Route C or D involve the use of templates capable of self-assembly, giving rise to organized phases. Path E involves integrative synthesis combining precedent paths from A to D and other processes, such as the use of lithography, casting, organogels or latex beads as templates, controlled phase separations, or external fields. (From Ref.[8].) *(View this art in color at www.dekker.com.)*

tetrahydrofuran (THF). This route results in transparent materials, where the inorganic particles are smaller and more homogenously dispersed than in a conventional blending process. Chemical control of the interactions between the inorganic (i.e., the –OH groups attached to the metal centers) and organic polymers at the hybrid interface permits avoiding or adjusting the phase separation.

A simultaneous polymerization process was developed by Novak, to generate hybrid materials in a single operation, to facilitate interpenetration of both domains (Fig. 1A).[20] Alkoxysilanes carrying polymerizable alkoxo groups (derived from methacrylate, methylmethacrylate, or norbornane) were used as precursors, to enhance the integration, and to minimize the shrinkage observed in pure silica systems. The control of polymerization kinetics of both inorganic and organic components results in large monolithic pieces with a wide polymer/silica composition domain.

Class II hybrid materials

Precursors. In these materials, strong links between the inorganic and organic domains are present. Heterofunctional inorganic precursors (RMX_{n-1}, where R is an organic group), where R is attached to the metal center, either covalently (C_{sp^3}–Si or C_{sp^3}–Sn) or by a coordination bond (usually a chelating group attached to transition metal centers such as Ti, Zr, etc.), can be used to build a covalent interface between the two types of components. R groups are not removed upon hydrolysis.

A large number of silicon precursors are commercially available, or can be prepared by well-established routes such as hydrosililation with $HSi(OR')_3$, or $HSiCl_3$.[21,22]

$$HSiX_3 + H_2C{=}CH{-}R'' \xrightarrow{cat} R''{-}CH_2{-}CH_2{-}SiX_3 \quad X = Cl \text{ or } -R \tag{4}$$

When the functional alkene is not available, other pathways are possible, such as substitution or addition reactions on $(R'O)_3Si(CH_2)_3Cl$, $(R'O)_3Si(CH_2)_3N{=}C{=}O$, or $(R'O)_3Si(CH_2)_3O_2CC(CH_3){=}CH_2$. For example,

$$R'O_3Si(CH_2)_3N{=}C{=}O + HOR \longrightarrow R'O_3Si(CH_2)_3NHCO_2R \tag{5}$$

Other possibilities are the reaction of $(R'O)_3Si(CH_2)_3Cl$ with a Grignard or organolithium reagents.[23,24] Currently, almost all organic moieties or organometallic fragments can be linked to silicon through a stable C–Si bond.[25]

Regarding nonsilicon precursors, C–Sn bonds are stable enough toward hydrolysis. Numerous precursors such as $R'SnX_3$ (X = Cl, –OR) and trichloro organostannanes are available. The trichloroorganotin precursors can also be transformed into trialkynylorganotins by reaction with alkynyllithium.

For the more electropositive metals or transition metals (Al, Ti, Zr, V, Nb, Ce, etc.), the C–M bond is easily cleaved by hydrolysis. Therefore, the links generally used to build Class II hybrids are formed by strong complexing organic ligands, obtained by deprotonation of HLZ (L being an anchoring function, Z, a general organic group), such as β-diketones, β-ketoesters, carboxylic acids, phosphates, or phosphonates. A proton exchange reaction leads to the modified alkoxide [Eq. (6), L is the complexing group].

$$M(OR)_n + HLZ \longrightarrow M(OR)_{n-1}(LZ) + HOR \tag{6}$$

Bidentate or cyclic ligands increase considerably the M–(LZ) bond strength toward hydrolysis, as they usually increase coordination around the metal center and lower the reactivity. This strategy has been extensively used to control hydrolysis–condensation processes of transition metal centers by decreasing their reactivity. Indeed, firmly attached complexing ligands reduce the functionality (and thus the connectivity) of the inorganic centers, act as a poison toward oxo-polymer growth, and provide an anchoring point to the organic component. The organic group can also give steric or solvophobic protection.

Examples. A huge quantity of Class II materials, mostly prepared from the functional precursors described above, has been so far described in the literature. Mixtures of functional precursors and ordinary alkoxides have also been employed, to increase the amount of inorganic component by coprocessing. Some of the hybrids thus obtained bear special names such as ORMOSIL (ORganically MOdified SILicates) and ORMOCERs (ORganically MOdified CERamics). The organic groups R play several roles:

1. Groups with simple functions, such as alkyl or aryl bound to Si or Sn, or complexing acetylacetone (acac) on transition metals. These groups act mainly as network modifiers of the inorganic framework. They are also used to control the kinetics of hydrolysis and condensation, and they can also lead to special properties such as hydrophobicity or plasticity to the final material. The resulting matrices are particularly interesting to host small optically active organic molecules.
2. The R groups can bear an active nonpolymerizable moiety. Thus, R groups are network modifiers, which give a special property to the material. Some of the numerous examples include chromophores for nonlinear optics, storage or lasing, crown ethers for transportation and ion scavenging, or organometallic fragments for catalysis.
3. The R groups can bear a polymerizable function such as methacrylate or epoxy acting as network formers. If the R–M bond is not cleaved, then R can also be considered a network modifier. Most of the works in this area are centered on silicon-based hybrids for protective coatings.

The systems derived from Zr-*n*-propoxide modified by acetoacetoxyethylmethacrylate (AAEM) constitute a complete example of a Class II hybrid (Fig. 1F). The heterofunctional precursor is $Zr(O{-}Pr^n)_{4-x}(AAEM)_x$. AAEM acts as a network former and modifier, by limiting the growth of the inorganic polymer, and allowing the formation of the organic polymer. Simultaneously, growth of the inorganic polymers also hinders AAEM polymerization. Thus, both polymerization processes are interdependent. The local and short-range structure of the polymers is dependent

on the complexation ratio, leading to dense Zr-oxo polymers associated with short poly(AAEM) chains (low AAEM/Zr ratio), or smaller and tenuous oxo-polymers cross-linked with longer poly(AAEM) chains (large AAEM/Zr ratio).[15]

Bridging heterofunctional precursors that present two or more trialkoxysilyl groups capping an organic molecular spacer (phenyl, biphenyl, alkene, or alkyne) have been synthesized.[7,23,24,26] The hydrolysis of these precursors leads to bridged polysilsesquioxanes (POSS). Precursors with varied functionality, rigidity, and morphology have been synthesized to prepare tailored pore size materials. The porous volume, shape, and surface area of the resulting hybrids depend on the precursor geometry and hydrolysis conditions (solvent, catalysis, etc.). Interestingly, $Si–C_{sp}$ bonds can be cleaved in soft conditions (methanol, 60°C, F^- catalysis), which permits removal of the alkyne spacers and generation of open porosity.[26]

Preformed polymers capped by trialkoxysilyl groups have also been used to generate hybrid materials, particularly to tune mechanical or optical properties. Polymers such as poly(dimethylsiloxane), poly(tetramethylene oxide), and poly(aryleneetherketone) undergo hydrolysis and condensation, and can cocondense with silica or transition metal oxo-polymers, yielding cross-linked strongly grafted hybrids, in which the inorganic oxo-polymers can be used as mineral fillers or matrices, depending on the relative proportions of both components.

Nanocomposite Hybrids: From Nanodispersions to Organization

The methods described above correspond to those attainable with conventional sol–gel chemistry. This strategy is simple, low cost, and yields amorphous hybrid materials, which can contain specific organic molecules, biocomponents or polyfunctional cross-linkable polymers (e.g., telechelic polymers). These materials exhibit an infinity of microstructures, can be transparent, and easily shaped as films or bulks (Fig. 2, Route A). However, they are generally polydisperse in size and locally heterogenous in chemical composition.

A better understanding and control of the local and semilocal structure of these materials and their degree of organization in different length scales are important issues, especially if tailored properties are sought for. For example, in nanocrystalline materials, electronic and optical properties can be tailored by varying particle size, and it is expected that ordered arrays can give rise to controlled magnetic or electronic coupling, triggering new properties. Inorganic precursors with preformed symmetry or anisotropies in their structure or morphology (e.g., lamellar materials, rods) can be combined with organic molecules or polymers to tailor mechanical properties. Ordered metallic nanoparticles give rise to interesting optical properties, derived from the coupling of plasmon resonances. Periodicity in the tens to the hundreds of nanometers (i.e., mesoscopic scale) can be attained by combining inorganic precursors and self-assembly or controlled phase segregation techniques.

Organization usually involves a controlled segregation at the nanoscopic level. Several approaches may be conceived to achieve such a control of the materials structure; they are schematized in Fig. 2:

- Self-assembling procedures (SA, Route B).
- The assembling of well-defined nanobuilding blocks (ANBB, Route C).
- The self-assembly of NBB, which combines the first two approaches (SANBB, Route D).
- Integrative synthesis, where SA, ANBB, and SANBB are combined with controlled phase segregation.

In the last 10 yr, the field of ''chemistry of organized matter'' has opened the path to create organized or textured inorganic or hybrid networks, templated by organic structure directing agents (Fig. 1, Routes B and D).[18,27–32] The success of this strategy is also clearly related to the ability to control and tune hybrid interfaces, which permits the versatile building of a continuous range of nanocomposites, from ordered dispersions of inorganic bricks in a hybrid matrix to highly controlled nanosegregation of organic polymers within inorganic matrices. In the latter case, one of the most striking examples is the synthesis of mesostructured hybrid networks (Routes B and D).

Nanocomposite Hybrids Derived from Lamellar[2]

Hybrid materials derived from the combination of organic molecules or polymers and delaminated clays, other lamellar oxides, and eventually sulfides or carbons are well known and present industrial interest (note that we will not refer to ordinary composites made up of modified silicates that are used as gelling agents, thickeners, or fillers). The lively color of the pigment Maya Blue developed in the eighth century by the Mayans is due to indigo dyes trapped in a lamellar mineral, palygorskite.[39] Oxide or silicate nanoplatelets finely dispersed in a polymeric matrix present interesting mechanical properties, owing to the ultralarge interfacial area between the organic and inorganic

[2]See the article ''Polymer/Clay Nanocomposites.''

components, which leads to dramatic changes in the conformation polymer molecules can adopt. This is exemplified by the nylon–clay hybrids (NCH) developed by Toyota, which show good mechanical properties and a high heat-distortion temperature in spite of the low content of the clay mineral, making NCH the first hybrid material applied to automotive engine parts.[40] In addition, the NCH film has low gas permeability. Additionally, the presence of nanodispersed matter can give rise to new electrical or optical properties. On the other hand, organic molecules or polymers embedded within clay or oxide matrices present interest in pigments, sorption, environmental issues, or drug delivery. Layered aluminosilicates (2 : 1 layered silicates, clay minerals, phylosilicates, smectites) are the most commonly used inorganic NBB. These silicates generally bear charge compensating alkaline cations or anions (in the case of layered double hydroxides, LDH) in the interlayer. Organic ions can be incorporated within the interlayer galleries either by coprecipitation or by ion exchange. Typically, cations such as organic ammonium and phosphonium are used to replace interlayer alkaline or alkaline earth cations present in clays. For LDH matrices, carboxylates, phosphates, sulfates, or phosphonic or sulfonic acids carrying organic residues are used to exchange anions. The trapped groups act as an immobilized phase, and present interesting sorption and phase behavior, depending on the degree of ion exchange. Monomers (typically acrylate) or even polymers can also be incorporated, leading to a wide range of compositions. Delamination of these precursors can take place in the adequate solvents, leading to highly disperse metal-oxo hybrid monolayers, which can be included within a matrix or eventually polymerized. When the inorganic and polymeric components are mutually compatible, the obtained systems are exfoliated and intercalated, and the final structure is a nanodispersion. In principle, a great variety of dispersion morphologies and secondary textures in the mesoscopic or macroscopic should be available. Several methods to prepare these nanocomposites include solution processing, mesophase mediated processing, in situ polymerization, or melt processing. A wide range of polymers has been used, from polystyrene to conductive polyaniline.[41]

Hybrid Nanocomposites from Functional Nanoentities: Assembly of NanoBuilding Blocks (ANBB)[8,15,19,42]

A further method to reach a better definition of the inorganic component consists in the use of perfectly calibrated nanosized objects, such as clusters or nanoparticles that keep their integrity in the final material. These NBB can be capped with functional (solvophylic/solvophobic, self-assembly active or polymerizable, Fig. 3) ligands, or connected through organic spacers, like telechelic molecules or polymers, or functional dendrimers (Fig. 1, Route C). The use of highly precondensed species presents several advantages:

- They exhibit a lower reactivity toward hydrolysis or attack of nucleophilic moieties than metal alkoxides.
- The NBB components are nanometric; nowadays, numerous synthesis procedures are available, which permit to obtain monodispersed nanoparticles with perfectly defined structures, which facilitates the characterization of the final materials.
- These NBB present per se interesting properties, which are indeed size tunable (luminescence, conductivity, and electronic and magnetic behaviors).

The variety found in the NBB (nature, structure, and functionality) and possible links allows one to build an amazing range of different architectures and organic–inorganic interfaces, associated to different assembling strategies. Moreover, the step-by-step preparation of these materials usually allows for high control over their semilocal structure.

Strategies combining the NBB approach with the use of organic templates that self-assemble and allow one to control the assembling step are also appearing (Fig. 1, Route D). This combination between the ''nanobuilding block approach'' and ''templated assembling'' will have a paramount importance in exploring the theme of ''synthesis with construction'' of hierarchically organized materials, in terms of structure and functions.

The NBB exhibit a large variety of composition, size, and interfaces between the organic and the inorganic components (covalent bonding, complexation, electrostatic interactions, etc.). Depending on the set of chosen experimental conditions, these NBB will keep or loose their integrity. They can be used as true building blocks that can be connected through organic spacers or condensation reactions, or as a reservoir of inorganic matter, which can be delivered at the hybrid interface to build an extended inorganic network. In the following section, several examples of hybrid materials and systems in which the core integrity of the NBB is preserved will be presented.

CLUSTER-BASED HYBRIDS[8,43]

Several well-documented routes exist for a variety of NBB such as oligosilsesquioxanes and derivatives, organotin-oxo clusters, organically functionalized heteropolyoxo-tungstates, transition metal oxo clusters,

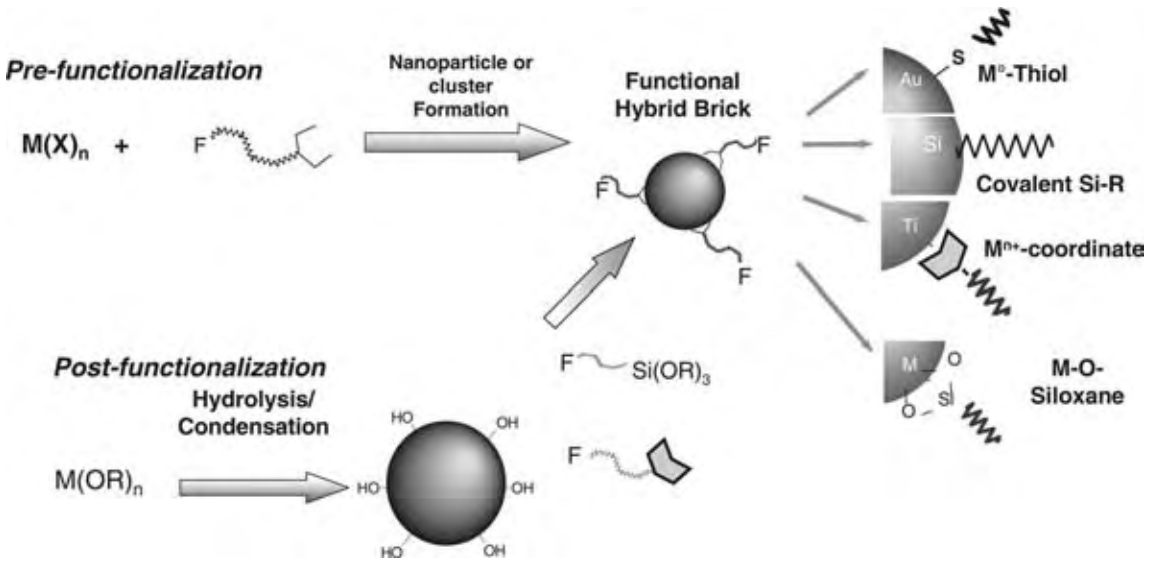

Fig. 3 Pre- and postfunctionalization routes leading to functional hybrid metal or oxide clusters and nanoparticles. Functional hybrids are the nanobuilding blocks (NBB) of complex hierarchical structures.

and finally with functionalized nanosized particles (metallic oxides, metals, chalcogenides).

A variety of Si-based building blocks have been used to elaborate hybrid materials, corresponding mostly to cage compounds of the general formula $[XSiO_{1.5}]_n$, where n is an even number ranging from 6 to 18.[44] The types of architectures that can be achieved depend on the nanobrick functionality. Nanobuilding blocks bearing a single double-bond yield upon polymerization (with or without a comonomer), linear polymeric backbones with pending silsesquioxane cubes. Such functional nanobricks allow a good dispersion and covalent anchoring of the nanoscale inorganic filler in the polymer, resulting in tuned changes in the thermal (i.e., glass transition temperatures) or mechanic (i.e., relaxation modulus) properties of the polymer with the inorganic loading.[8] Pendent POSS can also be introduced through polycondensation reactions as shown for segmented polyurethane-based elastomers. In cocondensed systems, the inorganic NBB can be selectively attached to one of the polymer segments, enhancing the tensile modulus and the strength of the elastomer.[45] All the examples presented above correspond to Class II hybrid materials, but POSS have also been simply blended with polymers to afford Class I hybrids. In such systems, the dispersability of the POSS is related to the organic side groups.

Tin–C_{sp^3} bonds are stable toward hydrolysis, and many organic functions can be added to Sn centers. Tin-6 and Tin-12 clusters have been used as NBB through different routes.[43] The Tin-6 cluster presents a variety of external functions (alkyl, vinyl, amine, etc.). Tin-12 or $\{(RSn)_{12}(\mu_3\text{-}O)_{14}(\mu_2\text{-}OH)_6\}^{2+}$ presents a versatile mixed interface. Assembly of these clusters within organic networks is possible by polymerization of the attached R groups containing double bonds. The positive charge of the cluster can be compensated with anionic monomers (acrylic acid, acrylamide), which can be subsequently polymerized. Compensating organic dianions or telechelic polymers can also be used to bridge the clusters and integrate them within polymeric matrices.

Several metal-oxo clusters (Ti^{IV}, Zr^{IV}, Ce^{IV}, Nb^{V}, and mixed composition) have been described in the literature.[8] Prefunctionalized clusters are interesting and controlled precursors for hybrids. Yet, because of their small size and high reactivity, functionalized clusters exhibit rather poor stability toward water or nucleophiles. Consequently, their assembly through radical initiated polymerization must be performed in nonprotic solvents such as toluene, benzene, or THF. Following this pathway, novel hybrid materials have been produced, in which the cluster size and identity is conserved. Clusters can also be connected by oxo bridges (in organic solvents, low water conditions) or organic spacers. The surface metallic atoms can be selectively complexed by groups such as carboxylate. Block copolymers or functional dendrimers with tuned functions, size, and symmetry have been used to create ordered NBB dispersions or mesoporous cluster-based solids. Mo-, V-, or W-based polyoxometallate (POM) NBB has also been used to generate hybrids with potential applications in electrochromism, photoelectrochemistry, sensors, catalysis, and light imaging.[46] Polyoxometallate-based Class I materials are based on weak interactions, as a result of the anionic charge carried by the POM. Polyoxometallates can be embedded in conducting polymers and used as

conductive electrodes. They have also been assembled in self-assembled monolayers or multilayers. The first example of Class II POM derivatives is the homopolymerization of difunctional POMs $[SiW_{11}O_{39}(RSi)_2O]^{4-}$ with unsaturated organic groups (vinyl, allyl, methacrylate, and styryl). These compounds present great potential in catalysis, chemotherapy, photo- and electrochromism.

NANOPARTICLE-BASED HYBRIDS[8]

Because of the stability problems that might be associated to small clusters with high reactivity, the devices sought nowadays are mainly based on nanoparticles (NP) ranging from 2 to 100 nm in diameter. Physical as well as wet chemical routes are converging toward a sound library of functionalized NP production procedures.[47–52] Functionalized NP already play an important role in pharmaceutical drug delivery systems, paint dispersion, tire reinforcement, catalyst optimization, and in many processes involving adhesives, biocements, varnishes, and lubricants. There are several ways to adapt the NBB approach to create nanoparticle-based hybrid materials. These include: 1) introducing NP into polymer or organic hosts; 2) synthesizing the nanoparticles inside such matrices; 3) connecting particles with adequate organic spacers; or 4) polymerizing functionalized metal-oxo nanoparticles. All these strategies have been shown above in the case of clusters. Building the hybrid structures requires a similar tuning at the hybrid interface level. Additionally, colloidal interactions must be taken into account. The resulting hybrid networks can be amorphous, nanostructured, or exhibit long-range ordering. The synthesis and nature of functionalized nanoparticles has been extensively reviewed.[50] (For a comprehensive review of synthesis methods and properties, see also Ref.[53].)

Organic functions can be added to the nanoparticle surface in a step subsequent to their synthesis (post-functionalization). This process strongly depends on the particle nature (Fig. 3).[54] Silica particles are functionalized by reactions in organic media with alcoxysilane [R′-Si(OR)$_3$] or chlorosilane (R′-SiCl$_3$) species; some organo-functionalized nanosilicas have already been commercialized by Degussa and Clariant. The hybridization strategy of nanosilicas has been used for the functionalization of alumina, zirconia, or titania nanoparticles with trimethoxysilylpropylmethacrylate, to design reactive ceramic fillers for PMMA-based composites. A variety of nanoparticles can be derivatized through the use of a functionalized complexing ligand (carboxylate, acetylacetone, thiols, silanes, etc.). Smart methods for polymerizing MMA at the surface of nanometric titania particles have already been developed in the paint and polymer industry.[55]

MULTISCALE ORDERING OF FUNCTIONAL COLLOIDAL NANOPARTICLES:[4]

Multiscale ordering of functional colloidal nanoparticles is a powerful technique for the creation of macroscopic devices. This can be performed via selective polymerization, self-assembly processes, or through controlled molecular recognition processes (Fig. 4). Further assembly between NBB is addressed following three main strategies, namely, electrostatic coupling, covalent, or self-assembly-based noncovalent binding.

Networks formed through electrostatic interactions: Mesoscopic structures of TiO_2 anatase nanoparticles have been formed through self-assembly processes involving Class I hybrid composites made of multiply charged polytitanate anions and tetramethylammonium cations. These anatase nanocrystals can self-assemble into highly ordered superlattices. The assembly of gold particles covered by quaternary ammonium bromide salts ($R_4N^+Br^-$) in 2D and 3D organized systems has been observed, the separation between the objects being controlled by the length of R. Nanosized silica NBB functionalized with primary amines can be coupled with a ''counter NBB'' displaying a complementary surface. The complementary NBB can be a gold nanoparticle, capped on its surface by thiol groups that carry alkylcarboxylic functions. Simple acid–base chemistry induces an immediate charge pairing, which results in the spontaneous formation of electrostatically bound mixed colloids.

Covalent networks: Covalent binding programmed assembly can be simply designed by mixing two sets of NBB presenting surfaces functionalized with complementary reactive functions (e.g., amine and aldehyde). A more sophisticated derivation is constituted by the so-called biomolecular route, which makes use of specific interactions, as those found in antigen–antibody pairs or streptavidin–biotin complexes, to induce assembling of NBB. A DNA-based method has also been presented, where noncomplementary DNA oligo-nucleotides attached on gold particles aggregate in the presence of an oligonucleotide duplex with ''sticky ends,'' which are complementary to the grafted sequences. The nanoparticles self-assemble into macroscopic materials, this assembly being reversible upon thermal denaturation.

Self-assembly-based networks: Ordered superlattices composed of nanosized semiconducting sulfides have been synthesized within lyotropic phases.[56] Hexagonal-packed arrays of nanocrystalline CdS (or similar structures such as ZnS, $Cd_{1-x}Zn_xS$, and CdSe) have been produced, a ''mineral copy'' of an (ethylene oxide)$_{10}$-oleyl/water mesophase presenting periodicities ranging between 7 and 10 nm.

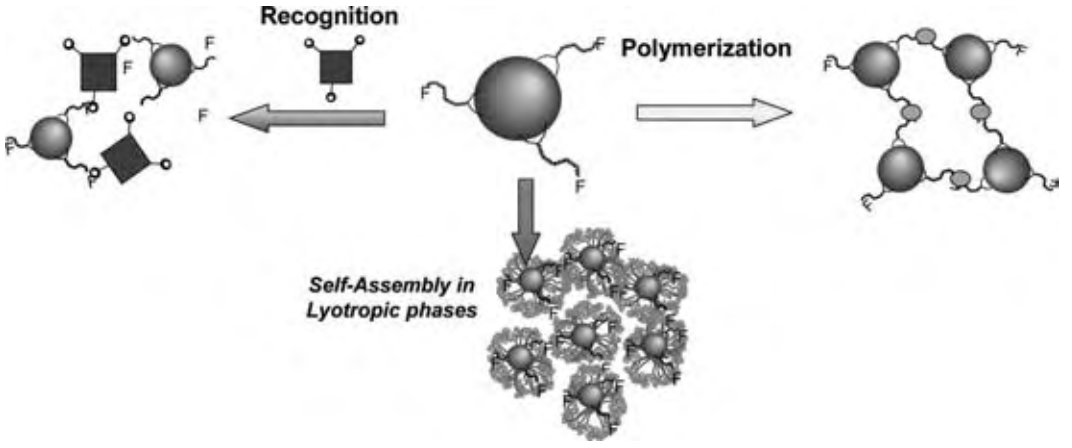

Fig. 4 Assembly strategies to organize NBB (functional clusters or nanoparticles) into hierarchical structures, by means other than colloidal interactions. *(View this art in color at www.dekker.com.)*

Textured Inorganic or Hybrid Materials with Tailored Porosity

Hybrid porous materials are interesting in that they combine inorganic–organic frameworks with tailored pores, leading to potential applications in catalysis, optics, sensing and separation, among others. Hybrid microporous materials have been mostly produced by hydrothermal synthesis, in a similar way to zeolites. The synthesis strategies and computational modeling leading to these solids have been extensively discussed in the literature, and will not be described in this entry.[57,58]

Sol–gel techniques can also be combined with the self-assembly of surfactants, leading to hybrid materials in which the function imparted by the organic component is to give order in the mesoscopic (2–50 nm) range. Inorganic condensation can proceed around micelles or micellar assemblies, leading to a hybrid composite in which the surfactant aggregates act as templates for cavities or pore arrays.[27] A variety of ionic and nonionic templates have been used to create porous matrices with organized monodisperse pores.[28] Template removal leads to mesoporous materials in the form of films, fibers, powders, monoliths, or macrospheres, which have promising applications in optics, electronics, chemical sensing, catalysis, separation, etc. Some templates can impart interesting properties to a hybrid nanostructured material; this is, for example, the case of sulfonated PS-based polymers, which can give rise to proton conducting robust hybrid membranes.[59] Apart from micellar templates, other methods to texture materials include organogel molecular assembly, latex or ceramic beads, or spinodal phase separation. The so-formed organic domains dimensionality and self-arrangement dictate the final porous structure of the inorganic network. A control at three levels is necessary to achieve such a control on the structure:

1. Tuning of the initial solution chemical composition allows selection of the desired stoichiometry, the reactivity, and adjustment of preferential interactions at the organic/inorganic interface when segregation and self-assembly take place.
2. Organized hybrid materials can be provoked through chemical (i.e., precipitation, gelation) or physical (i.e., evaporation, temperature) solicitations. This step is the most delicate one because phase segregation, self-assembly, and condensation must occur in this exact order to end up with the desire architecture.
3. Finally, the template has to be removed from the as-prepared hybrid materials to create monodisperse porosity.

So far, such nano-structuring approach has been well developed for pure or mixed metal oxide inorganic networks such as SiO_2, Al_2O_3, transition metal oxides, and nonoxide materials such as carbon, metals, or polymers.[60] Mesoporous materials have been prepared mostly by three different routes: precipitation methods, true liquid crystalline templating (TLCT), or evaporation-induced self-assembly (EISA). These alternative methods are complementary: while precipitation leads to high yields of a limited choice of inorganic networks, liquid TLCT or EISA permits a higher control of the inorganic condensation and processing as films, gels, powders, aerosols, or fibers.[27,28]

The use of functional precursors permits one to synthesize meso-organized materials with organic functions, either embedded within the walls or dangling in the pore interior. This can be performed by one-pot or postfunctionalization procedures

(Fig. 5).[61,62] A great number of organic functions have been included in mesoporous silica by cocondensation of silicon alkoxides and organosilane precursors [R′-$Si(OR)_3$, or bridging $(OR)_3Si$-R′-$Si(OR)_3$]. The connectivity, the hydrophilic–hydrophobic nature, and the specific interactions of the R′ group are essential for the placing of the organic functions either within or dangling from the walls. For example, polar R′ groups such as amino tend to place themselves at the organic/inorganic interface. Once the surfactant is removed by solvent extraction and the network stabilized by a chemical route, the R group remains covalently bonded to the framework and is in principle accessible through the porosity. Organic functions (pH probes, hydrophobic, electrochemical probes, etc.) can also be grafted onto silica or transition metal oxide walls by postfunctionalization by attaching organosilanes or complexing ligands (carboxylates, beta-diketonates, phosphonates, etc.) to the pore surface. This leads to hybrid mesostructured materials with tunable surfaces, opening a land of opportunities for designing new separation devices, catalysts, membranes, sensors, and nano-reactors. Biospecies such as active enzymes can be trapped within the pore network, by using adequate grafting groups and spacers.[63]

Morphology texturation by growth modifiers[27,64]

Organogelators are low-weight organic molecules that are able to form thermoreversible physical gels, exhibiting strongly anisotropic structures (i.e., fibers, ribbons, platelets), in a great variety of organic solvents. Combining this new family of texturing agents [with steroidal or diaminocyclohexane skeleton, 2,3-bis-*n*-decyloxyanthracene (DDOA) or 2,3-di-*N*-alkoxyphenazine (DAP)] with the sol–gel chemistry has recently permitted directing the condensation of silica into original shapes at the microscopic levels, and succeeded in transcripting the chiral information to a mineral network. DDOA has been successfully employed as template for fibrous silicas and aluminas with tuneable mesoporosity. Organically modified functionalized hybrid fibers with accessible and modifiable functionalities have also been synthesized from silicon alkoxides and organosilanes. Postfunctionalization can be performed in a second step with any other inorganic complex or even with fragile organic or biofunctions. Recently, novel organic–inorganic hybrids that present helical symmetries have been obtained through the hydrolysis of organosilica derivatives bearing an *R,R* or *S,S* chiral diureidocyclohexane spacer. Left- and right-handed helixes are self-generated depending of the configuration of the chosen organic subunit.

Texturation through phase separation

Phase separation in multicomponent systems can be used as a texturing tool.[65] In principle, three- or four-component systems (i.e., an inorganic alkoxide precursor, a texturing polymer—typically PEG, and a binary solvent) can lead to spinodal separation patterns upon solvent evaporation. Phase separation can be entropically or enthalpically driven, according to whether polymer or solvent droplets are segregated, respectively. The segregated droplets lead to pores in the micrometer range. Domain size, morphology, and dispersion depend on the rate and extent of species concentration and their diffusion in the medium. Mesoporosity can arise from template-inorganic residual interactions, leading to hierarchical porous systems. Original macrotextures shaped with coral-like, helical, or macroporous morphologies have been obtained; applications are sought in separation and chromatography. Functional nanoparticles can also be used as building blocks, in combination with biomimetic polymers such as poly-γ-benzyl-l-glutamate

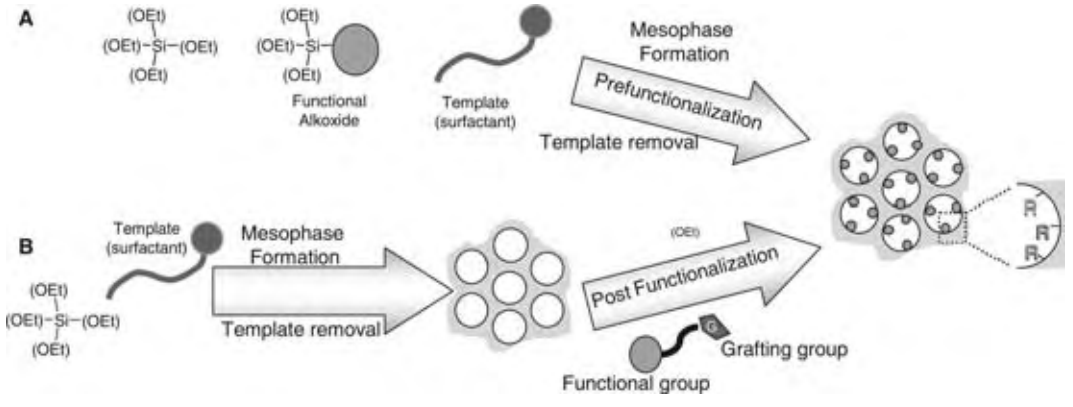

Fig. 5 Prefunctionalization (A) and postfunctionalization (B) routes toward hybrid materials organized in the mesoscopic scale. The meso-organized precursors are synthesized by reacting an inorganic precursor in the presence of a supramolecular template (surfactant). By Route A, organic functions can also be embedded within the walls. *(View this art in color at www.dekker.com.)*

(PBLG). By adjusting a single parameter, such as the template to inorganic ratio, a versatile tuning between templating effect and phase separation yields hierarchical porous materials presenting both micro and macro porosity with inorganic walls constituted of nano-crystalline cerium oxide particles.

BIOHYBRIDS[66–70]

In Nature, the combination of simple NBB such as silica, calcium carbonate, or calcium phosphate with organic biopolymers gives rise to biocomposites with well-defined mechanical properties and biological functions (protection, motion, sensing, storage, etc.). Natural materials such as teeth, bone, shells, etc., are a natural source of inspiration for the complex hybrid materials shown in the previous sections, where the structural role of the organic molecules was emphasized. But smaller biomolecules or molecule arrays (DNA, proteins, peptides, membranes, hormones) can perform highly selective and specific tasks such as molecular recognition, selective transport, or biocatalysis. Biomolecules are also fragile. Therefore, there is a great interest in immobilizing active species or even living organisms in suitable robust matrices.

Biohybrid materials are expected to find applications in smart biodevices such as sensors, biocatalysts, separation, and vectorization domains, etc. In the last few years, the encapsulation of biomolecules (proteins, enzymes, etc.) in silica gel has proven to be a promising alternative to biopolymer-based processes. Specific biosensors composed of enzymes immobilized in silica xerogels have recently been produced. Another developing domain concerns hybrids formed from inorganic nanoparticles or inorganic gels and biomolecules. Biotechnologies already use enzymes and bacteria as synthetic tools; their further encapsulation in solid matrices should bring modulated and enhanced biosynthetic properties. The exploitation of hybrid materials in domains including immunology tests, encapsulation, and/or vectorization is currently being tested. Good preservation of the enzyme activity can be tested by optical or electrochemical methods.

The possibility of using such inorganic hosts for whole-cell immobilization has been far less studied. In the case of bacteria, different approaches have been explored to maintain cell viability both during the encapsulation step and on a long-term scale. So far, the best conditions for bacteria survival involve an aqueous route using silicates and colloidal silica as inorganic precursors. Additives have been incorporated either during the gel formation or after bacteria encapsulation, leading to viability rates up to 85% after 1 mo of immobilization in silica.[71] The use of silica gels for the design of cell-based bioreactors or biosensors can now be envisioned.

CONCLUSIONS

Hybrid organic–inorganic materials are increasingly taking their position in the free spaces left between inorganic chemistry, polymer chemistry, organic chemistry, and biology. This land of research, initially worked out by the sol–gel community is at present thriving with the appearance of hybrid structures engineered from the molecular to the nanometric or micrometric scales, toward applications spanning biological and chemical sensing, catalysis, selective separation to optical communications. Nature is a source of inspiration for hybrid materials, in many properties such as sophistication, miniaturization, hierarchical organizations, hybridization, resistance, and adaptability. Hybrid materials that combine organic and inorganic components on a nanoscale with innovative controlled textures will allow designing of new or bioinspired materials reproducing principles or structures found in Nature.

Looking forward to the 21st century, nanosciences will be, as biology, one of the fields that will contribute to a high level of scientific and technological developments. Hybrid materials present the paramount advantage to both facilitate integration and miniaturization of the devices (nanomaterials, nanotechnologies) and afford a direct connection between inorganic, organic, and biological worlds. Functional precursors or functional NBB facilitate integrative synthesis pathways, where synergistic assembling and morphosynthesis can be strongly coupled. The chemical strategies offered by coupling soft chemistry processes with different macro templates (latex, bacteria, polymers, topological defects in LC, etc.), self-assembly processes, and external fields will allow, through an intelligent and tuned coding, to develop a new vectorial chemistry, able to direct the assembling of a large variety of structurally well-defined inorganic networks into complex architectures. The research of multiscale structured hybrids (from nanometer to millimeter) will open a land of opportunities for designing new materials. The future of this unifying field of research mainly depends on skills of all kind of chemists and is only limited by their imagination.

Hydrocracking

James G. Speight
CD & W Inc., Laramie, Wyoming, U.S.A.

INTRODUCTION

The use of hydrogen in thermal processes is perhaps the single most significant advance in refining technology during the 20th century. The process uses the following principle—the presence of hydrogen during a thermal reaction of a petroleum feedstock terminates many of the coke-forming reactions and enhances the yields of the lower boiling components, such as gasoline, kerosene, and jet fuel.

Hydrogenation processes for the conversion of petroleum fractions and petroleum products may be classified as destructive and nondestructive. Destructive hydrogenation (*hydrogenolysis* or *hydrocracking*) is characterized by the cleavage of carbon–carbon linkages accompanied by hydrogen saturation of the fragments to produce lower boiling products. Such treatment requires severe processing conditions and the use of high hydrogen pressures to minimize phase separation followed by polymerization and condensation reactions that lead to coke formation. Many other reactions, such as isomerization, dehydrogenation, and cyclization, occur under the drastic conditions employed. Thus, *hydroprocessing* is a thermal conversion process in which hydrogen is used to accomplish the objectives of the refiner. Hydrotreating is a process in which hydrogen is used to convert heteroatom constituents into their heteroatom hydrogen analogs and hydrocarbons:

$$R\text{–}S\text{–}R1 + H^2 \rightarrow RH + R^1H + H_2S$$

On the other hand, *hydrocracking* is a process in which thermal decomposition is extensive and the hydrogen assists in the removal of the heteroatoms (nitrogen and sulfur) as well as mitigating the coke formation that usually accompanies thermal cracking of high molecular weight polar constituents. In addition to hydrodesulfurization and hydrodenitrogenation, the removal of aromatic constituents from some product streams has also become essential. The high aromatic content in diesel fuel has been recognized both to lower the fuel quality and to contribute significantly to the formation of undesired emissions in exhaust gases. Indeed, as a result of the stringent environmental regulations, processes for aromatic reduction in middle distillates have received considerable attention in recent years. Studies have shown that existing middle distillate hydrotreaters designed to reduce sulfur and nitrogen levels would lower the diesel aromatics only marginally. The major differences between *hydrotreating* and *hydrocracking* are the time at which the feedstock remains at reaction temperature and the extent of the decomposition of the nonheteroatom constituents and products. The upper limits of hydrotreating conditions may overlap with the lower limits of hydrocracking conditions. And where the reaction conditions overlap, feedstocks to be hydrotreated will generally be exposed to the reactor temperature for shorter periods; hence the reason why hydrotreating conditions may be referred to as mild.

The Hydrocracking Process

The purpose of hydrocracking is to convert high-boiling feedstocks to lower boiling products by cracking the hydrocarbons in the feed and hydrogenating the aromatic and unsaturated materials in the product streams.[1–6]

Thus, the hydrocracking process is petroleum refining that combines catalytic cracking and hydrogenation by which high molecular weight viscous (usually non- or low-volatile) feedstocks are cracked (thermally decomposed) in the presence of hydrogen to produce lower molecular weight more volatile products. The process employs high pressure, high temperature, a catalyst, and hydrogen. Hydrocracking is used for feedstocks that are difficult to process by either catalytic cracking or reforming, because these feedstocks are characterized usually by high polycyclic aromatic content and/or high concentrations of the two principal catalyst poisons, sulfur and nitrogen compounds.

The hydrocracking process largely depends on the nature of the feedstock and the relative rates of the two competing reactions, hydrogenation and cracking. Heavy aromatic feedstocks are converted into lower-boiling products under high temperatures (400–480°C, 750–900°F) and high hydrogen pressures (1000–2000 psi, often as high as 6000 psi for very heavy feedstocks), in the presence of specialty catalysts. When the feedstock has a high content of paraffinic constituents, the primary function of hydrogen is to prevent the

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120008049

formation of polycyclic aromatic compounds that can result when paraffins are thermally decomposed at high temperatures. Another important role of hydrogen in the hydrocracking process is to reduce, or even prevent, the buildup of coke on the catalyst. Hydrogenation also serves to convert sulfur and nitrogen compounds present in the feedstock to hydrogen sulfide (H_2S) and ammonia (NH_3).

The hydrocracking process often produces relatively large amounts of iso-butane that can be used in alkylation units to prepare alkylate for gasoline blending. Hydrocracking, depending on the catalyst, can also cause isomerization of the paraffinic products that benefit liquid fuels in terms of pour point control and smoke point.

The hydrocracking process can either be a single-stage or a two-stage process.[4,6] In the single-stage process, the preheated feedstock and a hydrogen-rich gas (usually >60% v/v hydrogen) are allowed to contact the catalyst. However, the catalyst and process parameters must be versatile to allow hydrocracking, hydrodesulfurization, and hydrodenitrogenation to occur. This type of process may be preferred for gas oil feedstocks where contamination by high amounts of sulfur and nitrogen is not always a major issue. After the products leave the reactor, they are sent to a fractionator. Hydrogen and other hydrocarbon gases are separated for recycle to the front-end of the process. Hydrogen sulfide and ammonia are also removed from the product gases.

The two-stage process is more often applied to feedstocks that might also include heavy oil (either neat or blended with gas oil) where the gas oil might also act as a hydrogen donor in addition to feedstock. After the products leave the reactor, they are sent to a fractionator. Hydrogen and other hydrocarbon gases are separated for recycle. Hydrogen sulfide and ammonia are also removed from the product gases.

The single-stage reactor now becomes the first stage reactor in which the preheated feedstock is mixed with the recycled hydrogen-rich gas (make up hydrogen may also be introduced at this time) and sent to the first-stage reactor, where the catalysts convert sulfur and nitrogen compounds to hydrogen sulfide and ammonia. At this stage, hydrocracking may be limited through choice.

After the treated feedstock leaves the first stage, it is sent to a hydrocarbon separator where the treated feedstock is separated and the hydrogen is recycled to the first-stage feedstock. The treated feedstock is charged to a fractionator and depending on the products desired (gasoline components, jet fuel, and gas oil), the fractionator is operated to selectively separate part of the first stage reactor effluent.

The preheated fractionator bottoms are then mixed with a hydrogen-rich gas and charged to the second-stage reactor. As this material has already been subjected to some hydrogenation, cracking, and reforming in the first stage, the operations of the second stage are more severe (higher temperatures and pressures). Like the first-stage product, the second stage product is separated from the hydrogen and charged to the fractionator Fig. 1.

The single-stage process can be used to produce gasoline but is more often used to produce middle distillate from heavy vacuum gas oils (VGO).[4,6] The two-stage process was developed primarily to produce high yields of gasoline from straight-run gas oil, and the first stage may actually be a purification step to remove sulfur-containing (as well as nitrogen-containing) organic materials. In terms of sulfur removal, it appears that nonasphaltenes sulfur may be removed before the more refractory asphaltene sulfur, thereby requiring thorough desulfurization. This is a good reason for processes to use an extinction-recycling technique to maximize desulfurization and the yields of the desired product. Significant conversion of heavy feedstocks can be accomplished by hydrocracking at high severity. For some applications, the products boiling up to 340°C (650°F) can be blended to give the desired final product.

Because hydrocracking units operate at high temperatures and pressures, control of both hydrocarbon leaks and hydrogen releases is important to prevent fires. In addition, caution is required to ensure that explosive concentrations of catalytic dust do not form during recharging. Also, vigilance is necessary to protect against plugged reactor beds. Furthermore, unloading the spent catalyst (that may have coke deposited on it) requires additional precautions to prevent fires, some of which are the result of spontaneous ignition. The spent catalyst is often cooled before discharge or it should be protected from oxygen by a nitrogen blanket until it is cooled.

There is a potential for exposure to hydrocarbon gas and vapor emissions, hydrogen, and hydrogen sulfide gas because of high-pressure leaks. Large quantities of carbon monoxide may be released during catalyst regeneration and changeover. Catalyst steam stripping and regeneration create waste streams containing sour water and ammonia.

Process Design

As described earlier, the most common form of hydrocracking process is a *two-stage* operation.[4–6] This flow scheme has been very popular in the many refineries where it is necessary to maximize the yield of transportation fuels and has the flexibility to produce gasoline, naphtha, jet fuel, or diesel fuel to meet seasonal swings in product demand.

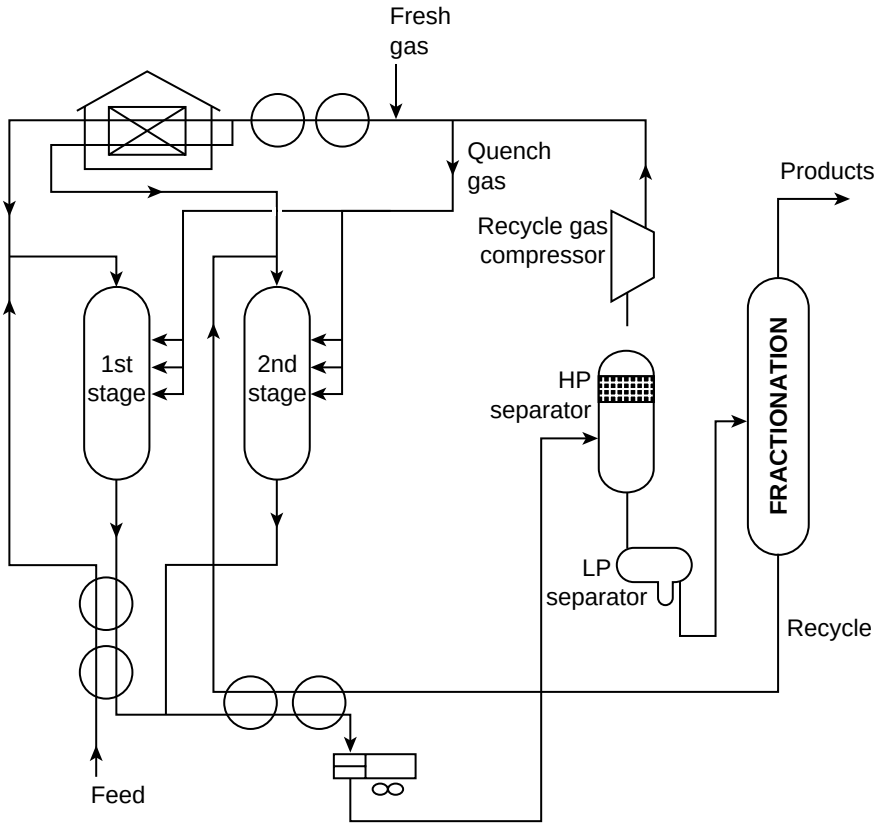

Fig. 1 A hydrocracking unit that can be operated as a single-stage or two-stage process.

This type of hydrocracker consists of two reactor stages together with a product distillation section. The choice of catalyst in each reaction stage depends on the product slate required and the character of the feedstock. In general, however, the first-stage catalyst is designed to remove nitrogen and heavy aromatics from raw petroleum stocks. The second-stage catalyst carries out a selective hydrocracking reaction on the cleaner oil produced in the first stage.

Both reactor stages have similar process flow schemes. The oil feed is combined with a preheated mixture of make up hydrogen and hydrogen-rich recycle gas and heated to reactor inlet temperature via a feed-effluent exchanger and a reactor charge heater. The reactor charge heater design philosophy is based on many years of safe operation with such two-phase furnaces. The feed-effluent exchangers take advantage of special high-pressure exchanger features that are designed to give leak-free end closures. From the charge heater, the partially vaporized feed enters the top of the reactor. The catalyst is loaded in separate beds in the reactor with facilities between the beds for quenching the reaction mix and ensuring good flow distribution through the catalyst.

The reactor effluent is cooled through a variety of heat exchangers including the feed-effluent exchanger and one or more air coolers. Deaerated condensate is injected into the first-stage reactor effluent before the final air cooler to remove ammonia and some of the hydrogen sulfide. This prevents solid ammonium bisulfide from depositing in the system. A body of expertise in the field of materials selection for hydrocracker cooling trains is quite important for proper design.

The reactor effluent leaving the air cooler is separated into hydrogen-rich recycle gas, a sour water stream, and a hydrocarbon liquid stream in the high-pressure separator. The sour water effluent stream is often sent to a plant for ammonia recovery and for purification so water can be recycled back to the hydrocracker. The hydrocarbon rich stream is pressure reduced and fed to the distillation section after light products are flashed off in a low-pressure separator.

The hydrogen-rich gas stream from the high-pressure separator is recycled back to the reactor feed by using a recycle compressor. Sometimes with sour feeds, the first-stage recycle gas is scrubbed with an amine system to remove hydrogen sulfide. If the feed sulfur level is high, this option can improve the performance of the catalyst and result in less costly materials of construction.

The distillation section consists of a hydrogen sulfide (H_2S) stripper and a recycle splitter. This latter column separates the product into the desired cuts. The column's bottom stream is recycled back to the second-stage feed. The recycle cut point is changed depending on the light products needed. It can be

as low as 160°C (320°F) if naphtha production is maximized (for aromatics) or as high as 380°C (720°F) if a low pour point diesel is needed. Between these two extremes, a recycle cut point of 260–285°C (500–550°F) results in high yields of high smoke point low freeze point jet fuel.

A *single-stage once-through* unit resembles the first stage of the two-stage plant. This type of hydrocracker usually requires the least capital investment. The feedstock is not completely converted to lighter products. For this application, the refiner must have a demand for highly refined heavy oil. In many refining situations, such an oil product can be used as lube oil plant feed or as fluid catalytic cracker feedstock or in low sulfur oil blends or as ethylene plant feed. It also lends itself to stepwise construction of a future two-stage hydrocracker for full feed conversion.

A *single-stage recycle* (SSREC) unit converts heavy oil completely into light products with a flow scheme resembling the second stage of the two-stage plant. Such a unit maximizes the yield of naphtha, jet fuel, or diesel depending on the recycle cut point used in the distillation section. This type of unit is more economical than the more complex two-stage unit when plant design capacity is less than about 10,000–15,000 bbl/day. Commercial SSREC units have operated to produce low pour point diesel fuel from waxy Middle Fast VGOs. Recent emphasis has been placed on upgrading lighter gas oils into jet fuels.

Building on the theme of *one-* or *two-stage* hydrocracking, the *once-through partial conversion* concept evolved. This concept offers the means to convert heavy VGO feed into high quality gasoline, jet fuel, and diesel products by a partial conversion operation. The advantage is lower initial capital investment and also lower utilities consumption than a plant designed for total conversion. Because total conversion of the higher molecular weight compounds in the feedstock is not required, once-through hydrocracking can be carried out at lower temperatures and in most cases at lower hydrogen partial pressures than in recycle hydrocracking, where total conversion of the feedstock is normally an objective.

Proper selection of the types of catalysts employed can even permit partial conversion of heavy gas oil feeds to diesel and lighter products at the low hydrogen partial pressures for which gas oil hydrotreaters are normally designed. This so-called *mild hydrocracking* has been attracting a great deal of interest from refiners who have existing hydrotreaters and wish to increase their refinery's conversion of fuel oil into lower boiling higher value products.

Recycle hydrocracking plants are designed to operate at hydrogen partial pressures from about 1200 psi to 2300 psi depending on the type of feed being processed. Hydrogen partial pressure is set in the design in part depending on required catalyst cycle length, and also to enable the catalyst to convert high molecular weight polynuclear aromatic and naphthene compounds that must be hydrogenated before they can be cracked. Hydrogen partial pressure also affects properties of the hydrocracked products that depend on hydrogen uptake, such as jet fuel aromatics content and smoke point and diesel cetane number. In general, the higher the feedstock endpoint, the higher the required hydrogen partial pressure necessary to achieve satisfactory performance of the plant.

Once-through, partial conversion hydrocracking of a given feedstock may be carried out at hydrogen partial pressures significantly lower than required for recycling and total conversion hydrocracking. The potential higher catalyst deactivation rates experienced at lower hydrogen partial pressures can be offset by using higher activity catalysts and designing the plant for lower catalyst space velocities. Catalyst deactivation is also reduced by the elimination of the recycle stream. The lower capital cost resulting from the reduction in plant operating pressure is much more significant than the increase resulting from the possible additional catalyst requirement and larger volume reactors.

Additional capital cost savings from once-through hydrocracking result from the reduced overall hydraulic capacity of the plant for a given fresh feed rate as a result of the elimination of a recycle oil stream. Hydraulic capacity at the same fresh feed rate is 30–40% lower for a once-through plant compared to the one designed for recycle.

Utilities savings for a once-through vs. recycle operation arise from lower pumping and compression costs as a result of the possible lower design pressure and also of lower hydrogen consumption. Additional savings are realized as a result of the lower oil and gas circulation rates required, because recycle of oil from the fractionator's bottom is not necessary.

Lower capital investment and operating costs are obvious advantages of once-through hydrocracking compared to a recycle design. This type of operation may be adaptable for use in an existing gas oil hydrotreater or atmospheric resid desulfurization plant. The change from hydrotreating to hydrocracking service will require some modifications and capital expenditure, but in most cases these changes will be minimal.

The fact that unconverted oil is produced by the plant is not necessarily a disadvantage. The unconverted oil produced by once-through hydrocracking is a high quality, low sulfur, and nitrogen material that is an excellent feed stock for an FCC unit or ethylene pyrolysis furnace or a source of high viscosity index lubricating oil base stock. The properties of the oil are a function of the degree of conversion and other plant operating conditions.

One disadvantage of once-through hydrocracking compared to a recycle operation is a somewhat reduced flexibility for varying the ratio of gasoline to middle distillate that is produced. A greater quantity of naphtha can be produced by increasing the conversion and jet fuel plus diesel yield can also be increased in this manner. But selectivity for higher boiling products is also a function of conversion. Selectivity decreases as once-through conversion increases. If conversion is increased too much, the yield of desired product will decrease, accompanied by an increase in light ends and gas production. Higher yields of gasoline or jet fuel plus diesel are possible from a recycle than from a once-through operation.

Middle distillate products made by once-through hydrocracking are generally higher in aromatic content of poorer burning quality than those produced by recycle hydrocracking. However, the quality is generally better when produced by catalytic cracking or from straight run. Middle distillate product quality improves as the degree of conversion increases and as hydrogen partial pressure is increased.

The hydrocracking process employs high-activity catalysts that produce a significant yield of light products. Catalyst selectivity for middle distillate is a function of both the conversion level and operating temperature, with values in excess of 90% being reported in commercial operation. In addition to the increased hydrocracking activity of the catalyst, percentage desulfurization and denitrogenation at start-of-run conditions are also substantially increased. End-of-cycle is reached when product sulfur has risen to the level achieved in conventional VGO hydrodesulfurization process.

An important consideration, however, is that commercial hydrocracking units are often limited by design constraints of existing VGO hydrotreating units. Thus, the proper choice of catalyst(s) is critical when searching for optimum performance. Typical commercial distillate hydrocracking catalysts contain both the hydrogenation (metal) and cracking (acid sites) functions required for service in existing desulfurization units.

Commercial Processes

The following processes are a sampling of those processes that are, or have been, in commercial practice.[4,6] This list is by no means exhaustive.

Gulf HDS Process

This is a regenerative fixed-bed process to upgrade residua by catalytic hydrogenation of refined heavy fuel oils or high quality catalytic charge stocks. Desulfurization and quality improvement are the primary purposes of the process, but if the operating conditions and catalysts are varied, light distillates can be produced and the viscosity of heavy material can be lowered. Long on-stream cycles are maintained by reducing random hydrocracking reactions to a minimum, and whole crude oils, virgin, or cracked residua may serve as feedstock. This process is suitable for the desulfurization of high-sulfur residua (atmospheric and vacuum), to produce low-sulfur fuel oils, or catalytic cracking feedstocks. In addition, the process can be used, through alternate design types, to upgrade high-sulfur crude oils or bitumen that are unsuited for the more conventional refining techniques.

H-Oil Process

The H-Oil process is a catalytic hydrogenation technique that uses a one-, two-, or three–stage ebullated-bed reactor in which considerable hydrocracking takes place during the reaction. The process is used to upgrade heavy sulfur-containing crude oils, residual stocks, and low-sulfur distillates, thereby reducing fuel oil yield.

IFP Hydrocracking Process

The process features a dual catalyst system: The first catalyst is a promoted nickel–molybdenum amorphous catalyst. It acts to remove sulfur and nitrogen and hydrogenate aromatic rings. The second catalyst is a zeolite that finishes the hydrogenation and promotes the hydrocracking reaction.

Isocracking Process

The process has been applied commercially in the full range of process flow schemes: single-stage, once-through liquid; single-stage, partial recycle of heavy oil; single-stage extinction recycle of oil (100% conversion); and two-stage extinction recycle of oil. The preferred flow scheme will depend on the feed properties, the processing objectives, and to some extent, the specified feed rate.

LC-Fining Process

The LC-Fining process is a hydrocracking process capable of desulfurizing, demetallizing, and upgrading a wide spectrum of heavy feedstocks by means of an expanded bed reactor. Operating with the expanded bed allows the processing of heavy feedstocks, such as atmospheric residua, vacuum residua, and oil sand bitumen.

Microcat-RC Process

The Microcat-RC process (also referred to as the M-Coke process) is a catalytic hydroconversion process operating at relatively moderate pressures and temperatures. The catalyst particles, containing a metal sulfide in a carbonaceous matrix formed within the process are uniformly dispersed throughout the feed. Because of their ultra small size (10^{-4} in. diameter), there are typically several more orders of magnitude of these microcatalyst particles per cubic centimeter of oil than is possible in other types of hydroconversion reactors using conventional catalyst particles. These results in smaller distances between particles and less time for a reactant molecule or intermediate to find an active catalyst site. Because of their physical structure, microcatalysts suffer none of the pore-plugging problems that plague conventional catalysts.

Mild Hydrocracking Process

The *mild hydrocracking process* uses operating conditions similar to those of a VGO desulfurizer to convert VGO to yield significant lighter products. Consequently, the flow scheme for a mild hydrocracking unit is virtually identical to that of a VGO desulfurizer.

Mild Resid Hydrocracking (MRH) Process

The mild resid hydrocracking process is a hydrocracking process designed to upgrade heavy feedstocks containing large amount of metals and asphaltene, such as vacuum residua and bitumen and to mainly produce middle distillates. The reactor is designed to maintain a mixed three-phase slurry of feedstock, fine powder catalyst and hydrogen, and to promote effective contact.

Residfining Process

Residfining is a catalytic fixed-bed process for the desulfurization and demetallization of residua. The process can also be used to pretreat residua to suitably low contaminant levels prior to catalytic cracking.

Unicracking Process

This is a fixed-bed catalytic process that employs a high-activity catalyst with a high tolerance for sulfur and nitrogen compounds and can be regenerated. The design is based upon a single-stage or a two-stage system with provisions to recycle up to extinction.

Veba Combi-Cracking (VCC) Process

The VCC process is a thermal hydrocracking/hydrogenation process for converting residua and other heavy feedstocks. The process is based on the Bergius–Pier technology that was used for coal hydrogenation in Germany until 1945. The heavy feedstock is hydrogenated (hydrocracked) using a commercial catalyst and liquid-phase hydrogenation reactor operating at 440–485°C (825–905°F) and 2175–4350 psi pressure. The product obtained from the reactor is fed into the hot separator operating at temperatures slightly below the reactor temperature. The liquid and solid materials are fed into a vacuum distillation column, the gaseous products are fed into gas-phase hydrogenation reactor operating at an identical pressure. This high temperature, high pressure coupling of the reactor products with further hydrogenation provides a specific process economics.

Catalysts

Hydrocracking catalysts typically contain separate hydrogenation and cracking functions. Palladium sulfide and promoted group VI sulfides (nickel molybdenum or nickel tungsten) provide the hydrogenation function. These active compositions saturate aromatics in the feed, saturate olefins formed in the cracking, and protect the catalysts from poisoning by coke. Zeolites or amorphous silica-alumina provide the cracking functions. The zeolites are usually type Y (faujasite), ion exchanged to replace sodium with hydrogen and make up 25–50% of the catalysts. Pentasils (silicalite or ZSM-5) may be included as dewaxing catalysts.

Hydrocracking catalysts, such as nickel (5% by weight) on silica-alumina, work best on feedstocks that have been hydrofined to low nitrogen and sulfur levels. The nickel catalyst then operates well at 350–370°C (660–700°F) and at a pressure of about 1500 psi to give good conversion of feed to lower boiling liquid fractions with minimum saturation of single-ring aromatics and a high iso-paraffin to *n*-paraffin ratio in the lower molecular weight paraffins.

Catalyst operating temperature can influence reaction selectivity because the activation energy for hydrotreating reactions is much lower than that of hydrocracking reactions. Therefore, raising the temperature in a residuum hydrotreater increases the extent of hydrocracking relative to hydrotreating, which also increases the hydrogen consumption.

Clays have been used as cracking catalysts particularly for heavy feedstocks and have also been explored in the demetallization and upgrading of heavy crude oil. The results indicated that the prepared catalyst

was mainly active toward demetallization and conversion of the heaviest fractions of crude oils.

Zeolite catalysts have also found use in the refining industry during the last two decades. Like the silica-alumina catalysts, zeolites also consist of a tetrahedral framework usually with a silicon or an aluminum atom at the center. The geometric characteristics of the zeolites are responsible for their special properties, which are particularly attractive to the refining industry. Specific zeolite catalysts have shown up to 10,000 times more activity than the so-called conventional catalysts in specific cracking tests. The mordenite-type catalysts are particularly worth mentioning because they have shown up to 200 times greater activity for hexane cracking in the temperature range 360–400°C (680–750°F).

Other zeolite catalysts have also shown remarkable adaptability to the refining industry. For example, the resistance to deactivation of the type Y zeolite catalysts containing either noble or nonnoble metals is remarkable, and catalyst life of up to 7 years has been obtained commercially in processing heavy gas oils in the Unicracking-JHC processes. Operating life depends on the nature of the feedstock, the severity of the operation, and the nature and extent of operational upsets. Gradual catalyst deactivation in commercial use is counteracted by incrementally raising the operating temperature to maintain the required conversion per pass. The more active a catalyst is, the lower the temperature required. When processing for gasoline, lower operating temperatures have the additional advantage—less of the feedstock is converted to iso-butane.

Zeolite catalysts provide the cracking function in many hydrocracking catalysts, as they do in fluid catalytic cracking catalysts. Zeolites are crystalline aluminosilicates, and among all commercial catalysts, the zeolite used at present is faujasite. Pentasil zeolites, including silicalite and ZSM-5 are also used for their ability to crack long chain paraffins selectively.

Typical levels are 25–50%, the weight of zeolite in the catalysts, with the remainder being the hydrogenation component and a silica (SiO_2) or alumina (Al_2O_3) binder. Exact recipes are guarded as trade secrets.

While zeolite catalysts provided a breakthrough that allowed catalytic hydrocracking to become commercially important, continued advances in the manufacture of amorphous silica alumina made these materials competitive in certain kinds of applications.

Typical catalysts of this type contain 60–80% of silica alumina, with the remainder being the hydrogenation component. The compositions of these catalysts are closely held secrets. Over the years, broad ranges of silica/alumina molar ratios have been used in various cracking applications, but silica is almost always in excess for high acidity and stability. A typical level might be 25% alumina (Al_2O_3).

Amorphous silica-alumina is made by a variety of precipitation techniques. The whole class of materials traces its beginning to silica gel technology, in which sodium silicate is acidified to precipitate the hydrous silica-alumina sulfate; sulfuric acid is used wholly or partly for this precipitation, and a mixed gel is formed. The properties of this gel, including acidity and porosity, can be varied by changing the recipe-concentrations, order of addition, pH, temperature, aging time, and the like. The gels are isolated by filtration and washed to remove sodium and other ions.

Careful control of the precipitation allows the pore size distributions of amorphous materials to be controlled rather well, but the distributions are still much broader than those in the zeolite catalysts. This limits the activity and selectivity. One effect of the reduced activity has been that these materials have been applied only in making middle distillates: diesel and turbine fuels. At higher process severities, the poor selectivity results in production of unacceptable amounts of methane (CH_4) to butane (C_4H_{10}) hydrocarbons.

Hydrocarbons, especially aromatic hydrocarbons, can react in the presence of strong acids to form coke. This coke is a complex polynuclear aromatic material that is low in hydrogen. Coke can deposit on the surface of a catalyst, blocking access to the active sites, and reducing the activity of the catalyst. Coke poisoning is a major problem in fluid catalytic cracking catalysts, where coked catalysts are circulated to a fluidized bed combustor to be regenerated. In hydrocracking, coke deposition is virtually eliminated by the catalyst's hydrogenation function.

In a well-designed hydrocracking system, the hydrogenation function adds hydrogen to the tarry deposits. This reduces the concentration of coke precursors on the surface. There is, however, a slow accumulation of coke that reduces activity over a 1–2 year period. Refiners respond to this slow reduction in activity by raising the average temperature of the catalyst bed to maintain conversions. Eventually, however, an upper limit to the allowable temperature is reached and the catalyst must be removed and regenerated.

Catalysts carrying coke deposits can be regenerated by burning off the accumulated coke. This is done by service in rotary or similar kilns rather than leaving catalysts in the hydrocracking reactor, where the reactions could damage the metals in the walls. Removing the catalysts also allows inspection and repair of the complex and expensive reactor internals. Regeneration of a large catalyst charge can take weeks or months, so refiners may own two catalyst loads, one in the reactor, one regenerated and ready for reload.

The thermal reactions also convert the metal sulfide hydrogenation functions to oxides and may result in agglomeration. Excellent progress has been made since the 1970s in regenerating hydrocracking

catalysts; similar regeneration of hydrotreating catalysts is widely practiced.

After combustion to remove the carbonaceous deposits, the catalysts are treated to disperse active metals. Vendor documents claim more than 95% recovery of activity and selectivity in these regenerations. Catalysts can undergo successive cycles of use and regeneration, providing long functional life with these expensive materials.

As illustrated earlier, for various forms of more conventional hydrocracking, the type of catalyst used can influence the product slate obtained. For example, for a mild hydrocracking operation at constant temperature, the selectivity of the catalyst varies from about 65% to about 90% by volume. Indeed, several catalytic systems have now been developed with a group of catalysts, specifically, for mild hydrocracking operations. Depending on the type of catalyst, they may be run as a single catalyst or in conjunction with a hydrotreating catalyst.

CONCLUSIONS

The purposes of hydroprocessing are (1) to improve existing petroleum products or develop new products or even new uses; (2) to convert inferior or low-grade materials into valuable products; and (3) to transform near-solid residua into liquid fuels. The distinguishing feature of the hydrogenating processes is that, although the composition of the feedstock is relatively unknown and a variety of reactions may occur simultaneously, the final product may actually meet all the required specifications for its particular use.

Hydrocracking is similar to catalytic cracking, with hydrogenation superimposed and with the reactions taking place either simultaneously or sequentially. Hydrocracking was initially used to upgrade low-value distillate feedstocks, such as cycle oils (highly aromatic products from a catalytic cracker that usually are not recycled to extinction for economic reasons), thermal and coker gas oils, and heavy-cracked and straight-run naphtha. These feedstocks are difficult to process either by catalytic cracking or reforming, because they are usually characterized by a high polycyclic aromatic content and/or by high concentrations of the two principal catalyst poisons, sulfur and nitrogen compounds.

Hydrocracking allows refiners the potential to balance fuel oil supply and demand by adding VGO cracking capacity. Situations where this is the case include: (1) refineries with no existing VGO cracking capacity; (2) refineries with more VGO available than VGO conversion capacity; (3) refineries where addition of vacuum residuum conversion capacity has resulted in production of additional cracking feedstocks boiling in the VGO range (e.g., coker gas oil); and (4) refineries that have one of the two types of VGO conversion units but could benefit from adding the second type. In some cases, a refiner might add both gas oil cracking and residuum conversion capacity simultaneously.

Those refiners who do choose gas oil cracking as part of their strategy for balancing residual fuel oil supply and demand must decide whether to select a hydrocracking unit or a fluid catalytic cracking unit. Although the two processes have been compared vigorously over the years, neither of the processes has evolved to be the universal choice for gas oil cracking. Both processes have their advantages and disadvantages, and process selection can be properly made only after careful consideration of many case-specific factors. Among the most important factors are: (1) product slate required; (2) amount of flexibility required to vary the product slate; (3) product quality (specifications) required; and (4) the need to integrate the new facilities in a logical and cost-effective way with any existing facilities.

Hydrodesulfurization

James G. Speight
CD & W Inc., Laramie, Wyoming, U.S.A.

INTRODUCTION

The hydrodesulfurization process is a specific hydrogenation process and, as employed in petroleum refining, can be classified as nondestructive or destructive.

Nondestructive, or simple, hydrogenation is generally used for the purpose of improving product quality without an appreciable alteration of the boiling range. Mild processing conditions are employed so that only the more unstable materials are attacked and the sulfur, nitrogen, and oxygen compounds undergo hydrogenolysis to split out hydrogen sulfide (H_2S), ammonia (NH_3), and water (H_2O), respectively. An example is the hydrodesulfurization of naphtha with temperatures in the range of 330–370°C (625–695°F) and hydrogen partial pressures of 100–500 psi.

On the other hand, destructive hydrogenation (hydrocracking) is characterized by the cleavage of carbon–carbon bonds with concurrent addition of hydrogen to the fragments to produce saturated lower-boiling products. Such treatment requires severe reaction temperatures (usually of the order of 360–410°C, 680–770°F) as well as high hydrogen pressures to minimize reactions that lead to the formation of undesirable products such as coke.

HYDRODESULFURIZATION CHEMISTRY

Kinetic studies using individual sulfur compounds have usually indicated that simple first-order kinetics with respect to sulfur is the predominant mechanism by which sulfur is removed from the organic material as hydrogen sulfide. However, there is still much to be learned about the relative rates of reaction exhibited by the various compounds present in petroleum (see Ref.[1] and references cited therein).

The reactions involving the hydrogenolysis of sulfur compounds encountered in hydroprocessing are exothermic and thermodynamically complete under ordinary operating conditions. The various molecules have very different reactivity, with mercaptan sulfur much easier to eliminate than thiophene sulfur or dibenzothiophene sulfur.

The structural differences between the various sulfur-containing molecules make it impractical to have a single rate expression applicable to all reactions in hydrodesulfurization. Each sulfur-containing molecule has its own hydrogenolysis kinetics, which is usually complex because several successive equilibrium stages are involved and these are often controlled by internal diffusion limitations during refining.

The development of general kinetic data for the hydrodesulfurization of different feedstocks is complicated by the presence of a large number of sulfur compounds each of which may react at a different rate because of structural differences as well as differences in molecular weight. This may be reflected in the appearance of a complicated kinetic picture for hydrodesulfurization in which the kinetics is not, apparently, first order. The overall desulfurization reaction may be satisfied by a second-order kinetic expression, when it can, in fact, also be considered as two competing first-order reactions. These reactions are: 1) the removal of nonasphaltene sulfur and 2) the removal of asphaltene sulfur. It is the sum of these reactions that gives the second-order kinetic relationship.

In addition, the sulfur compounds in a feedstock may cause changes in the catalyst upon contact and, therefore, every effort should be made to ensure that the kinetic data from such investigations are derived under standard conditions. In this sense, several attempts have been made to accomplish standardization of the reaction conditions by presulfiding the catalyst, passage of the feedstock over the catalyst until the catalyst is stabilized, obtaining the data at various conditions, and then rechecking the initial data by repetition.

Thus, it has become possible to define certain general trends that occur in the hydrodesulfurization of petroleum feedstocks. One of the more noticeable facets of the hydrodesulfurization process is that the rate of reaction declines markedly with the molecular weight of the feedstock. For example, examination of the thiophene portion of a (narrow-boiling) feedstock and the resulting desulfurized product provides excellent evidence that benzothiophenes are removed in preference to the dibenzothiophenes and other condensed thiophenes. The sulfur compounds in heavy oils and residua are presumed to react (preferentially) in a similar manner.

It is also generally accepted that the simpler sulfur compounds (e.g., thiols, R-SH, and thioethers, R-S-R^1) are (unless steric influences offer resistance to the

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120008050

hydrodesulfurization) easier to remove from petroleum feedstocks than the more complex cyclic sulfur compounds such as the benzothiophenes. It should be noted here that, because of the nature of the reaction, steric influences would be anticipated to play a lesser role in the hydrocracking process.

Residua hydrodesulfurization is considerably more complex than the hydrodesulfurization of model organic sulfur compounds or, for that matter, narrow-boiling petroleum fractions. In published studies of the kinetics of residua hydrodesulfurization, one of three approaches has generally been taken:

1. The reactions can be described in terms of simple first-order expressions.
2. The reactions can be described by the use of two simultaneous first-order expressions—one expression for easy-to-remove sulfur and a separate expression for difficult-to-remove sulfur.
3. The reactions can be described using a pseudo-second-order treatment.

Each of the three approaches has been used to describe hydrodesulfurization of residua under a variety of conditions with varying degrees of success, but it does appear that pseudo-second-order kinetics is favored. In this particular treatment, the rate of hydrodesulfurization is expressed by a simple second-order equation:

$$C/(1 - C) = k(1/\mathrm{LHSV})$$

where C is the wt% of sulfur in product/wt% of sulfur in the charge, k is the reaction rate constant, and LHSV is the liquid hourly space velocity (volume of liquid feed per hour per volume of catalyst).

Application of this model to a residuum desulfurization gave a linear relationship. However, it is difficult to accept the desulfurization reaction as a reaction that requires the interaction of two sulfur-containing molecules (as dictated by the second-order kinetics). To accommodate this anomaly, it has been suggested that, as there are many different types of sulfur compounds in residua and each may react at a different rate, the differences in reaction rates offered a reasonable explanation for the apparent second-order behavior. For example, an investigation of the hydrodesulfurization of an Arabian light-atmospheric residuum showed that the overall reaction could not be adequately represented by a first-order relationship. However, the reaction could be represented as the sum of two competing first-order reactions and the rates of desulfurization of the two fractions (the oil fraction and the asphaltene fraction) could be well represented as an overall second-order reaction.

Other kinetic work has shown that, for a fixed level of sulfur removal, the order of a reaction at constant temperature can be defined with respect to pressure:

$$k = 1/\mathrm{LHSV}(P_\mathrm{h})^n$$

where P_h is the hydrogen partial pressure, LHSV is the liquid volume hourly space velocity, k is a constant, and n is the order of the reaction. It has been concluded, on the basis of this equation, that the hydrodesulfurization of residuum is first order with respect to pressure over the range 800–2300 psi, although it does appear that the response to pressure diminishes markedly (and may even be minimal) above 1000 psi.

One marked effect of a hydrodesulfurization process is the buildup of hydrogen sulfide and the continued presence of this reaction product in the reactor reduces the rate of hydrodesulfurization. Thus, using the two first-order models, the effect of hydrogen sulfide on the process can be represented as:

$$k/k_0 = 1/(1 + k_1 P_{\mathrm{H_2S}})$$

where k is the rate constant with hydrogen sulfide present, k_0 is the rate constant in the absence of hydrogen sulfide, and k_1 is a constant.

Data obtained using this equation showed that a change in hydrogen sulfide concentration from 1% to 12% (by volume) could reduce by 50% the rate constants for the easy-to-desulfurize and the difficult-to-desulfurize reactions. On the basis of the data available from kinetic investigations, the kinetics of residuum hydrodesulfurization may be represented by the following general equation:

$$-\mathrm{d}s/\mathrm{d}t = \left[P_\mathrm{H}^n/(1 + k_\mathrm{a}A + k_\mathrm{s}P_{\mathrm{H_2S}})^m\right]k_i S_i$$

where s is the weight fraction of sulfur in the liquid phase, t is the residence time, P_H is the partial pressure of hydrogen, A is the weight fraction of asphaltenes in the liquid phase, $P_{\mathrm{H_2S}}$ is the partial pressure of hydrogen sulfide, S_i is the weight fraction of sulfur associated with component i in the range of i–j, k_a is the adsorption constant for asphaltenes, k_s is the adsorption constant for hydrogen sulfide, and k_i is the specific reaction rate constant for component i.

The latter constant, k_i, in the above relationship is a function of the chemistry of the component, the catalyst activity, and the reaction temperature. Therefore,

$$k_i = k_0(A/A_0)\mathrm{e}^{E/RT}$$

where k_0 is the reaction rate constant at standard catalyst activity, A_0 is the standard catalyst activity, A is

the catalyst activity, ΔE is the activation energy, R is the gas constant, and T is the absolute temperature.

This relationship gives activation energies for the hydrodesulfurization of various residua in the range 27–35 kcal/mol. In this context, it was interesting to note that the deasphalting of Khafji residuum had no effect on the activation energy of 30 kcal/mol and it was suggested that the activation energies of the various components in a particular residuum might be approximately the same.

THE HYDRODESULFURIZATION PROCESS

The hydrodesulfurization process operates using high hydrogen pressure, typically 1500–500 psi, and temperatures range from 290°C to 370°C (550–700°F). Several process configurations are used, depending on the feed and the design criteria.[1,2]

Process Description

The hydrodesulfurization process is essentially the reaction of hydrogen with a predominantly hydrocarbon feedstock to produce a desulfurized hydrocarbon product and hydrogen sulfide.[2,3] In the process, the feedstock is first pressurized to a pressure that is a little higher than that of the reactor section, mixed with hot recycle gas, and preheated to the temperature of the reactor inlet. The hot feedstock (and the recycle gas) is then introduced to the catalyst in the reactor where temperatures ranging from 290°C to 455°C (550–850°F) and pressures in the range 150–3000 psi prevail.

The use of a recycle gas technique in the hydrodesulfurization process minimizes losses of hydrogen—a very expensive commodity in petroleum refining. The hydrodesulfurization process requires high partial pressures of hydrogen to promote high desulfurization reaction rates and to diminish coke (carbon) deposition on the catalyst. To maintain high partial pressures of hydrogen, it is necessary to introduce hydrogen into the reactor at several times the rate of hydrogen consumption, and it is possible to recover most of the unused hydrogen in the separator after which it is then recycled for further use. Indeed, if it were not possible to recover most of the unused hydrogen, the process economics would probably be very questionable. However, tolerable amounts of hydrogen may be lost as a result of the solubility of the gas in the liquid hydrocarbon product or even during the removal of the hydrogen sulfide (and the light hydrocarbon gases) from the recycle gas.

Hydrogen requirements for the hydrodesulfurization process depend on the nature of the feedstock as well as on the extent of the desulfurization.[1,4] For example, the heavier feedstocks require substantially more hydrogen to produce a given product than the lighter feedstocks, or to yield a product with a predetermined amount of sulfur. The theoretical hydrogen requirements often differ markedly from the experimental values because of the nitrogen and oxygen contents of the feedstock. The metals content of the feedstock may also influence the hydrogen consumption by altering the characteristics of the catalyst. It is conceivable that metals deposition onto the catalyst may serve to increase the hydrocracking activity of the catalyst, thereby promoting higher consumption of hydrogen in the process.

Reactor Design

Reactor designs for hydrodesulfurization of various feedstocks vary in the way in which the feedstock is introduced into the reactor and in the arrangement, as well as the physical nature, of the catalyst bed. The conditions under which the hydrodesulfurization process operates (i.e., high temperatures and high pressures) dictate the required wall thickness (determined by the pressure/temperature/strength ratio). In addition, resistance of the reactor walls to corrosive attack by hydrogen sulfide and hydrogen (to name only two of the potential corrosive agents of all of the constituents in, or arising from, the feedstock) can be a problem. Precautions should be taken to ensure that wall thickness and composition yield maximum use and safety.

Reactors may vary from as little as 4 ft in diameter to as much as 20 ft in diameter and have a wall thickness anywhere from 4.5 to 10 in. or so.[3] These vessels may weigh from 150 tons to as much as 1000 tons. Obviously, before selecting a suitable reactor, shipping and handling requirements (in addition to the more conventional process economics) must be given serious consideration.

Once-through reactors, where the incompletely converted or unconverted fraction of the feedstock is separated from the lower-boiling products, are now being replaced by recycle reactors. In these reactors, any unconverted feedstock is sent back (recycled) to the reactor for further processing. In such a case, the volume flow of the combined (fresh and unconverted) feedstock is the sum of the inputs of the fresh feedstock and recycled feedstock:

$$F_T = F_F + F_R$$

where F_T is the total feedstock in the unit, F_F is the fresh feedstock, and F_R is the recycled feedstock. Thus, the recycle ratio, R, is the ratio of the recycled

feedstock to the fresh feedstock:

$$R = F_R/F_F$$

The recycle ratio may also be expressed as a percentage in some texts or references. However, the recycled feedstock, having been through the reactor at least once, will have a lower reactivity than the original feedstock, thereby reducing the reactivity of the feedstock in each recycle event.

The downflow fixed-bed reactor has been used widely for hydrodesulfurization processes and is so called because of the feedstock entry at the top of the reactor while the product stream is discharged from the base of the reactor. The catalyst is contained in the reactor as stationary beds with the feedstock and hydrogen passing through the bed in a downward direction. The exothermic nature of the reaction and the subsequent marked temperature rise from the inlet to the outlet of each catalyst bed require that the reaction mix be quenched by cold recycle gas at various points in the reactor, hence the incorporation of separate catalyst beds as part of the reactor design.

To combat the inevitable loss in desulfurizing activity of the catalyst that must be presumed to occur with time under any predetermined set of reaction conditions, the bed inlet temperature may be increased slowly, thereby increasing the overall temperature of the catalyst bed and so maintaining constant catalyst activity. Thus, depending on the nature of the feedstock, there may be a considerable difference between the start-of-run temperature and the end-of-run temperature.

In fixed-bed reactors, the catalyst may be poisoned (deactivated) progressively. For example, the first catalyst bed will most likely be poisoned by vanadium and nickel deposition initially at the inlet to the bed and then progressively through the bed as the active zone is gradually pushed downward into the bed. Once catalyst poisoning has progressed through the bed, the catalyst may have to be discarded or regenerated. However, catalyst regeneration may only suffice for a limited period of time and the catalyst may have to be completely replaced. This is especially true in the case of feedstocks such as residua and heavy oils.

Removal of the metal contaminants is not usually economical, or efficient, during rapid regeneration. In fact, the deposited metals are believed to form sulfates during removal of carbon and sulfur compounds by combustion, which produce a permanent poisoning effect. Thus, if fixed-bed reactors are to be used for residuum or heavy-oil hydrodesulfurization (in place of the more usual distillate hydrodesulfurization), it may be necessary to first process the heavier feedstocks to remove the metals (especially vanadium and nickel) and so decrease the extent of catalyst bed plugging. Precautions should also be taken to ensure that plugging of the bed does not lead to the formation of channels within the catalyst bed, which will also reduce the efficiency of the process and may even lead to pressure variances within the reactor because of the distorted flow patterns with eventual damage.

The radial-flow fixed-bed hydrodesulfurization reactor is a variation of the downflow fixed-bed reactor. Again, the feedstock enters the top of the reactor but instead of flowing downward through the catalyst bed, the feedstock is encouraged to flow through the bed in a radial direction and then out through the base of the reactor. There are certain advantages of this type of reactor, not the least of which is a low pressure drop through the catalyst bed; in addition, a radial bed reactor has a larger catalyst cross-sectional area as well as a shorter bed depth than the corresponding downflow reactor. It is this latter property that gives rise to the smaller pressure drop across the catalyst bed.

However, there are more chances of localized heating in the catalyst bed and (in addition to the more expensive reactor design per unit volume of catalyst bed) it may be more difficult to remove contaminants from the bed as part of the catalyst regeneration sequence. For this reason alone, it is preferable that this type of reactor is limited to hydrodesulfurization of low-boiling feedstocks such as naphtha and kerosene and application to the higher-boiling heavy oils and residua is usually not recommended.

In summary, fixed-bed processes have advantages in ease of scale-up and operation. The reactors operate in a downflow mode, with liquid feed trickling downward over the solid catalyst concurrent with the hydrogen gas. The usual catalyst is cobalt/molybdenum (Co/Mo) or nickel/molybdenum (Ni/Mo) on alumina (Al_2O_3) and contains 11–14% molybdenum and 2–3% of the promoter nickel or cobalt. The alumina typically has a pore volume of 0.5 ml/g. The catalyst is formed into pellets by extrusion, in shapes such as cylinders (ca. 2 mm in diameter), lobed cylinders, or rings.

These trickle bed reactors normally operate in the downflow configuration and have a number of operational problems, including poor distribution of liquid and pulsing operation at high liquid and gas loading. Scale-up of these liquid–gas–solid reactors is much more difficult than for a gas–solid or gas–liquid reactor. Nevertheless, the downflow system is convenient when the bed is filled with small catalyst particles. And, because the catalyst particles are free from diffusional limitations, these reactors are quite effective as filters of the incoming feed. Any suspended fine solids, such as fine clays from production operations, accumulate at the front end of the bed. Eventually, this will lead to high-pressure differentials between the inlet and outlet end of the reactor.

The main limitation of this type of reactor is the gradual accumulation of metals when heavy feedstocks are processed. The metals accumulate in the pores of the catalyst and gradually block access for hydrogenation and desulfurization. The length of operation is then dictated by the metal-holding capacity of the catalyst and the nickel and vanadium content of the feed. As the catalyst deactivates, the reactor feed temperature is gradually increased to maintain conversion. Toward the end of a run this mode of operation leads to accumulation of carbonaceous deposits on the catalyst, further reducing the activity.

The upflow expanded-bed reactor operates in such a way that the catalyst remains loosely packed and is less susceptible to plugging and therefore more suitable for the heavier feedstocks as well as for feedstocks that may contain considerable amounts of suspended solid material. Because of the nature of the catalyst bed, such suspended material will pass through the bed without causing frequent plugging problems. Furthermore, the expanded state of motion of the catalyst allows frequent withdrawal from, or addition to, the catalyst bed during operation of the reactor without the necessity of shutdown of the unit for catalyst replacement. This property alone makes the ebullated reactor ideally suited for the high-metal feedstocks (i.e., residua and heavy oils) that rapidly poison a catalyst with the ever-present catalyst replacement issues.

In the reactor, the feedstock and hydrogen are caused to flow upward through the catalyst bed in which each catalyst particle is reputed to have independent motion and can therefore (in theory) migrate throughout the entire catalyst bed. The heat of the reaction (which could be a problem in other reactors if it were not controlled) is dissipated in raising the temperature of fresh feedstock to that existing in the reactor. Spent catalyst can be withdrawn from the reactor and replaced with fresh catalyst on a daily basis if necessary and the need for time wasting and costly shutdowns can thus be eliminated.

Expanded-bed reactors normally operate with 1/32 in. extruded catalysts that require partial recycle of the liquid products to maintain the catalyst particles in an expanded and fluidized state.

The nearly completely random motion of the catalyst bed virtually ensures an isothermal operation, but the efficiency of the hydrodesulfurization reaction tends to suffer because of the back mixing of the product and feedstock. Hence, to effect sulfur removal at over 75% efficiency, it may be necessary to operate with two or more reactors in series. The need for two or more of these units to effectively desulfurize a feedstock may be cited as a disadvantage of the reactor, but the ability of the reactor to operate under isothermal conditions as well as the onstream catalyst addition–withdrawal system and the fact that the reactor size required for an expanded catalyst bed is often smaller than that required for a fixed bed can be cited in support of such a unit.

It is also possible to use finely divided catalyst in the expanded-bed reactor. If the catalyst is a suitable size (50–200 μm, i.e., 50×10^{-4} cm to 200×10^{-4} cm), it is possible to operate the expanded-bed reactor without recycling the liquid products to maintain the catalyst in the fluidized state. In addition, the finely divided catalyst has a relatively larger number of external pores on the surface than the extruded catalyst and is less likely to have metal contaminants plugging up these pores because of their size. The overall effect of a finely divided catalyst in this reactor is more efficient sulfur removal for a given set of process conditions.

CATALYSTS

Many of the catalysts for the hydrodesulfurization process are produced by composting a transition metal (or its salt) with a solid support.[4] The metal constituent is the active catalyst. The most commonly used materials for supports are alumina, silica, silica–alumina, kieselguhr, magnesia (and other metal oxides), as well as the zeolites. The support can be manufactured in a variety of shapes or may even be crushed to particles of the desired size. The metal constituent can then be added by contact of the support with an aqueous solution of the metal salt. The whole is then subjected to further treatment that will dictate the final form of the metal on the support (i.e., the metal oxide, the metal sulfide, or even the metal itself).

Molybdenum sulfide (MoS_2), usually supported on tailored alumina, is widely used in petroleum processes for hydrogenation reactions. It is a layered structure that can be made much more active by addition of cobalt or nickel. When promoted with cobalt sulfide (CoS), making what is called cobalt–molybdenum catalysts, it is widely used in hydrodesulfurization processes. The nickel sulfide (NiS) promoted version is used for hydrodenitrogenation as well as hydrodesulfurization. The closely related tungsten compound (WS_2) is used in commercial hydrocracking catalysts. Other sulfides [iron sulfide (FeS), chromium sulfide (Cr_2S_3), and vanadium sulfide (V_2S_5)] are also effective and are used in some catalysts. A valuable alternative to the base metal sulfides is palladium sulfide (PdS). Although it is expensive, palladium sulfide forms the basis for several very active catalysts. Zeolites loaded with transition metal sulfides have also been used as hydrodesulfurization catalysts.

The surface area of the catalyst is usually large (200–300 m^2/g), but almost this entire surface is contained within the pore space of the alumina. Cobalt and molybdenum are two of the more common metals

that are used as hydrodesulfurization catalysts and, as such, are dispersed in a thin layer within the pore system of the alumina. When these metals are used together as a hydrodesulfurization catalyst, the catalyst is more tolerant to poisoning agents, and is usually classed as being suitable for a wide variety of feedstocks, but more particularly to the heavy oils and residua. Other metals may be used such as a combination of nickel and molybdenum, but this catalyst is a more active hydrogenation catalyst than the cobalt–molybdenum catalyst and consumes more hydrogen per mole of sulfur removed. However, the nickel–molybdenum catalyst is useful for the hydrodesulfurization of catalytic cracking feedstocks (where maximum hydrogen consumption is desirable). The catalyst is more selective for nitrogen removal from feedstocks and presumably can tolerate higher nitrogen feedstocks without losing as much activity in a given time than the cobalt–molybdenum catalyst. Another catalyst that has received some attention is nickel–tungsten on alumina, which is a very active hydrogenation catalyst and displays a high activity in hydrocracking reactions.

Hydrodesulfurization catalysts are normally used as extrudates or as porous pellets, but the particle size and pore geometry have an important influence on process design, especially for the heavier feedstocks. The reaction rates of hydrodesulfurization catalysts are limited by the diffusion of the reactants into, and the products out of, the catalyst pore systems. Thus, as the catalyst particle size is decreased, the rate of desulfurization is increased but the pressure differential across the catalyst bed also diminishes and a balance must be reached between reaction rate and pressure drop across the bed.

Hydrodesulfurization catalysts are usually more active in the sulfide form with the external sulfur being applied either during the preparation from a sulfur-containing source or during the initial contact of the catalyst with the sulfur-containing feedstock. Chemically, the sulfiding process is a reduction in the oxide form of the metal (cobalt, nickel, etc.) on the alumina support by conversion to the metal sulfide. This can be achieved, in the absence of a sulfur-containing feedstock, by injecting hydrogen sulfide or any other low-boiling sulfide (carbon disulfide, dimethyl sulfide, and the like) directly into the recirculating hydrogen stream. If the feedstock is present and contains above 1% sulfur, addition of an external source is not necessary. Temperatures for the sulfiding process usually range from 290°C to 315°C (550–600°F), while minimum pressures of about 150 psi are also recommended.

CATALYST BED PLUGGING

Catalyst bed plugging can arise in a variety of ways, but the overall effect of bed plugging is always the same: expensive shutdowns and possibly the complete renewal of the expensive catalyst. Thus, the deposition of rust, coke, or metal salts (e.g., sodium chloride) from heavier and dirtier feedstock may contribute to the plugging of a catalyst bed. Vanadium and nickel may also be deposited onto the surface of the catalyst as well as into the pore system. Asphaltene deposition from residua and heavy oils is also a potential means of bed plugging; coagulation of the asphaltenes becomes appreciable at temperatures above 420°C (790°F) with the formation of hard, coke-like materials on the catalyst.

The exothermal nature of the reaction may also contribute indirectly to catalyst plugging. For example, lack of proper control over the heat liberated during the hydrodesulfurization process may lead to the formation of localized hot spots in the catalyst that can then initiate asphaltene coagulation at these points. In a similar manner, adsorption of the lighter constituents from a whole crude (heavy oil) or from, say, an atmospheric residuum could leave tarry materials within the void space of the catalyst, thereby leading to the eventual denaturing of the catalyst with a concurrent loss in catalyst efficiency. Finally, another cause of bed plugging may be the physical nature of the catalyst itself. Agglomeration of catalyst particles may lead to the formation of catalyst lumps within the bed, which again leads to catalyst inefficiency, presumably through formation of localized hot spots within the bed. The resulting end point of any of the above deficiencies will be an increased pressure drop through the catalyst bed that eventually requires process shutdown.

Catalyst bed plugging (and a subsequent expensive shutdown) may be minimized by using corrosion-resistant alloys throughout the entire system of feed lines, heaters, reactors, etc., thereby reducing the risk of rust accumulation in the feedstock. Removal of debris that has accumulated in the feedstock from the transportation and storage aspects may be achieved by mechanical filtering. Every attempt should be made to desalt the crude oil to remove any inorganic materials (sodium chloride, etc.) that may originate from the brines that are associated with crude oils as they are pumped to the surface of the earth. In the processing of the heavier feedstocks, it may be advisable to suspend the top layer of catalyst in basket-type devices so that this layer, when plugged, can be conveniently removed and replaced. It may be necessary to use two or more reactors in parallel rather than one large reactor—this would not only lead to more catalyst surface area for collecting debris, but if shutdown was inevitable, one of the reactors could be left onstream while the other reactor was being cleaned. Alternatively, upflow reactors would create the tendency for any debris in the feedstock to fall out of the catalyst,

and a circulating stream of liquid below the catalyst bed could be channeled through a filter to remove any solid materials. In a similar manner, prefiltering of the feedstock through a bed of bauxite or similar material will facilitate removal of debris and, in the presence of hydrogen, may also encourage removal of vanadium.

CATALYST POISONING

Hydrocarbons, especially aromatic hydrocarbons, can undergo multiple condensation reactions in the presence of catalysts to form coke. This coke is a complex polynuclear aromatic material that is low in hydrogen. Coke can deposit on the surface of a catalyst, blocking access to the active sites and reducing the activity of the catalyst. Poisoning by coke deposits is a major problem in fluid catalytic cracking catalysts where catalysts containing deposited coke are circulated to a fluidized bed combustor to be regenerated. In hydrocracking, coke deposition is virtually eliminated by the catalyst's hydrogenation function. However, the product referred to as ''coke'' is not a single material. The first products deposited are tarry deposits that can, with time and temperature, continue to condense to a solid deposit.

In a hydrodesulfurization system, the hydrogenation function adds hydrogen to the tarry deposits. This reduces the concentration of coke precursors on the surface. There is, however, a slow accumulation of coke that reduces activity over a 1–2 yr period. Refiners respond to this slow reduction in activity by raising the average temperature of the catalyst bed to maintain conversions. Eventually, however, an upper limit to the allowable temperature is reached and the catalyst must be removed and regenerated.

The metallurgy of the reactor, product quality considerations, or catalyst selectivity sets the upper temperature limits. Metallurgy considerations result from decreases in wall strength at higher temperatures. Product quality can be compromised at higher temperatures because thermal cracking reactions begin to compete with acid cracking as temperatures approach 400°C (750°F). Selectivity changes result from all the possible side reactions, which become more important as the temperatures rise.

Burning off the accumulated coke can regenerate catalysts containing deposited coke. This is achieved using rotary or similar kilns rather than leaving catalysts in the hydrocracking reactor, where the reactions could damage the metals in the walls. Removing the catalysts also allows inspection and repair of the complex and expensive reactor internals, discussed below. Regeneration of a large catalyst charge can take weeks or months, so refiners may own two catalyst loads, one in the reactor, one regenerated and ready for reload.

In addition, organometallic compounds produce metallic products that influence the reactivity of the catalyst by deposition on its surface. The transfer of metal from the feedstock to the catalyst constitutes an irreversible poisoning of the catalyst. After combustion to remove the carbonaceous deposits, the catalysts are treated to redisperse active metals.

PROCESS VARIABLES

The major process variables are 1) reactor temperature; 2) hydrogen pressure; 3) LHSV; and 4) hydrogen recycle rate.

Reactor Temperature

The temperature in the hydrodesulfurization reactor is often considered to be the primary means by which the process is controlled. For example, at stabilized reactor conditions, a rise of 10°C (18°F) in the reaction temperature will substantially increase, and may even double, the reaction rate. Generally, an increase in the temperature (from 360°C to 380°C, i.e., from 680°F to 715°F) will increase the conversion slightly or for a fixed conversion of about 90% enable the quantity of catalyst necessary for the process to be halved.

In the same manner as in hydrocracking, hydrogen is added at intermediate points in hydrodesulfurization reactors. This is important for control of reactor temperatures. The mechanical devices in the reactor, called reactor internals, that accomplish this step are very important to successful processes. If redistribution is not efficient, some areas of the catalyst bed will have more contact with the feedstock.

There are, however, limits to which the temperature can be increased without adversely affecting process efficiency; at temperatures above 410°C (770°F), thermal cracking of the hydrocarbon constituents becomes the predominant process that can lead to formation of considerable amounts of low-molecular-weight hydrocarbon liquids and gases. In addition, increasing the partial pressure of the hydrogen cannot diminish these high-temperature cracking reactions. In addition, excessively high temperatures (above 400°C or 750°F) lead to deactivation of the catalyst much more quickly than lower temperatures.

Hydrogen Pressure

The overall effect of increasing the partial pressure of hydrogen is to increase the extent of the conversion through an increase in catalyst activity. This is to be

expected because the essential function of the catalyst is to serve as a means by which the reactants are brought together, thereby promoting interaction between the feedstock constituents and the hydrogen. As with the temperature variable, there are also limitations to increasing the partial pressure of the hydrogen. Use of excessively high partial pressures (for conventional feedstocks—above 1000 psi; for heavy feedstocks this figure could be as high as 2000 psi) may only serve to saturate the catalyst, and any increase in the partial pressure of the hydrogen will affect the conversion only slightly.

Liquid Hourly Space Velocity

The LHSV is the ratio of the hourly volume flow of liquid in, say, barrels to the catalyst volume in barrels, and the reciprocal of the LHSV gives the contact time. Because the catalyst volume for the process will be constant, the space velocity will vary directly with the feed rate. A decrease in the LHSV (or, alternatively, an increase in the contact time) will usually bring about an increase in the efficiency (or extent) of the hydrodesulfurization process. To maintain a fixed rate of hydrodesulfurization when the feed rate is increased, it may be necessary to increase the temperature.

Hydrogen Recycle Rate

The optimum use of hydrodesulfurization catalysts requires a relatively high hydrogen partial pressure, and it is therefore necessary to introduce with the feedstock quantities of hydrogen that are considerably greater than required on the basis of stoichiometric chemical consumption. In all cases, process economics dictate that unused hydrogen should be recycled after it has been partially (or completely) freed from hydrogen sulfide that was produced in the previous pass.

The overall hydrogen consumption is a summation of several processes:

1. Removal of the sulfur, nitrogen, and oxygen in the feedstock as the hydrogenated analogs, i.e., hydrogen sulfide, ammonia, and water, respectively.
2. Addition of hydrogen to unsaturated (olefin) functions in the products as will occur in the prevailing conditions of the hydrodesulfurization process.
3. Destruction, by saturation (i.e., addition of hydrogen), of certain aromatic compound types.
4. Stabilization of unsaturated short-lived organic intermediates that exist during hydrocracking.

Thus, if the hydrogen is not recycled, the process economics is unfavorable and, in addition, the efficiency of the hydrodesulfurization reaction may be adversely affected because of the possible competing reactions outlined above.

The hydrodesulfurization process involves catalytic treatment with hydrogen to convert the various sulfur compounds present to hydrogen sulfide. The hydrogen sulfide is then separated and converted to elemental sulfur by the Claus process. From this point some of the hydrogen sulfide is oxidized to sulfur dioxide by air and sulfur is formed by the overall reaction.

CONCLUSIONS

Petroleum refining has entered a significant transition period as the industry moves into the 21st century. Refinery operations have evolved to include a range of next-generation processes (that include hydrotreating of heavy oils and residua) as the demand for transportation fuels and fuel oil has shown a steady growth.

Hydroprocessing petroleum fractions has long been an integral part of refining operations, and in one form or another, hydroprocesses are used in every modern refinery. The primary goal of the recent hydrodesulfurization processes is to convert heavy feedstocks to lower-boiling products and during the conversion there is a reduction in the sulfur content. The technology of hydroprocesses is well established for gas oil and lower-boiling products but processing heavy oils and residua presents several problems that are not found with distillate processing and that require process modifications to meet the special requirements that are necessary for heavy feedstock desulfurization.

Hydrodynamics of Trickle-Bed Reactors

K. D. P. Nigam

Department of Chemical Engineering, Indian Institute of Technology, New Delhi, India

INTRODUCTION

Three-phase reactors consisting of flow of liquid and gas with a fixed bed of catalyst have various applications, particularly in the petroleum industry for hydroprocessing of oils. Mainly, trickle-bed reactors (TBRs) are used for this purpose. Trickle-bed reactors are catalytic randomly packed fixed-bed tubular devices traversed vertically downward by a gas–liquid stream (Fig. 1). The reactor is widely used in many gas–liquid–solid catalytic industrial applications like petroleum refining [hydrotreatment (hydrodesulfurization, hydrodenitrogenation, alkylation, etc.) and hydrocracking of petroleum fractions], petrochemical (hydrogenation of naphtha cracked main products for getting different usable products, hydrogenation of higher aldehydes, reactive distillation) and chemical industries (for oxidation and absorption purposes), waste treatment, and biochemical and electrochemical processing.[1] Typical process conditions and hydrogen consumption in TBR for various hydrotreating processes are given in Table 1.[2] The importance of hydroprocessing has been accelerated because of the imposition of stringent environmental regulations on petroleum products to achieve future goals of sustainability and a cleaner environment and a more demanding situation of middle distillates (mainly transportation fuels) against the availability of heavier and high-sulfur crudes.

The TBR reactor configuration ensures flexibility of operation and high throughputs of gas and liquid. Owing to a motionless catalyst bed, nearly plug flow is achieved in TBRs and in that respect, they are superior to other three-phase reactors where the catalyst is either slurried or fluidized.[3] Trickle-beds are usually operated at elevated pressures of about 2–30 MPa to slow down catalyst deactivation, increase the concentration of the gaseous component in the liquid phase, attain high conversion, achieve better heat transfer, and handle large gas volumes at less capital expense. High catalyst load, easy catalyst separation, and no catalyst attrition are other advantages for this type of reactor, whereas high pressure drop, flow maldistribution, and long diffusion distance are the areas concerned in the performance of TBR. Being a cocurrent mode of operation with respect to the flow of liquid and gas, it is also disadvantageous as conversion is suppressed by competitive adsorption because of different products (where most part of the bed is under NH_3 and H_2S rich condition for the case of hydroprocessing).

HYDRODYNAMIC PARAMETERS

The different hydrodynamic parameters that are important for the design and scale-up of TBR, are pressure drop, liquid holdup, flow regime, liquid distribution, and wetting efficiency. The interactions of different hydrodynamic parameters are shown in Fig. 2. It is established that pressure drop increases with the increase of operating pressure, gas mass flux, liquid mass flux, and viscosity of the liquid phase. Pressure drop is decreased with the increase of bed porosity and structure of the bed. The structure of the bed is dependent on the type of loading of catalyst (sock loading and dense loading). Though the dense loading gives higher pressure drop than that of sock loading, it improves the performance in TBR. The H_2/hydrocarbon ratio reduces up to 40% in dense loading for getting the same result even when keeping all other operating parameters the same with respect to sock loading.[4] Liquid holdup reduces with the raise of operating pressure. At relatively low gas mass flux, it decreases more rapidly than at higher gas mass flux. Though at higher liquid mass flux external wetting efficiency of the catalyst particles is not a crucial hydrodynamic parameter, it is important in TBR as it deals with very low liquid velocity. It has more importance in small-scale TBRs that are generally used for the development of better technology and catalyst evaluation because of lower cost and safer operation.[5] Wetting efficiency increases with a raise of gas mass flux and operating pressure as these process variables increase spreading of liquid over catalyst particles because of the increase in shear stress on the gas–liquid interface.[6] The increase in liquid mass flux increases the liquid holdup and wetting efficiency. Liquid distribution is an important parameter for proper utilization of the catalyst. Properly designed liquid distributors,

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007996

properly designed structure of catalyst, and appropriate method of packing are necessary for getting uniform liquid distribution.

Pressure Gradient and Liquid Holdup

Accurate knowledge of two-phase frictional pressure drop and liquid holdup is essential for design, scale-up, and performance of TBR. The hydrodynamics is affected differently in each flow regime.[7–10] Of particular interest in the industry is the extensively used trickle flow encountered at low gas and liquid superficial velocities.

Two-phase pressure gradient is defined as the variation of the internal pressure per unit reactor length. The pressure gradient is related to the mechanical energy dissipation owing to the two-phase flow through the fixed bed of solid particles. It is needed in evaluating the mechanical energy losses, in sizing equipment for pumping and compression of the fluid, and most of the other relevant design variables like gas–liquid mass transfer, liquid–solid mass transfer, and heat transfer are often estimated using the knowledge of two-phase frictional pressure drop and liquid holdup.[11]

Liquid holdup (h_L) is defined as the volume of liquid contained in the bed per unit bed volume. It is a function of the physical properties of the fluid phases and the bed characteristics. It is a basic parameter for reactor design, because it is related to other important parameters, namely, pressure gradient, gas–liquid interfacial area, the mean residence time of the liquid phase, catalyst loading per unit volume, axial dispersion coefficient, mass transfer characteristics, and heat transfer coefficient at the wall, etc. The optimal value of liquid holdup is desirable for better performance of TBR as a high value of liquid holdup will increase mass transfer resistance while too low a value of liquid holdup will decrease the proper utilization of the catalyst bed. Sometimes, the term total liquid saturation (β_t) is used to describe the amount of liquid in the bed. It is defined as the volume of liquid present in a unit void volume of the reactor. Thus, the liquid holdup and total liquid saturation are related as:

$$h_L = \varepsilon\beta_t \tag{1}$$

As the catalyst particles are porous, the total liquid saturation (β_t) is the sum of internal or intraparticle liquid saturation and interparticle or external liquid saturation. The external liquid saturation is further divided into residual or static liquid saturation (β_s), and free draining or dynamic saturation (β_d). The static liquid saturation is a function of liquid physical properties and particle shape, size, and wettability. The dynamic liquid saturation is the fraction of volume of liquid collected after draining of the reactor on simultaneously closing the inlet and outlet streams.

Table 1 Typical operating conditions for different hydrotreating processes used in trickle-bed reactors

Hydrotreating process	Temperature (°C)	Hydrogen partial pressure (atm)	LHSV	Hydrogen consumption (Nm^3/m^3)
Naphtha	320	10–20	3–8	2–10
Kerosene	330	20–30	2–5	5–15
Atm. gas oil	340	25–40	1.5–4	20–40
VGO	360	50–90	1–2	50–80
ARDS	370–410	80–130	0.2–0.5	100–175
VGO HCR	380–430	90–200	0.5–1.5	150–300
Residue HCR	400–440	120–210	0.1–0.5	150–300

VGO, vacuum gas oil; ARDS, atm. residue desulfurization; VGO HCR, vacuum gas oil hydrocracking; Residue HCR, residue hydrocracking.

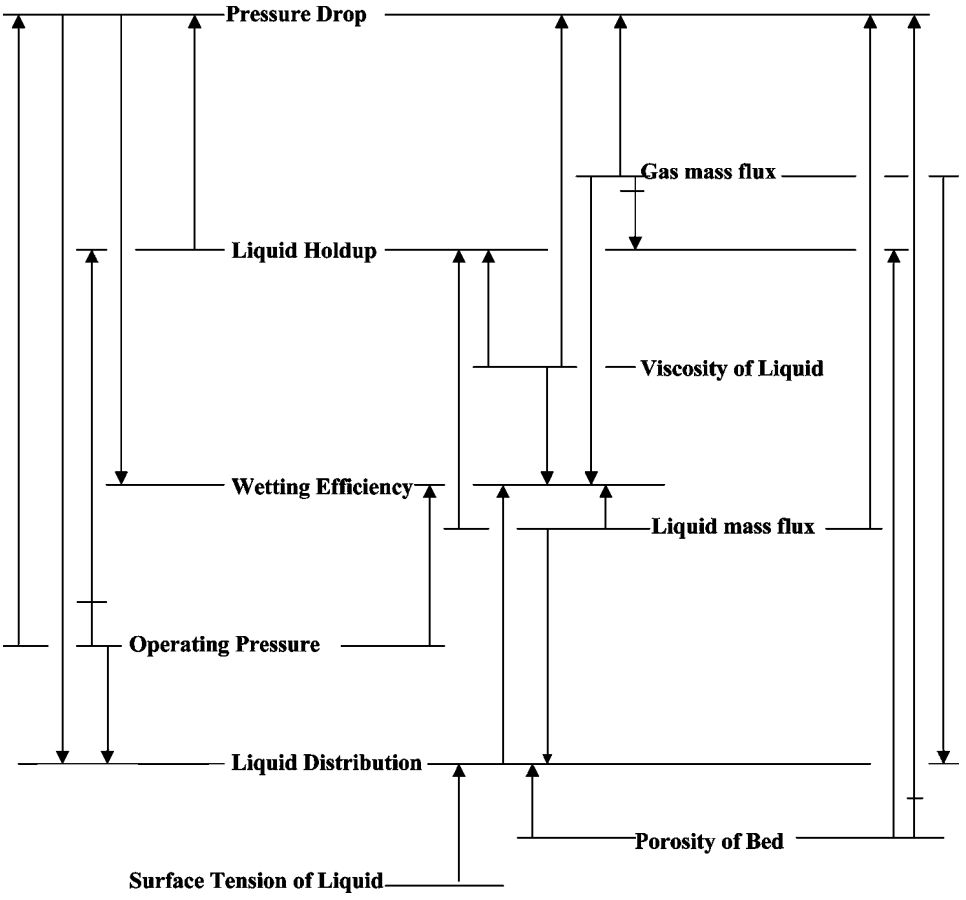

Fig. 2 Cause–effect diagram of different hydrodynamic parameters in TBR with the process variables and properties of gas and liquid (cause effect, increasing effect and decreasing effect).

There are three different techniques for measuring liquid holdup in a laboratory TBR operated under high pressure: 1) tracer method; 2) drainage method; and 3) gravimetric or weighing method. In the tracer method, the tracer is introduced in the liquid stream and the concentration of the tracer is analyzed at the outlet of the stream. Different types of common tracers are used. These are organic liquids (e.g., heptane and hexane), electrolytes (NaCl, KCl, NH_4Cl, etc.), and radioisotope tracers (bromine-82, molybdenum-99, and technetium-99m, etc.). For analyzing the tracer concentration at the outlet, gas chromatograph and refractometer are used for the case of organic liquid as a tracer. Conductivity measurements are taken when the tracer is an electrolyte.

For the case of radioisotope tracer experiments, nonintrusive methods are used to get the outlet concentration of tracer by utilizing collimated scintillation detectors. Radioisotope tracers have many advantages such as on-line detection, high detection sensibility, and availability in different compatible forms over conventional tracers.[12] This method can also help in troubleshooting and checking the performance of industrial TBR under operational conditions.

In the drainage method, the dynamic liquid holdup is measured in which the inlet and outlet streams are simultaneously shut off and the liquid drained from the reactor is measured. In the gravimetric method, the column is weighed during continuous operation. From the weight obtained, the weight of the dry column is subtracted so that the value of the liquid holdup can be obtained. The method permits the determination of both dynamic and static holdup. However, its application encounters two difficulties: one is linked with the effect of auxiliary equipment (connections with the fluid inlet and outlet lines) and the other with the inaccuracy of measuring differences between heavy weights. The tracer method and drainage method give comparable values of liquid holdup and are recommended for measuring liquid holdup in TBR at high pressure operation.[11,13–15] Nemec et al. measured liquid holdup in TBR at high pressure (up to 7 MPa) with the weighing method and recommended this procedure as it is less time-consuming compared to the other two methods and is less costly compared to the tracer method.[16] The volumetric liquid–liquid mass transfer coefficients between dynamic and static zones and volumetric liquid–solid mass transfer coefficients between static liquid and porous particles can also be evaluated from tracer studies.[17]

Recently, magnetic resonance imaging (MRI) technique has been applied for the measurement of liquid

holdup.[18] In this technique, high-resolution images are taken that are able to characterize liquid rivulets within the bed and to detect the presence of thin water films on the surfaces of the packing elements. Hence, magnetic resonance signal is detected only from the liquid.

The correlations and models that have been established on the basis of atmospheric pressure data are summarized in Refs.[1,19–22]. Investigations in pressurized TBR have been performed by Ellman et al., Wammes et al., Larachi et al., and Al-Dahhan et al.[20,21,23–28] These studies have shown that the hydrodynamic parameters are considerably affected by the gas density, and the correlations and models based on data at atmospheric pressure are not valid in the whole range of operating pressure.

The existing hydrodynamic models can be broadly classified into two different categories on the basis of empirical approach and theoretical approach. The empirical approach is based on dimensional analysis to produce explicit correlations for pressure drop and liquid holdup using flow variables and packing characteristics or using the Lockhart–Martinelli parameter, which was proposed for open horizontal tubes.[19–21,24–27,29–35] The theoretical approach involves balance equations deduced from the mass and momentum conservation laws. The different forces acting in the flow of gas and liquid over the catalyst particle are derived from different approaches. Sáez and Carbonell expressed the volume-averaged momentum equations for steady, one-dimensional incompressible flow of gas and liquid to derive the equations for liquid holdup and pressure drop expressed in terms of relative permeability.[36] The relative permeability of each phase has been correlated as a function of liquid saturation of each phase depending on the experimental results. In this concept, the phase interaction terms are considered to be negligible. The phenomenological slit model developed by Holub et al., Al-Dahhan and Dudukovic, and Iliuta et al. involves momentum and mass balances for the local flow in the assumed geometry and mapping the average bed properties to the assumed geometry.[22,28,37,38] It is a modified form of the Ergun equation. Initially, Holub et al. modeled the complex geometry of the actual void space in the catalyst bed at the pore level by the much simpler flow inside a rectangular slit.[22,38] In their model, the width of the slit is a function of bed porosity, the liquid was assumed to flow equally on the upper and lower surfaces, and the angle of inclination of the slit to the vertical axis is related to a tortuosity factor for the packed bed. The surface area per unit volume of solid in this rectangular slit was made equal to the surface area per unit volume of solid in the reactor. They introduced the concept of slip of the velocity and shear at the gas–liquid interface by introducing two slip parameters:

$$V_{i,\mathrm{G}} = f_{\mathrm{v}} V_{i,\mathrm{L}} \tag{2}$$

$$\tau_{i,\mathrm{L}} = f_{\mathrm{s}} \tau_{i,\mathrm{G}} \tag{3}$$

where $V_{i,\mathrm{L}}$ and $V_{i,\mathrm{G}}$ are interfacial velocity of gas and liquid respectively; $\tau_{i,\mathrm{L}}$ and $\tau_{i,\mathrm{G}}$ are interfacial shear stress of liquid and gas respectively; f_{s} and f_{v} are shear and velocity slip factors respectively.

The resulting pressure drop and liquid saturation model of Holub et al. indicates zero shear stress at the gas–liquid interface. Attou et al. considered a model based on macroscopic mass and momentum conservation laws in which the drag force has a contribution of both particle–liquid and gas–liquid interactions.[39] The liquid–solid and gas–liquid interaction forces are formulated on the basis of the Kozeny–Carman equation by taking into account the presence of liquid films and the gas–liquid slip motion. The gas–liquid interaction forces are generated because of the gas–liquid drag for the relative motion between the liquids and the force by which the gas pushes the liquid against the solid particles. The fundamental force balance model developed by Tung and Dhir involves force balance equations in liquid and gas phase in an elemental reactor volume.[40] Recently, Narasimhan et al. extended this approach with particle–gas drag, particle–liquid drag, and liquid–gas interfacial drag in addition to taking into consideration the excess drag for the tortuosity effect.[41] The tortuosity corrects the gravity term in the liquid phase and gas phase force balance equation, which has the expression

$$\tau = g\cos\theta - \mu g \sin\theta \tag{4}$$

where θ accounts for the distance traveled in the tortuous path and μ accounts for the excess loss in force caused by drags on the liquid and liquid following tortuous path. The comparison of different hydrodynamic models for TBR has been described by Kundu et al.[42]

Flow Regime

In TBR, basically four flow regimes have been observed depending on the gas and liquid and packing characteristics.[1]

Trickle flow regime

Trickle flow occurs at low liquid and gas flow rates. In trickle flow, the liquid flows down the reactor on the surface of the packing in the form of rivulets and films while the gas phase travels in the remaining void space. This regime is also termed gas continuous regime or

homogenous flow or low-interaction regime because very little interaction between gas and liquid exists in this regime.

Pulse flow regime

The pulse flow occurs at relatively high gas and liquid input flow rates. It refers to the information of slugs that have a higher liquid content than the remainder of the bed. The pulsing behavior refers to gas and liquid slugs traversing the reactor alternately.

Spray flow regime

Spray flow regime occurs at high gas flow rates and low liquid flow rates. The liquid phase moves down the reactor in the form of droplets entrained by the continuous gas phase.

Bubble/dispersed bubble flow regime

The bubble flow regime occurs at high liquid flow rates and low gas flow rates. The entire bed filled with the liquid and gas phase is in the form of slightly elongated bubbles. If the gas flow rate is increased, the bubbles become highly irregular in shape. For the foaming systems, an increase in gas and/or liquid flow rates leads to foaming, foaming pulsing, pulsing, and spray flow regime.

Flow regime transition between trickle flow and pulse flow

The knowledge of the hydrodynamics regime prevailing in the reactor is crucial in the design of TBR, as with the change in the hydrodynamic regime, all the hydrodynamic and kinetic parameters of the reactor also change considerably. The industrial TBRs are operated in the pulse flow regime. The transition between the two regimes is not very sharp. Operation in the trickle flow regime ensures a large liquid-residence time and provides a large single-pass conversion of the liquid reactant. This is therefore useful for reactions that are kinetic controlled. Operation in the pulsing regime provides an increase in the mass transfer coefficients and is therefore suitable for relatively fast mass transfer limited reactions. Heat transfer rate is also intensified because of the vigorous interactions between the phases, and this is of crucial importance in vessels packed with catalyst, in which highly exothermic reactions occur, e.g., in hydroprocessing. Catalyst utilization is also increased because of increased wetting of the catalyst particles. Peclet number (= LV/D, where L = catalyst bed length, V = superficial velocity, D = dispersion coefficient) also increases while changing the flow regime from trickle flow to pulse flow.[43,44] This is because the exchange rate between the two streams in the pulse flow regime is high and the pulses probably cause mixing between the different parallel flowing liquid streams in the column. Thus, if plug flow is required to attain a high yield, a pulse flow regime is preferred to a trickle one. Uniformity of flow through the bed is also obtained in pulse flow regime. Flexibility in changing the operating gas and liquid flow rates is also greater in the pulsing regime. Therefore, it is necessary to know the flow regime in which the reactor is operating for a given condition. It is also important to know whether the same flow regime will be maintained in scaling up from laboratory to pilot- or commercial-scale reactors.

Several investigators have studied the flow pattern in TBR at atmospheric pressure and presented their data in terms of flow maps. Various coordinates have been used by different investigators to present the flow maps to take into account the variation in density, viscosity, and surface tension of the fluids. The shift in the boundary between the trickle flow and the pulse flow regimes occurs at higher velocities of liquid and gas by increase in operating pressure.[24,45] This is because of a decrease in liquid holdup at higher operating pressure, in which the mean liquid film thickness becomes smaller and, consequently, the liquid film cannot collapse any more to initiate the pulses. The flow regime transition occurs at higher gas and liquid velocities as the packing hydrophobicity increases and the transition shifts to lower mass flow rates of liquid and gas as the concentration of surfactant increases.[46] The transition boundary shifts toward higher throughputs for small-size catalyst particles.[47]

The most commonly used method for detecting the flow regime transitions involves the visual observation of the flow pattern across the column walls. The subjective nature of this method results in the uncertainty of the flow regime boundaries. Another possible method is the measurement of conductivity traces. On the other hand, because of the various variables such as physical fluid properties, surface tension, bed porosity, size and shape of solid particles, which can significantly affect the flow regime, the existing flow maps are valid only in the particular range of conditions in which the experimental data are obtained. Other phenomena such as hysteresis and packing wettability have proven to be difficult in the use of these flow maps. Considering these limitations, theoretical or semiempirical models have been developed to predict the transition between the trickle and pulse regimes.

Liquid Distribution

Liquid distribution plays an important role in determining the reactor performance in TBR. To guarantee

uniform liquid distribution in a TBR has been a tough problem that has drawn much attention. The liquid tends to flow preferentially along the existing filaments where the porosity is high. The introduction of gas flow into the liquid–solid system smoothens the liquid distribution to some extent because of the competition between the liquid and gas phases for the interstitial pore space.[48]

Improper liquid distribution will result in nonoptimal use of catalyst, rapid deactivation of a part of the catalyst by creating hot spots or thermal instability, which means that improving flow distribution increases capacity and cycle length for existing plants. In highly exothermic reactions, the liquid is vaporized and the heat generated is not carried away by the liquid, leading to rapid deactivation of the catalyst.

The role played by the initial liquid distribution at the top of the bed is of decisive importance. A poorly designed liquid distributor can have a serious impact on the performance of TBR. The method of packing the catalyst particles, particularly the cylindrical extrudates, also affects the liquid distribution in TBR. If the cylindrical extrudates are packed with their major axis pointing downward toward one side of the reactor, the liquid will flow toward that side.[49] Al-Dahhan et al. reported that the essential requirement of the packed bed is to ensure reproducibility of the packing.[50] This is because even if a uniform liquid distribution is achieved at the distributor, significant bypassing (channeling) and/or segregation could occur because of the improper way in which the catalyst and fines are packed. The effect of prewetting of the catalyst bed is significant on the liquid distribution, as reported by Ravindra et al. and Kundu et al.[51,52] This prewetting effect can be explained in terms of liquid spreading over the dry catalyst particles (where pores are only responsible) and prewetted catalyst particles (where liquid film is only responsible).[53]

So, liquid distribution in TBR mainly depends on three factors:

1. Structure of the packed bed.
2. Gas–liquid–solid interaction.
3. Design of the distributor.

The above factors are well explained by Maiti et al.[54] Under the structure of the packed bed, the liquid distribution is dependent on: 1) porosity distribution; 2) D/d_p ratio (D is the diameter of reactor and d_p is the equivalent particle diameter); 3) H/d_p ratio (orientation problem) (H is the height of the catalyst bed); and 4) method of loading—convex, concave, and random (sock and dense loading).

Numerous studies on porosity distribution in randomly packed beds are available (Refs.[55,56] for experimental studies and Ref.[57] for computational study). These studies have shown that the porosity is higher near the vicinity of the wall and fluctuates significantly in the near-wall region (width of about four to five particle diameters). At a large ratio of D/d_p, there will also be lesser portions of wall and a large inner part of the catalyst bed, which will decrease the nonuniform distribution of liquid. Conversely, at a small ratio of D/d_p, the flow will be uneven because of the large portion of the wall. This effect is called the wall effect. Herskowitz and Smith suggested a value of 18 for the D/d_p ratio above which wall effect can be eliminated.[58] Al-Dahhan and Dudukovic proposed a value of 20, while Saroha et al. reported a value of 25 for D/d_p ratio.[28,48]

The dependence of gas–liquid–solid interaction on liquid distribution relies mainly on the gas and liquid mass fluxes and physical properties of liquids (surface tension, etc.). The design of liquid distributors in commercial hydroprocessing reactors is well explained by Jacobs and Milliken.[59] Three main factors are considered during the designing of the liquid distributor: 1) center-to-center spacing, which is directly proportional to particle size, is chosen as an optimum value so that radial mixing compensates for maldistribution; 2) liquid discharge pattern; and 3) wall coverage, in which the problem arises because of the absence of distributors located close to the reactor wall.

Different procedures for studies of liquid distribution in TBR are available in the literature. Though the liquid distribution studies using the collector at the outlet of the bed are mostly utilized because of its simplicity to carry out the experiments, there is a chance of flow redistribution at the exit region. So, recent studies emphasize the tomographic technique and the video imaging technique that provide the information on flow distribution more quantitatively and are useful for the validation of the computational fluid dynamics (CFD) model.[60] Marcandelli et al. suggested the residence time distribution (RTD) technique for the liquid distribution studies in a commercial reactor, which is also quantitative.[61] They also reported that liquid collectors and tomography are not good techniques for the liquid distribution studies in a commercial reactor because of unavailability of quantitative information and low spatial resolution with inapplicability in a porous medium, respectively.

CONCLUSIONS

In the past 50 yrs. much attention has been focused on pressure drop, liquid holdup, flow regime transition, and liquid distribution in TBR. Though significant progress in modeling the hydrodynamics of TBR theoretically has been made, the prediction of some

hydrodynamic parameters like pressure drop in TBR is still not so accurate because of the complexity of the gas–liquid flow pattern and their interaction. CFD simulation can be applied for the above purpose. The pulse flow regime is industrially favorable; more studies on flow behavior under this regime should be carried out. A good liquid distributor, appropriate structure of the bed, and starting with prewetted bed can improve liquid distribution in TBR. More emphasis is expected on studies of the effect of wettability on liquid distribution. To get a better estimation of structural information and flow field, MRI method can be applied because of its direct way of measurement. A high-quality distributor is to be developed based on cold flow modeling and supported by CFD calculations of commercial operating conditions with special emphasis on discharge pattern. The effect of flow dynamics on even and uneven irrigation of the particle may be explored.

The above aspects taken together will provide a holistic approach in the design of TBR, that will help to meet the EURO III and IV standards (5 and 10 ppmw) of the transportation fuels for a much better, cleaner, and greener environment.

INTRODUCTION

A hydrogel is a three-dimensional polymer network made of a hydrophilic polymer or a mixture of polymers. In general, at least 10–20% of the total weight of a hydrogel is water. When a hydrogel is dried, it is called xerogel, or simply a dried hydrogel. When a dried hydrogel is placed in an aqueous environment, it can absorb a large amount of water and swell isotropically to maintain its original shape. Swollen hydrogels maintain their shape without dissolving even in abundant water because of the presence of chemical or physical cross-linking of polymer chains. The extent of swelling depends inversely on the cross-linking density. When more than 95% of the total weight is water, the hydrogel is also called superabsorbent. It is not unusual to see hydrogels with more than 99% of water.

Because of the presence of high water content and the rubbery property, hydrogels have been frequently compared with the natural tissues. The similarity to natural tissues renders hydrogels useful in biomedical and pharmaceutical applications. Further, depending on the chemical structures of the constituting polymers, hydrogels can be tailored to respond to external stimuli, such as temperature, pH, solvent composition, electric field, light, and specific biomolecules. Those hydrogels can undergo change in swelling/deswelling, shape change, and sol–gel transformation upon stimulation by external factors, and they are often called ''smart hydrogels.'' Such an interesting nature of the smart hydrogels has allowed their use in controlled drug delivery, biomechanical devices, and separation systems.

The advent of nanotechnology has provided new avenues for engineering materials in nano- and microscales. In recent years, there have been extensive studies on potential applications of hydrogels in nanotechnology. Most of the studies have tried to exploit the unique properties of hydrogels, such as the hydrophilic nature of the surface, soft physical properties, and environmental sensitivity. Of particular interest has been nanoscale fabrication and manipulation of hydrogel-based materials that may lead to scientific and technological advances. Here, we review the current technologies on the preparation and potential applications of hydrogel-based nanomaterials, including hydrogel nanoparticles, hydrogel-coated nano/micro devices, inorganic (or organic) nanoparticle-entrapped hydrogels, and molecularly imprinted hydrogels.

HYDROGELS IN NANOTECHNOLOGY

The hydrophilic polymer molecules of a hydrogel are interconnected by cross-linking, and this structure prevents dissolution of the polymer chains in an aqueous solution despite absorption of a large amount of water by the hydrogel. Hydrogels are generally classified into chemical and physical gels, according to the type of cross-links. Chemical gels are produced by cross-linking of hydrophilic polymers via covalent bonding. In an aqueous solution, they absorb water until they reach equilibrium swelling, which depends on the cross-linking density. On the other hand, physical gels are generated by noncovalent bonding, such as molecular entanglements, electrostatic interactions, hydrogen bonding, and hydrophobic interactions. These interactions, in contrast to covalent bonding, are reversible and can be disrupted by changes in physical conditions, such as temperature, pH, ionic strength, and stress.

Fig. 1 illustrates representative mechanisms of hydrogel formation. There are a number of different

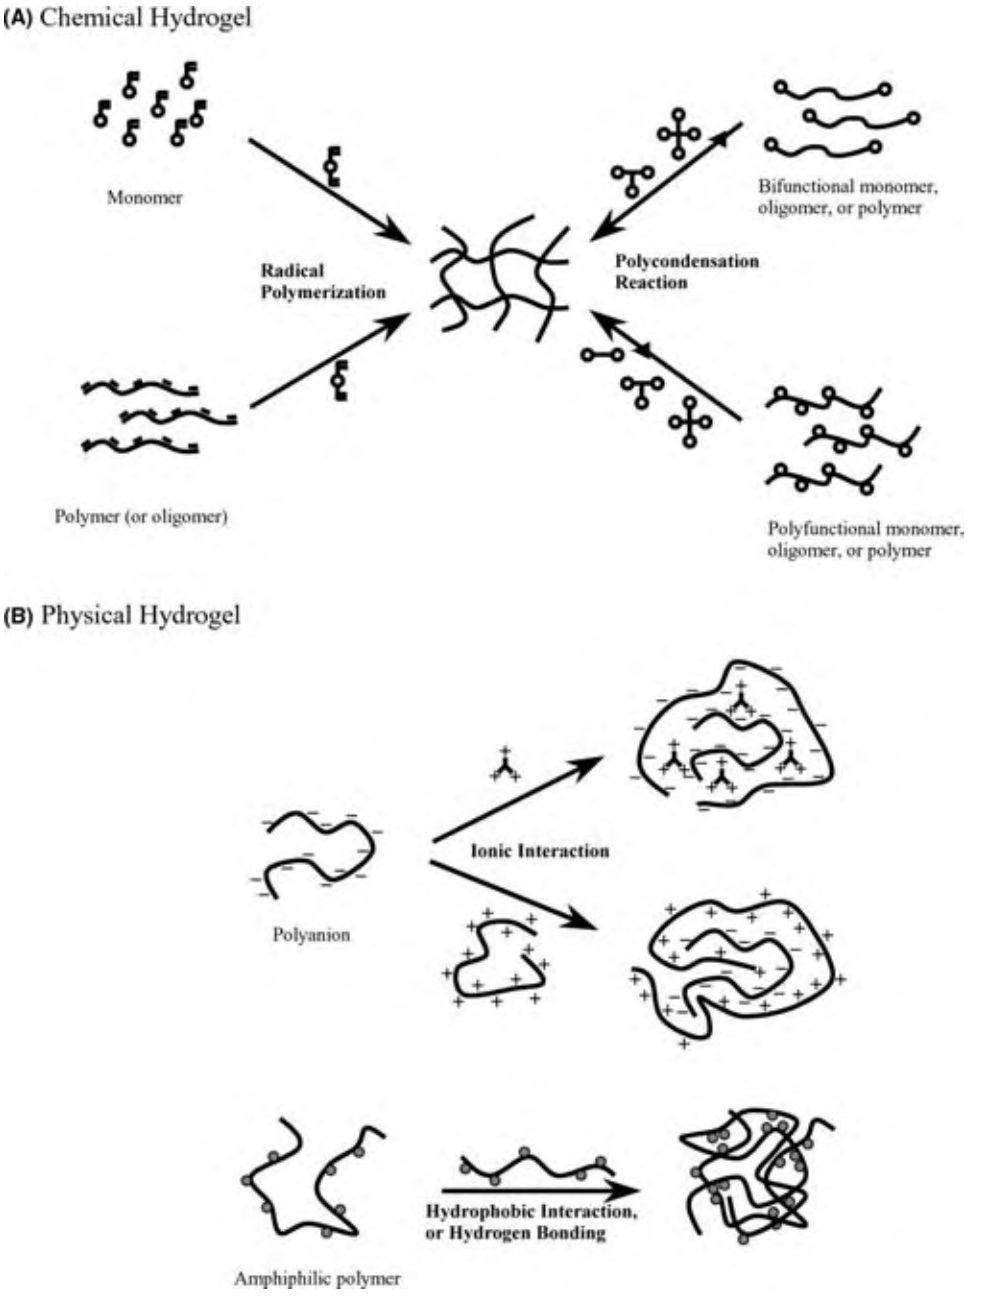

Fig. 1 Representative methods of hydrogel formation. (A) Chemically cross-linked hydrogels are prepared from monomers, oligomers, or polymers in the presence of cross-linking agents. The chemical cross-linking proceeds via radical polymerization or polycondensation reaction. (B) Physically cross-linked hydrogels can be formed by ionic interactions, hydrophobic interaction, or hydrogen bonding.

macromolecular structures that form physical or chemical hydrogels. Hydrogels can be designed to undergo biodegradation in a physiological solution,[1–3] exhibit rapid response to physical stimuli,[4–6] or reach the equilibrium swelling level within a few minutes.[7–9]

Furthermore, there are differences in preparation methods and properties between chemical and physical gels, and each gel type has its own advantages and disadvantages for the design of specific materials or devices involving nanotechnology. Physical gels have been primarily used for biomedical applications, especially in the form of polymer micelles or self-aggregates for controlled drug delivery to the specific sites of action. They are spherical in shape and have the mean diameter ranging from nanometers to micrometers. Because nanoparticles are frequently administrated via the systemic route, it is desirable to construct them with biodegradable polymers so that they can degrade

into low molecular weight entities eligible for renal excretion. Chemical gels that are covalently cross-linked provide a variety of potential applications because of their high stability in harsh environments, such as high temperature, acidic/basic solutions, and high stresses. In addition to drug delivery, chemical hydrogels have been considered as the constituents of diagnostic, electronic, and photonic devices.[10–12]

Nanoparticle-Bearing Hydrogels

Incorporation of functional nanoparticles into a hydrogel matrix produces unique properties, which cannot be found in other conventional organic/inorganic materials. Nanoparticles can be entrapped into a hydrogel matrix by chemical bonding or physical interactions with the polymer backbone of the hydrogel that have rubber elasticity and the stimuli-sensitive swelling/shrinking behavior. The entrapment of polymer nanoparticles, forming a crystalline colloidal array (CCA), into a hydrogel matrix has displayed different colors without adding coloring agents, responding to external stimuli.[10,13] By incorporating 10–12 nm magnetite (Fe_3O_4) or maghemite (γ-Fe_2O_3) into a hydrogel matrix, the shape of hydrogels can be modulated by applying magnetic field.[14,15]

Monodispersed colloidal particles are reported to form CCAs via slow particle sedimentation, centrifugation, and spin coating.[10,13,16] The CCA diffracts visible and near-infrared light at wavelengths dependent on the lattice spacing, which produces an intense color. By combining the characteristic of the CCA with stimuli-sensitive hydrogels, novel functional hydrogels have recently been prepared. Of various hydrophilic polymers, poly(*N*-isopropylacrylamide) (PNIPAM) and its copolymers have been widely used to prepare chemical gels containing CCAs, because they show fast stimuli-sensitive volume phase transition and are readily prepared by the free radical polymerization of monomers in the presence of a difunctional cross-linking agent.[10–12,14] Weissman et al.[10] prepared PNIPAM hydrogels by photopolymerization in the presence of polystyrene nanoparticles (99 nm in diameter) as a CCA component and *N*,*N*-methylene-*bis*-acrylamide as a cross-linking agent. This chemically cross-linked CCA hydrogels exhibited various colors according to the temperature that changes the hydrogel volume affecting the array lattice constant. Polyacrylamide-based hydrogels have also been investigated to entrap the CCA lattice.[13] Although polyacrylamide does not provide thermo-sensitive volume transition like PNIPAM, it allows incorporating molecular-recognition groups (e.g., crown ethers for metal ions and glucose oxidase for glucose) during its polymerization or by simple chemical modification. The recognition events may make the gel swell because of changes in environments within the hydrogel matrix, such as an osmotic pressure and pH, which increases the mean separation between the colloidal spheres, and thus changes the diffracted light to longer wavelengths. More recently, the use of monodispersed nanoparticles as a hydrogel matrix has been developed.[11,16,17] This technique involves preparation of monodispersed hydrogel nanoparticles by radial polymerization in the presence of the cross-linker and surfactant, and formation of nanoparticle networks (colloidal crystal gels) by centrifugation[16] or chemical cross-linking.[11,17] The resultant hydrogel matrices displayed a bright iridescence in the visible region of the spectrum and underwent a reversible color change in response to changes in the temperature or pH. For chemically cross-linked nanoparticle networks, the color was changed depending on the concentration and size of the nanoparticles.

Nanoparticles have also been incorporated into a hydrogel matrix to develop novel materials sensitive to stimuli, such as light[18] and magnetic fields.[14] The gold nanoshell, composed of a thin layer of gold surrounding a dielectric core (e.g., gold sulfide), is one of the representative nanoparticles that have been incorporated into chemical gels, resulting in unique optical properties.[19–21] The diameters of both the core and shell are known to be responsible for the optical properties of nanoshells.[19,20] As the core size and shell thickness can be readily manipulated during the fabrication process, the optical extinction profiles of the nanoshells can be adjusted to observe light at desired wavelengths. Recently, by using nanoshells which absorb near-infrared light, hydrogel/nanoshell composites have been prepared for photothermally modulated drug delivery.[22] Embedding the nanoshells in PNIPAM hydrogel produced unique properties by which the composite hydrogel exhibited volume transition upon the irradiation of near-infrared light, i.e., the nanoshells in the hydrogel matrix converted light to heat, raising the temperature of the composite above the low critical solution temperature of PNIPAM. Because near-infrared light is capable of being transmitted through tissue, such hydrogels bearing gold nanoshells may have promising potential as an injectable drug delivery system for low molecular weight drugs, peptides, proteins, and genes.[18,19,21,22]

Molecularly Imprinted Hydrogels

Design of a precise macromolecular architecture that can selectively recognize target molecules has gained significant attention because of its potential applications for separation processes, immunoassays,

biosensors, and catalysis.[23,24] Molecular imprinting technology has been developed as a response to the need to create such architectures. In general, molecular imprinting within polymers involves formation of prepolymerization complex between the template molecule and functional monomers, polymerization in the presence of a cross-linking agent and an appropriate solvent, and removal of the template.[25] Once the template is removed, the polymer network may have specific recognition elements for the target (or template) molecules. This nanoimprinting process is of great importance because it can create three-dimensional binding cavities for specific target molecules.

Because most recognition processes are associated with three-dimensional structure of the recognition site, it is preferable to limit the movement of the polymer chain that may affect affinity or selectivity to target molecules. Therefore, conventional methods to prepare molecularly imprinted polymers have used high ratios of the cross-linking agent to functional monomers, which leads to formation of rigid polymer matrix with low average molecular mass between cross-links.[26] On the contrary, imprinting within hydrogels requires different methods because they undergo changes in three-dimensional structure upon coming in contact with water. To maintain imprinting structure in an aqueous environment, hydrogels have been prepared by spatially varying cross-linking density.[25,27] As density fluctuations in the polymer network include microregions of localized higher cross-linking, hydrogels could retain an effective imprinting structure as well as proper rigidity to produce adequate specificity. Another promising strategy for imprinting within hydrogels is to match polymerization and rebinding solvents in terms of dielectric constant, polarity, and protic nature. This may reduce differences in swelling behavior, resulting in high binding affinity to target molecules. Also, in designing the network architecture for hydrogels, it is important to choose the length of the functional monomer and the molecular mass of the cross-linking monomer to endow with specificity to target molecules.[25,28]

Molecular imprinting provides shape-specific cavities (or nanovacuoles) that match the template molecule or chemical groups capable of specifically interacting with the template molecule. Of various polymers, ethylene glycol dimethyacrylate and methacrylic acid have been most widely used for the formation of imprinted polymers, where template molecules can be antibiotics,[29,30] carbohydrates,[19] peptides,[31] and enzymes.[32] Alvarez-Lorenzo et al.[33,34] and Hiratani et al.[35] have developed molecularly imprinted hydrogels by polymerizing in the presence of template molecule, functional monomer, and thermo-sensitive monomer. These hydrogels showed high affinity to target molecules as well as stimuli-sensitive recognition, by which the imprinted sites disappeared upon gel swelling and reformed upon shrinking.

The imprinted hydrogels, sensitive to analyte, have been the focus of many investigations for controlled drug release. A few examples are shown in Fig. 2. Fig. 2A shows that enzymes may be included in the hydrogel to invoke local pH changes by binding to analyte, and thus initiate the hydrogel swelling, modulating the drug release rate;[36,37] in Fig. 2B, cross-links can lose their function by free analytes and this leads to hydrogel swelling to change the drug release rate;[38,39] and in Fig. 2C, binding of analytes to specific sites or functional groups on the polymer backbone may change hydrophilicity (or hydrophobicity) of hydrogels, inducing swelling (or shrinking) in an aqueous environment.[40] It should be emphasized, however, that the currently available imprinting techniques involve nonspecific binding sites that decrease the specificity to target molecules. The precise control of the network structure of hydrogels via nanotechnology will contribute to a number of applications, including microfluidic devices, biomimetic sensors, drug delivery system, and membrane separation technology.

Hydrogel Nanoparticles

Because of their biocompatibility and soft rubbery nature, hydrogels have been extensively studied in biomedical and pharmaceutical fields. Macroscopic hydrogels have been studied for sustained drug delivery owing to their slow swelling kinetics. Microparticulate hydrogels for drug delivery have been examined more widely because of their unique properties resulting from small size. Initially, hydrophobic nano- and microparticles have been used extensively for systemic drug delivery, but it was soon found out that they were readily taken up by the reticuloendothelial system, and thus exhibited short residence time in blood. Thus, in an attempt to improve hydrophilicity for prolonged circulation time, the surfaces of the hydrophobic nanoparticles have been modified by conjugating, blending, and coating with hydrophilic polymers, such as polyethylene glycol (PEG) and PEG-containing block copolymers.[41,42]

Hydrogel nanoparticles have a special role in drug delivery in the sense that they have all the advantages of both nanoparticles and hydrogels with regard to the particle size and hydrophilicity. Hydrogel nanoparticles can swell rapidly because of large surface area and short diffusion path length for water. They can be modified to have reactive groups on the surface and are useful to introduce functional moieties, such as targeting and other bioactive moieties. Hydrogel nanoparticles consisting of stimuli-responsive polymers may exhibit corresponding responsive properties, which

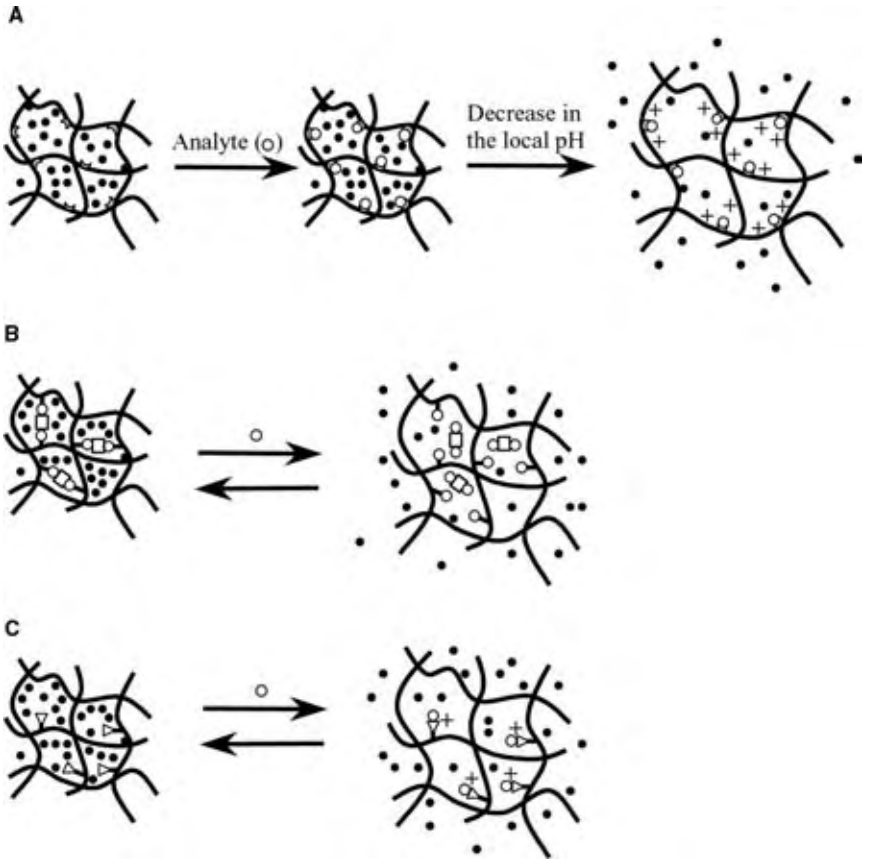

Fig. 2 Molecularly imprinted hydrogels for drug delivery. (A) Binding of analytes (○) to enzyme (ℭ) induces changes in the local pH. For cationic hydrogels, the acidic local pH results in ionization and swelling of hydrogel, resulting in faster release of drug (●). (B) Cross-linking agents (□) bind to analytes (○) anchored to the polymer backbone to maintain the hydrogel structure, which can swell and release the incorporated drugs as the concentration of free analyte increases, replacing the polymer-bound analytes. (C) Binding of analyte (○) of specific site or functional groups (▽) on the polymer backbone increases hydrophilicity of hydrogel, which induces swelling and drug release. (Modified from Ref.[26].)

are often found to become much faster than bulk hydrogels. Studies of hydrogel nanoparticle have intensified during the past decade because of enormous potentials in the development and implementation of new stimuli-responsive or smart materials, biomimetics, biosensors, artificial muscles, drug delivery systems, and chemical separation systems.

Chemically cross-linked hydrogel nanoparticles have been prepared in the presence of hydrophilic monomers, cross-linking agents, and emulsifiers. Advances in technology have enabled precise control of the core–shell structure of hydrogel nanoparticles.[43] The core–shell nanoparticles have been synthesized to modify surface properties of core particles or to provide stimuli-sensitivity for nonresponsive particles. Recently, multiresponsive core–shell hydrogel nanoparticles have also been developed by Jones and Lyon[43] and Gan and Lyon[44] They synthesized temperature- and pH-responsive hydrogel nanoparticles with core–shell morphologies, where core particles composed of PNIPAM were prepared via aqueous free radical polymerization, and then used as nuclei for subsequent polymerization of acrylic acid copolymers. Their swelling/deswelling thermodynamics were easily controlled by chemical manipulation of the core and shell structures, thus displaying both temperature and pH dependence. Without chemical cross-linking, core–shell hydrogel nanoparticles can also be prepared on the basis of the electrostatic interaction between water-soluble polymers.[45] Prokop et al.[46] have demonstrated that by atomizing the aqueous solution containing core polymer with negative charge, the nanosize droplets are encapsulated with cationic polymer solution by the electrostatic interaction (Fig. 3). This methodology showed promising potential as a protein delivery system.

Self-assembled hydrogel nanoparticles based on hydrophobically modified polysaccharides have been extensively studied as a drug carrier because of their excellent biocompatibility and ease of preparation. It is well known that polymeric amphiphiles, upon contact with an aqueous environment, spontaneously form micelles or micelle-like self-aggregates via undergoing intra- or intermolecular associations between hydrophobic moieties, primarily to minimize interfacial free energy. Hydrophobically modified polysaccharides are also known to self-assemble in aqueous media to form a unique core–shell structure that consists of hydrophobic segments and hydrophilic segments, respectively (Fig. 4). This type of hydrogels have multiple inner cores, which physically crosslink the hydrophilic polymer chains.[47] A number of polysaccharides have been investigated to create self-assembling systems, including dextran,[48] glycol chitosan,[49,50]

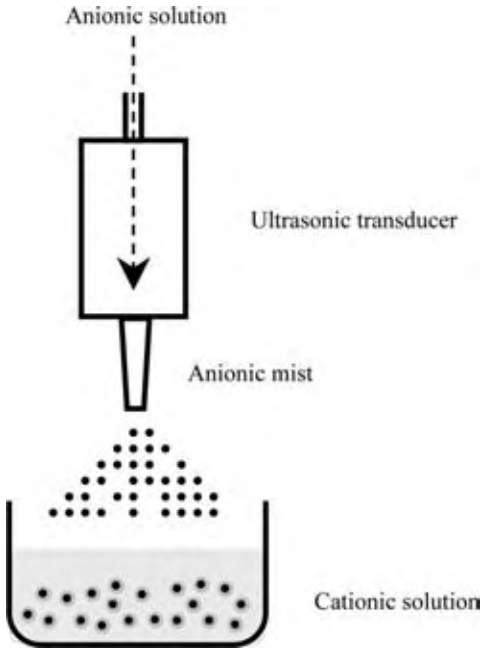

Fig. 3 Formation of the core–shell type hydrogel nanoparticles by electrostatic interactions. The anionic solution which contains core polymer is introduced as a mist into a cationic solution of shell polymer. (Modified from Ref.[45].)

pullulan,[51,52] and curdlan,[53] These polysaccharides are natural water-soluble polymers that are inherently biocompatible and biodegradable. The core–shell structure of self-assembled hydrogels can be employed as a potential delivery system that can effectively deliver hydrophobic drugs. It has been recently demonstrated that hydrophobically modified polysaccharides capable of forming nano-sized self-aggregates can imbibe hydrophobic drugs and release them in a sustained manner.[49] Hydrophobic moieties, conjugated to

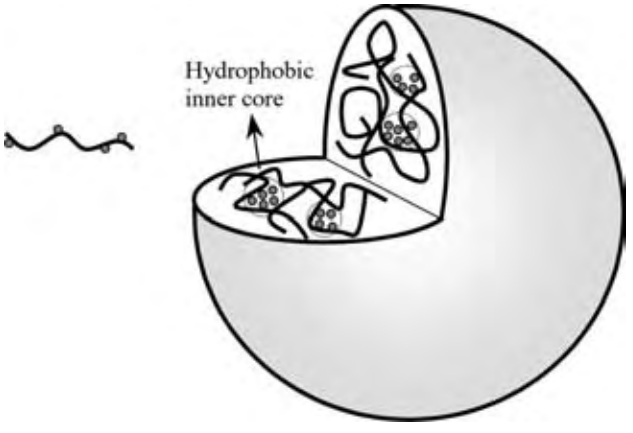

Fig. 4 Self-assembled hydrogel nanoparticles of hydrophobically modified polysaccharides. Note that nanoparticles have multiple inner cores which physically cross-link the hydrophilic polysaccharide chain. (Modified from Ref.[47].)

polysaccharides, can either be small molecules (e.g., cholesterol, alkyl chains, and bile acids)[47,51,53–55] or oligomers.[56] The conjugation of stimuli-sensitive hydrophobic moieties to polysaccharides may produce hydrogel nanoparticles, responsive to corresponding stimuli.[57] For example, Na et al.[53,56,57] have recently developed pH-sensitive hydrogel nanoparticles as an anticancer drug carrier. The extracellular pH of most solid tumors and inflammatory regions in the body is known to be lower than that in the normal tissues and blood (pH 7.4). To target the extracellular matrix of such disease sites, they prepared pullulan acetate-based nanoparticles bearing sulfonamide moieties, which show the hydrophobic nature at the low pH. The resulting nanoparticles rapidly released the anticancer drug (doxorubicin) at pH <7.0, whereas the drug release rate was substantially reduced at normal tissue pH (7.4).

Hydrogel Coating on the Surfaces

Surfaces of hydrophobic substrates have been frequently modified with hydrophilic polymers to achieve desirable properties for in vivo applications. Surface modification with hydrophilic polymers is known to minimize nonspecific interactions with blood proteins, cells, and tissues. The hydrophilic polymers commonly used for surface coating include PEG, polysaccharides, and poly(vinyl alcohol). To physically coat hydrophilic polymers on the nanoparticles, the solvent extraction/evaporation method has been used.[58,59] After the oil-in-water emulsion is prepared by adding the organic solution containing a hydrophobic polymer into the aqueous solution of a hydrophilic homopolymer or a block copolymer, the organic solvent is removed by evaporation or extraction, thus forming the hydrogel layer on the formed nanoparticles. The outer layer of a hydrophilic polymer in the nanoparticle is anchored by various interactions with the core polymer chains, such as physical entanglement, hydrophobic interaction, and hydrogen bonding. This approach has been frequently used for surface modification of biodegradable nanoparticles, such as poly(D,L-lactide) (PLA),[58] poly(lactide-co-glycolide),[59] and polyphosphazene.[60]

The hydrogel coating on the nanoparticles has also been achieved by radical polymerization. For poly (isobutyl cyanoacrylate) (PIBCA), the monomer was emulsified in an aqueous solution containing PEG that acts as a nucleophile initiator of polymerization through its hydroxyl terminal groups.[61] Once the aqueous pH is adjusted to 1, polymerization is initiated, thus forming PEG-coated PIBCA nanoparticles.[62,63] PNIPAM has been coated on the nanoparticles by radical polymerization in the presence of hydrophobic

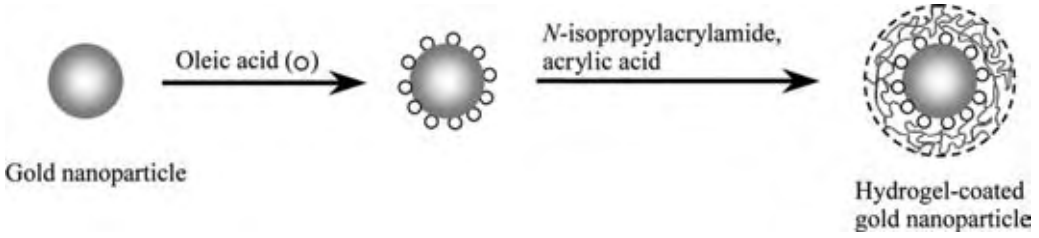

Fig. 5 Hydrogel-coated gold nanoparticles prepared by surfactant-free emulsion polymerization. After coating oleic acids on the gold nanoparticle, polymerization was carried out in the presence of *N*-isopropylacrylamide, acrylic acid, and ammonium persulfate (initiator). The size of resulting nanoparticles was in the range of 100–230 nm. (Modified from Ref.[69].)

nanoparticles to be coated, *N,N'*-methylenebisacrylamide (cross-linker), ammonium persulfate (initiator), and sodium dodecyl sulfate (emulsifier). The thickness of the outer hydrogel layer on the nanoparticles was readily controlled by varying the concentrations of the monomer and emulsifier.[64]

Hydrogels that coat metal and semiconductor nanoparticles are of considerable interest because of their unique size-dependent physicochemical properties.[65–67] Precise control of the structure and surface properties of nanoparticle would make them more attractive for use in biomedical applications. Inorganic nanoparticles have been conjugated to biomolecules such as sugars, peptides, proteins, and DNA. Such conjugates showed many advantages as fluorescent biological labels,[66–68] primarily appearing from inorganic nanoparticles, including high quantum efficiencies, optical activity over biocompatible wavelengths, and chemical or photochemical stability. It should be emphasized that in spite of numerous potential applications, inorganic

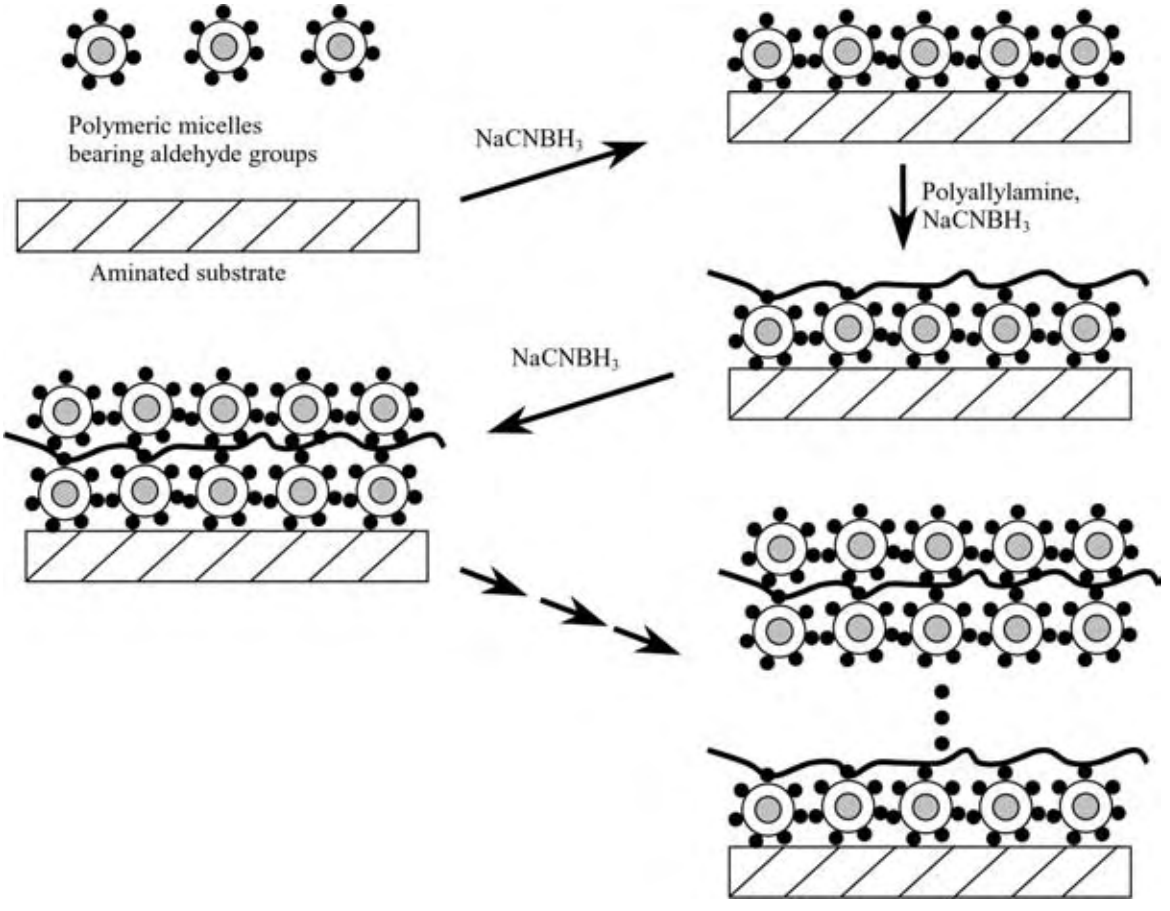

Fig. 6 Schematic illustration of the multilayered micellar coating on the surface. Polymeric micelles to be coated were first stabilized by polymerization of the hydrophobic inner core. The stable micelles were then immobilized on the aminated substrate by the reaction with aldehyde groups on the surface of polymeric micelle. (Modified from Ref.[74].)

nanoparticles have suffered from their aggregation and lack of biocompatibility. Hydrogel coating on such nanoparticles may not only prevent their aggregation by changing the surface hydrophilicity, but also improve their biocompatibility. Furthermore, use of stimuli-responsive hydrogels may provide unique properties for nanoparticles. Recent efforts have led to the development of hydrogel-coated inorganic nanoparticles that exhibit structural changes responsive to stimuli such as light. For example, hydrogel-coated gold nanoparticles have been prepared using surfactant-free emulsion polymerization method, as shown in Fig. 5.[69] The hydrogel layer was constructed with a mixture of *N*-isopropylacrylamide and acrylic acid, and its thickness could be varied by adjusting the amount of monomer and initiator, as well as the reaction time. The results revealed that the hydrogel can be thermally activated by exposure to light via the strong plasmon absorption of the gold nanoparticle core.

As mentioned earlier, the surface coating with hydrogel can improve the biocompatibility as well as provide specific functions. One of the promising strategies to improve the surface characteristics is to attach polymeric micelles onto the surfaces, thus forming the polymeric micelle-entrapped hydrogel layer. This approach is useful to maximize the number of tethered hydrophilic chains because the polymeric micelle has a high density of hydrophilic polymer on the surface, resulting in an effective nonfouling property. Further, as the polymeric micelles contain hydrophobic inner core as a reservoir of hydrophobic drugs, the surface coating with polymeric micelles may allow developing of biocompatible devices that can release the drug in a sustained manner. The structure of the polymeric micelles, however, is readily disrupted upon attachment to the surface, leading to the formation of a loosely packed layer structure.[70,71] In an attempt to stabilize the polymeric micelles, Ijima et al.[72] prepared heterobifunctional block copolymer of PEG–PLA, in which PEG had a reactive aldehyde group at the chain end, whereas PLA possessed a methacryloyl group that can be polymerized in the presence of the initiator. This amphiphilic copolymer was then exposed to an aqueous solution, which enabled it to form the polymeric micelle, followed by the polymerization of the hydrophobic inner core. The resulting micelles showed high stability in harsh environments.[72] The aldehyde groups at the end of PEG chain was used to chemically attach to the surfaces bearing the amino groups so that a single layer of polymer micelle is formed on the surface.[73] By introducing amino groups on the top of the micellar layer through tethering polyallylamine, multilayered highly organized micellar hydrogel can be coated on the surfaces.[74] Fig. 6 shows the schematic illustration of the formation of the multilayered micellar coating on the surface. The resulting surface with micellar hydrogel layers exhibited excellent resistance to protein adsorption. In addition, the incorporation of the hydrophobic drug into the micellar hydrophobic core (~10 nm in diameter) made it possible to release the drug in a controlled manner, depending on the number of coated layers.[75]

CONCLUSIONS

Recent advances in nanotechnology have enabled us to extend potential applications of micro- and nanoparticulate hydrogels. Combination of hydrogel and nanotechnology may afford a powerful means for manipulating the properties of surfaces and interfaces. Fabrication of nanostructures using hydrogels involves hydrophilic nanoparticles, molecular imprinting, nanoparticle-entrapped hydrogel, and nanoengineering for surface modification. These technologies will accelerate the development of various drug delivery and biomedical devices, as well as other electronic and photonic devices.

Hydrogen Bonding

J. Richard Elliott, Jr.
Department of Chemical Engineering, University of Akron, Akron, Ohio, U.S.A.

INTRODUCTION

Hydrogen bonding is well known as one of the elementary forces that bond atoms to form materials. Many of its properties are familiar, especially in biological systems, but its impact on chemical processing is also evident in the phase diagrams that dictate the nature of separation processes. By understanding these impacts and their explanation, it is possible to anticipate trends in behavior, which may suggest new process alternatives.

To review briefly, an excellent illustration of its role is in the special properties of water. For example, though similar in size and mass, the boiling temperature of methane is 111 K while that of water is 373 K, which is nearly a factor of 4. Furthermore, this strong attractive force causes liquid water at equilibrium to be relatively dense for the repulsive forces to provide balance. Based on molecular simulations parameterized to match vapor pressure and liquid density, we can estimate the effective diameter of methane to be 0.367 nm, while that of water is 0.306. This implies a packing fraction at the triple point of 0.44 for methane, compared to 0.50 for water. Note that hard spheres spontaneously crystallize to an expanded fcc structure with a packing fraction of 0.545 at liquid packing fractions of 0.495.[1] Hence, a liquid packing fraction of 0.50 is surprising. This effect is attributable to the tetrahedral coordination required for water to fully engage in a three-dimensional hydrogen bonding network. The tetrahedral hydrogen bonding disrupts simple crystallization and actually reduces the density on solidification, notably in floating ice. The tetrahedral structure of ice, along with similar structures in gas hydrates, is clear evidence of a form of bonding that is remarkably strong and not spherically symmetric.

A related anomaly is the hydrophobic effect. As hydrocarbon moieties cannot hydrogen bond, they disrupt water's hydrogen bonding network at substantial energetic penalty. This causes a large, positive Gibbs energy of mixing leading to liquid–liquid separation. Obviously, ''oil and water do not mix,'' but many subtle behaviors are possible when hydrocarbon and hydrogen bonding moieties are combined in a single molecule. Surfactants orient with their polar head groups toward water and their tails toward hydrocarbon regions. Similarly, polar moieties in proteins orient toward the outer regions, while hydrophobic moieties orient toward the center. Polar moieties may also hydrogen bond internally to form α-helices and β-sheets. The complex interaction between these hydrophobic and hydrophilic forces enables the delicate balance that creates unique protein structures, which is further clear evidence that these forces are irrefutable and nonnegligible.

The subject of hydrogen bonding may seem too abstract for a treatise on chemical processing. On the other hand, aspects of hydrogen bonding do contribute in a relatively simple manner to phase equilibria between homogenous solutions. Hydrogen bonding is significant in alcohols, aldehydes, amines, amides, and carboxylic acids as well as water. In mixtures, hydrogen bonding can occur between proton donors like alcohols and proton acceptors like imines, esters, ethers, and ketones. In most cases, the effects of hydrogen bonding are neglected in models of chemical processes or treated vaguely as giving rise to spherically symmetric local compositions. While it is possible to empirically correlate the impacts of these interactions with complex mixing rules, greater physical insight can be achieved by treating the interactions explicitly and systematically analyzing the impacts and trends.[2] In this way, an intuitive sense of the impact of hydrogen bonding on phase equilibria relevant to chemical processing may be developed.

In the presentation below, we discuss a single theoretical perspective on hydrogen bonding that should suffice to illustrate the phenomenology as concisely as possible. That theoretical perspective is Wertheim's.[3,4] The primary alternative is chemical theory, which treats hydrogen bonding as a series of chemical reactions. Elliott and Lira present an introduction to chemical theory and its generalization to Wertheim's theory.[5] Chemical theory is more general in its capacity to describe anomalous types of hydrogen bonding like enhanced formation of rings or specific oligomers like trimers or hexamers. But the application of chemical theory with that level of detail quickly becomes intractable for chemical processes that may include as many as 200 components. Wertheim's theory provides a reasonable balance between explicit treatment of hydrogen bonding and

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007809

its phenomenology on the one hand, and the general applicability on the other.

WERTHEIM'S THEORY

Wertheim's theory expresses the extent of hydrogen bonding in terms of the fraction of hydrogen bonding sites that are not bonded. The key equation can be recognized as a form of the law of mass action

$$1 - X_i^{A_k} = X_i^{A_k} \sum_j^{N_C} \sum_{l=1}^{N_j^D} x_j \alpha_{ij}^{A_k D l} X_j^{D l} \quad (1)$$

where $X_i^{A_k}$ is the fraction of the kth acceptors that are not bonded on the ith component, x_j is the mole fraction of the jth component, and $\alpha_{ij}^{A_k D l}$ is effectively a reaction equilibrium constant.

$$\alpha_{ij}^{A_k D l} = \rho K_{ij}^{A_k D l} \left[\exp\left(\beta \varepsilon_{ij}^{A_k D l} \right) - 1 \right] \quad (2)$$

where ρ is the molar density, $K_{ij}^{A_k D l}$ is the molar "bonding volume" and $\varepsilon_{ij}^{A_k D l}$ is the bonding energy between the kth acceptor on the ith component and the lth donor on the jth component, $\beta = 1/k_B T$ where k_B is Boltzmann's constant.

With these definitions, the left-hand side of Eq. (1) is clearly the fraction bonded, the sum of products of reactant combinations on the right-hand side. Note that an analogous set of equations is obtained for donor fractions by swapping the acceptor and donor labels. Together, these equations comprise a determinate system that can be solved for all bonding fractions of donors and acceptors. Keep in mind that X^A and X^D relate to fractional bonding at a given site, not for a molecule. Thus, the presence of donors and acceptors on the same molecule can lead to the formation of hydrogen bonded chains that strongly influence the true number of molecules in solution.

The bonding volume and bonding energy are, in principle, adjustable parameters that must be characterized for each type of acceptor–donor interaction. In practice, however, Elliott and Natarajan provided a general rule for estimating the bonding volume from the molecular volume and they showed how well-known guidelines for the bonding energy can be applied to reduce the number of parameters in the equation of state to the usual three.[6] An advantage of Wertheim's theory is that the bonding volume parameter has a very clear geometrical definition in terms of the assumed molecular potential function. This facilitates explicit recognition of hydrogen bonding effects through molecular simulation.

The thermodynamics of hydrogen bonding can be described in terms of the Helmholtz energy:

$$\frac{A^{HB}}{RT} = \sum_i^{N_C} \sum_k^{N_k^D} \ln\left(X_i^{A_k} \right) + \frac{1 - X_i^{A_k}}{2} + \ln\left(X_i^{D_k} \right) + \frac{1 - X_i^{D_k}}{2} \quad (3)$$

Differentiating the Helmholtz energy, one obtains other thermodynamic properties, like the compressibility factor, pressure, and internal energy. To clarify, consider the example of a single component with a single acceptor and a single donor. Noting that $X^A = X^D$, by symmetry in this instance, a simple quadratic equation results in

$$X^A = X^D = \frac{-1 + \sqrt{1 + 4\alpha}}{2\alpha} \quad (4)$$

Simplifying Eq. (3) leads to

$$\frac{A^{HB}}{RT} = 2\ln(X^A) + 1 - X^A \quad (5)$$

Thus, an equation of state is obtained that functions much like any other equation of state. That is, given a temperature and density, one obtains an estimate of α from Eq. (2), and consequently an estimate of X^A and A^{HB}. Contributions for disperse attraction and repulsion can be computed from density and temperature in the usual way. Combining the terms provides a complete estimate of the total Helmholtz energy, which can be differentiated to obtain the pressure. The only fundamental difference between this equation of state and those that treat hydrogen bonding implicitly is the intermediate step of computing X^A.

A popular equation for combining disperse attraction and repulsion with hydrogen bonding is the model of Statistical Associating Fluid Theory (SAFT).[7] A similar but simpler equation is the Elliott–Suresh–Donohue (ESD) model.[8] The ESD equation was used by Elliott and Natarajan in their generalized analysis and is more convenient for application in the present context, so the discussion here presents sample results based on the ESD equation.[6] An executable computer program can be obtained for performing the calculations described in Ref.[8a]. Results with the SAFT model are expected to be similar. The ESD equation is given for mixtures as

$$\frac{P\underline{V}}{n_T RT} = 1 + \frac{4\langle c\eta \rangle}{(1 - 1.9\eta)} - \frac{9.5\langle qY\eta \rangle}{1 + 1.7745\langle Y\eta \rangle} + Z^{HB} \quad (6)$$

where $\underline{V}$ = total volume (e.g., cm^3); $\eta = n/\underline{V}^*\Sigma x_i b_i$; b = the molecular volume (cm^3/mol); n = the superficial number of moles in the system (computing component mole numbers based on the molecular weight of a monomer); c = a ''shape factor'' representing the effect of nonsphericity on the repulsive term; $q = 1 + 1.90476(c - 1)$ is a shape factor that represents the effect of nonsphericity on the attractive term; $\varepsilon_{ij} = (1-k_{ij})^* (\varepsilon_i^* \varepsilon_j)^{0.5}$, the energy of disperse attraction (equivalent to well-depth of a square-well potential); $Y_{ij} = \exp(\varepsilon_{ij}/kT) - 1.06$; $\langle c\eta \rangle = n_T/\underline{V}^* \Sigma\Sigma x_i x_j (b_i c_j + b_j c_i)/2$; $\langle qY\eta \rangle = n_T/\underline{V}^* \Sigma\Sigma x_i x_j Y_{ij} (b_i q_j + b_j q_i)/2$; and $\langle Y\eta \rangle = n_T/\underline{V}^* \Sigma x_i b_i Y_{ii}$.

SAMPLE RESULTS OF WERTHEIM'S THEORY

We can illustrate the impact of hydrogen bonding in chemical processing with a few examples. The first example illustrates the impact on a system that solvates and associates, exhibiting only vapor–liquid equilibrium (VLE) behavior. Association is defined as hydrogen bonding of a component with itself. Solvation is hydrogen bonding between two different compounds. The second two examples illustrate the behavior of a system in which only one component associates. The lack of solvation gives rise to clear differences in the phase diagram at constant temperature. At constant pressure, the impact is to induce liquid instability at low temperatures. The role of hydrogen bonding is also evident in vapor pressure and density trends, as illustrated in the two final examples.

Fig. 1A illustrates the phase behavior of the system ethyl ether + methanol. Two characterizations of this system are presented. The solid line explicitly treats the solvation interaction ($k_{ij} = 0.03$; $\varepsilon_{ij}^{HB} = 17.5\,kJ/mol$) whereas the dashed line assumes zero solvation energy ($k_{ij} = -0.0393$). Note that the maximum pressure was constrained to match the experimental value for purposes of this comparison. A simple optimization would cause the dashed line to fit better at low ether compositions, but miss the azeotropic pressure and mask the distinctions between the two models. Several effects are clear. First, implicit treatment of the solvation energy results in a negative value for the disperse binary interaction parameter (k_{ij}). A strong solvation interaction should be suspected any time k_{ij} is found to be negative. Second, the shape of the phase diagram is altered by the presence of solvation interactions. The skewness shifts toward the associating component. The shift in skewness affects the composition of the azeotrope in a very sensitive manner. Third, the disperse binary interaction parameter, k_{ij}, is positive when hydrogen bonding is explicitly recognized, as would be expected from the differences in polarity between the two components. This recognition enhances the physical meaning of the parameters.

One advantage of enhancing the physical meaning of the parameters is that the strength of the solvation interactions can be anticipated to some extent through independent measurements, like those leading to the Kamlet–Taft parameters.[11] Kamlet et al. correlated an extensive collection of UV/visible, NMR, FTIR, and solubility data in terms of acidity (α) and basicity (β) parameters. To our knowledge, no attempt has been made to systematically translate their results in terms of Wertheim's theory, but it should be feasible. Such a translation would bring together a wealth of spectroscopic expertise with the rigorous insight afforded by present molecular simulations. Coleman et al. have performed similar measurements with FTIR relevant to polymer blending.[12]

Fig. 1B illustrates a somewhat simpler binary system than Fig. 1A in terms of its hydrogen bonding

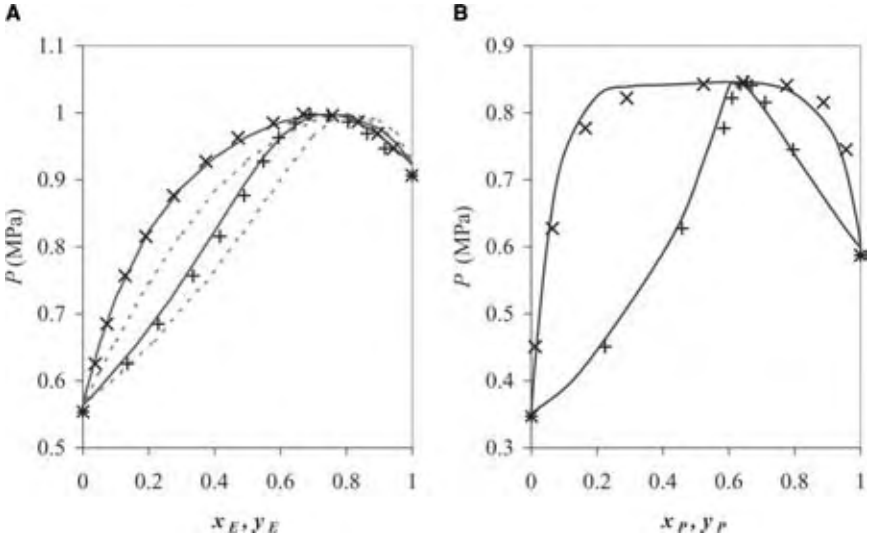

Fig. 1 Phase diagrams of methanol mixtures with (A) ethyl ether at 115°C and (B) *n*-pentane at 99.6°C. (From Refs.[9,10].) *(View this art in color at www.dekker.com.)*

behavior. The *n*-pentane + methanol system exhibits no solvation, but the pentane is very similar in nature to ethyl ether. For example, the boiling temperatures of pentane and ether are just 1.6°C apart, and they both have five backbone atoms making them similar in size and shape. Comparing Figs. 1A and B side by side shows the shift that occurs in the hydrogen bonding effect when one component is a hydrocarbon. The most striking feature is that the azeotropic pressure is 0.025 MPa higher than the highest vapor pressure for the pentane system, compared to just 0.008 for the ether. The corresponding maximum Gibbs excess energies are 1.7 and 0.8 kJ/mol. When the solvation effect is neglected in the ether + methanol system, a value of $k_{ij} = -0.0393$ is required to fit the azeotropic pressure, compared to a value of $k_{ij} = 0.05$ for the pentane + methanol system. These differences are various reflections of the moderation in nonideality that comes from the solvation effect. The $P-x$ projection appears much flatter for the pentane system because of the quick rise in the Gibbs excess energy. This flatness is usually a precursor to incipient liquid instability, but Thomas et al. have observed simple vapor–liquid behavior in the pentane + methanol system at 303 K.[13] One might expect liquid instability to occur at lower temperatures, however. The onset of liquid instability is readily observed in methanol + *n*-hexane, a system similar to the *n*-pentane system of Fig. 1B. A $T-x$ projection of the methanol + hexane system at 0.141 MPa is illustrated in Fig. 2A. Fig. 2A also illustrates a limitation of the hydrogen bonding theory in its present state. It is straightforward to correlate the behavior of either the VLE or the liquid-liquid equilibrium (LLE), but not both simultaneously. Two correlations are illustrated in Fig. 2A. The dashed line shows the result when the default characterization of methanol is applied and the liquid binodal is correlated ($c = 1.120$; $k_{ij} = 0.025$). In this case, the VLE region is misrepresented. The solid line shows the result when the characterization of methanol is customized to describe the VLE region by slightly adjusting the shape factor ($c = 1.095$; $k_{ij} = 0.030$). In this case, the LLE is misrepresented. The inaccuracy in these cases is an indication that there are other forces at work besides the hydrogen bonding and dispersion forces. The most likely explanation is the influence of polar moments and polarizability. The theory of polarity and polarizability in solution is not as thoroughly developed and tested as that of Wertheim and hydrogen bonding. Gray and Gubbins present a review of the current status.[15] Rigorous treatment of polarity and polarizability can be quite challenging, but local composition theories may offer effective means of accounting for these effects. Despite the inaccuracy involved in trying to represent VLE and LLE with a single set of parameters, most applications focus on one region or the other. In these cases, the key is to adapt the model to fit the desired region and the manner in which this may be achieved is illustrated by the example of methanol + *n*-hexane.

The excess volume is a very simple property that provides another indication of the impact of hydrogen bonding. Fig. 1B shows the excess volume for the methanol + *n*-hexane system at 45°C. Clearly, the excess volume is positive, but the mixture volume at 50 mol% methanol is roughly 90 L/mol, compared to 0.7 L/mol for the excess volume, a deviation of 0.8%. The magnitude of this deviation is similar to that of many mixtures that have difficulty packing, but in this case we can attribute the deviations to hydrogen bonding. Diluting the methanol with hexane breaks down the hydrogen bonding network. This causes the solution to expand. The ethanol + water system provides an interesting contrast. For ethanol + water, the

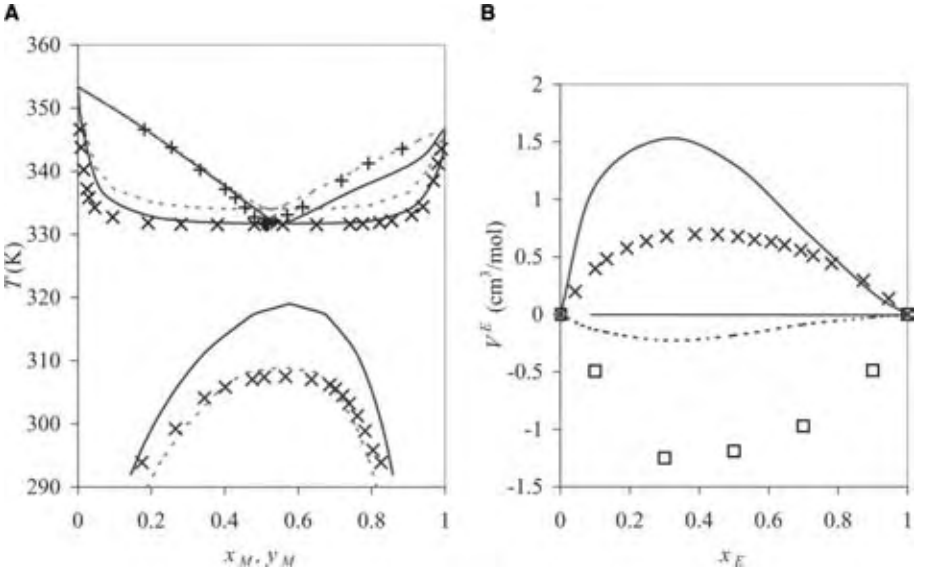

Fig. 2 Thermodynamics of the methanol + *n*-hexane system: (A) temperature-composition diagram and (B) excess volume. (From Ref.[14].) *(View this art in color at www.dekker.com.)*

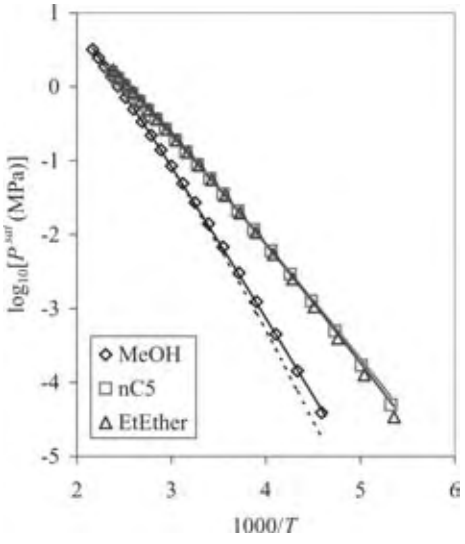

Fig. 3 The impact of hydrogen bonding on vapor pressure. *(View this art in color at www.dekker.com.)*

excess volume is negative, reflecting improved packing relative to the pure components. However, note that the excess Gibbs energy is positive for the ethanol + water system. Thus, the packing is enhanced, but the energy lost in breaking water's network overwhelms the packing efficiency. The hydrogen bonding theory fails to provide a quantitative description of this behavior, but the correct qualitative trend for such a complex phenomenon is noteworthy.

As a final example, we consider the impact of hydrogen bonding on the shape of the vapor pressure curve. Fig. 3 shows that modeling methanol as a hydrocarbon with the same critical properties and acentric factor gives a vapor pressure curve that diminishes too quickly at low temperatures. The hydrogen bonding contribution tends to flatten that curvature, raising the vapor pressure. Similar, but more pronounced behavior was observed for acetic acid.[8] Vapor pressure is an extremely important property when it comes to distillation modeling. Having a physical explanation for why the curve changes is thus quite valuable. With Wertheim's theory, this physical explanation comes complete with the ability to correlate the vapor pressure quantitatively.

HYDROGEN BONDING IN POLYMER BLENDS

A well-known problem in polymer processing is the incompatibility of polymer blends. Even small amounts of nylon in polyester, for example, can lead to reduced optical clarity and discoloration that undermines product marketability. Many other examples of polymer miscibility issues abound. According to Utracki, the majority of polymer blends being sold are actually immiscible blends that have been processed in such a way as to manage the compatibility problems.[16]

One way of managing compatibility problems is through an understanding of the hydrogen bonding in the blends. The dispersion energy is the root cause of the compatibility problem. Hydrogen bonding interactions can be specifically tailored in such a way as to counteract the disperse interactions. For example, polybutylmethacrylate (PBMA) and polyvinylphenol (PVPh) have solubility parameters that would normally make them highly incompatible (8.7 vs. 10.8), but the solvation interaction between the phenol and the carbonyl is strong enough to create a miscible blend below $\approx$160°C.[12,17] Blends that are compatibilized by hydrogen bonding tend to exhibit lower critical solution temperatures. This means that they go from single phase to two phase on heating. The reason is that hydrogen bonding is an exothermic reaction and exothermic reactions decrease in conversion as temperature is increased. A decrease in hydrogen bonding undermines the ability of the specific interactions to overcome the incompatible disperse interactions and the solution becomes unstable. A large number of examples have been reviewed by Coleman et al.[12] Furthermore, Coleman and Painter have developed a hydrogen bonding theory that describes many of the nuances that can occur in these kinds of blends.[18] Their theory is equivalent to Wertheim's theory except when dimer formation becomes peculiar. However, the dimer peculiarities can generally be neglected with little reduction in accuracy.

Polymer blending becomes even more complicated when three or more polymers are mixed. Such a scenario is suggested by adding a third component to enhance compatibility between two incompatible polymers. For example, PVPh could be added to a blend of PBMA and polymethylmethacrylate (PMMA) in the hope of bridging hydrogen bonds from the carbonyl through the PVPh to the pyridine. The third component would behave in the same was as a cosolvent or entrainer in VLE. Unfortunately, ternary polymer blends are subject to an additional, unfavorable contribution from the dispersion energy known as "$\Delta\chi$" effect.[19] Owing to the $\Delta\chi$ effect, islands of immiscibility can occur in a ternary phase diagram even when all binary combinations are completely miscible. Coupled to the $\Delta\chi$ effect, the third component has at least a small preference for one component or the other and then partitions with that component to such an extent that one of the components is left relatively isolated. As a specific example, Pomposo et al. analyzed the ternary system of PMMA + PVPh + polyethylmethacrylate (PEMA). Remarkably, PEMA and PMMA are immiscible, despite their minimal difference in structure. Pomposo et al. found that roughly 60 wt% PVPh is required at 165°C for the ternary blend to be miscible. At this composition, the blend should be

considered simply as "dirty" PVPh, rather than compatibilized PEMA + PMMA. The solution to this problem will likely involve some combination of block copolymer additive with custom tailored hydrogen bonding. Many problems remain to be solved before chemical processes based on this approach become viable.

CONCLUSIONS

We have outlined the impacts of hydrogen bonding on a number of key properties of interest in chemical processing. Most notably, the impact on phase diagrams promotes improved understanding of how the phenomena arise. Note that we have not attempted an exhaustive review of phase diagrams. An excellent overview of phase diagrams in chemical engineering is provided by Walas.[20] Furthermore, we have not attempted to cover aqueous or electrolyte systems as each of these comprise specialized topics in themselves.

Among the solutions considered, the hydrogen bonding is weak relative to aqueous systems, leading to more subtle variations in phase behavior as the disperse interactions compete with hydrogen bonding. The variations become evenmore subtle as one considers mixtures of amines or aldehydes with nonassociating species. Nevertheless, the trends are similar to the trends presented here even for these more weakly associating species. Wertheim's theory can achieve qualitative accuracy over a broad range of conditions. By narrowing down the range of conditions to a specific target, quantitative accuracy can usually be achieved while maintaining the clear physical picture afforded by the very general theory.

Hydrogenation

Xiaobo Yang
Institute of Physical Chemistry and Electrochemistry, University of Hanover, Hanover, Germany

INTRODUCTION

Hydrogenation is applied in the manufacture of a wide variety of commercial products, including oleochemicals, such as edible fats and oils, fatty acids, fatty amines, etc.; specialty chemicals, e.g., pharmaceuticals, flavors and fragrances, herbicides, pesticides; and petrochemicals. While metal hydrides and other hydrogen transfer reagents are useful for hydrogenation experimentation in laboratory and small-scale processes, most hydrogenation processes are carried out through activation of molecular hydrogen in the presence of a catalyst, either in the heterogenous or in the homogenous mode. Mechanisms of hydrogen activation over catalysts and the way the activated hydrogen species performs the hydrogenation of unsaturated chemicals, as well as factors influencing and determining the hydrogenation selectivity are the topics being briefly introduced. Extensive examples of both heterogenously and homogenously catalyzed hydrogenation processes are discussed with respect to the choices of pertinent catalysts, suitable reactors, and conditional parameters, like the reaction temperature and H_2 pressure. Possibilities of combining a hydrogenation reactor to separation and recycling units are shown as well. Heterogenously catalyzed hydrogenation has been long established, and keeps defeating the homogenous processes in many aspects. Heterogenous catalysts, i.e., finely divided or porous metal powders or dispersed metallic nanoparticles on various solid supports, are usually highly stable. In the liquid phase operating mode, they are easily separated from products, regenerated, and recycled. Other advantages of heterogenous processes include a wide range of applicable reaction conditions, the possibility of hydrogenating barely reducible functional groups, e.g., aromatic rings, and the ability to combine with other catalytic functions to achieve, e.g., hydrogenolysis. High selectivity of a heterogenous hydrogenation process is realizable through catalyst modifications and fine-tuning of the conditional parameters. However, homogenous hydrogenation becomes a more feasible method, when mild conditions, high selectivity, in particular enantioselectivity, are required. The wide choice of ligands with variable structural features for metal–organic catalysts provides a precise control of the hydrogenation procedure in the homogenous mode. The future development of hydrogenation processes reveals, besides others, one trend, i.e., to heterogenize the homogenously catalyzed processes by entrapping or anchoring the metal organic active species on suitable solid materials, such as porous inorganic oxides and polymers.

GENERAL TERMS

Hydrogenation is the process of adding H_2 to multiple bonds, reducing them to lower bond orders. In principal all kinds of unsaturated multiple bonds such as C=C, C≡C, C=O, C=N, C≡N, N=O, N=N, N≡N in a chemical are potentially to be hydrogenized. However, the most simple and common type of hydrogenation is performed on C=C double bonds, producing saturated alkanes. Other examples are hydrogenation of nitrogen forming ammonia, hydrogenation of carbon monoxide forming methanol or hydrocarbons. When all the unsaturated bonds in a chemical are reduced during a hydrogenation process, the process is called total hydrogenation. When particular unsaturated bonds of a compound still remain after a hydrogenation process has been performed, it is called partial hydrogenation or selective hydrogenation. In other cases, a reaction of H_2 with unsaturated compounds results in breaking up (dissociation) of the molecule at the position of a multiple bond; this is called destructive hydrogenation or hydrogenolysis.

HYDROGENATION AGENT

To perform hydrogenation on an unsaturated compound one needs, besides others, active hydrogen species. That is, hydrogen has to be present, as an intermediate state, in the atomic form, either neutral or ionic, because molecular hydrogen with two covalently bonded atoms does not react with the unsaturated compound. There are various ways to achieve atomic hydrogen intermediates for a hydrogenation process: 1) using an ionic metal hydride as a hydrogenation agent; 2) using a catalyst to activate (break up) molecular hydrogen; or 3) transfer of hydrogen atoms in the presence of catalysts from one organic compound

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007811

to another, achieving effectively hydrogenation of the latter compound.

Hydride as Hydrogenation Agent

Metal hydrides can be roughly classified into three categories, i.e., ionic, covalent, and interstitial.[1] Ionic hydrides are those compounds of alkali or alkaline earth metals with hydrogen, in which hydrogen has obtained an electron from the very electropositive metal, and forms a hydride ion (H^-). A hydride can be binary, when it involves only two elements including hydrogen, e.g., LiH and MgH_2. It can as well be tertiary when one more metal element is included, e.g., $NaBH_4$ and $LiAlH_4$. Principally, all these ionic hydrides can be used as hydrogenation agents. However, binary hydrides are usually too strongly basic and too reactive. Besides hydrogenation they decompose through an acid–base pathway as shown in Scheme 1, which prevents their use for an effective hydrogenation. Tertiary hydrides are less reactive and are feasible hydrogenation agents. $NaBH_4$ can be used with H_2O as a solvent; $LiAlH_4$ is effective in diethylether, tetrahydrofuran, and liquid ammonia.

It is advantageous to use hydrides because hydrogenation can be carried out at mild conditions and selectively upon those functional groups of chemicals like carbonyl compounds, amides, sulfonates, halogenides, epoxides, and alkynes, etc., whereas C=C double bonds in the chemicals can remain unattacked. With carbonyl as an example it is shown in Scheme 2 that the hydrogenation using a hydride proceeds through a nucleophil mechanism, where the carbonyl becomes activated through coordination with the metal ion.

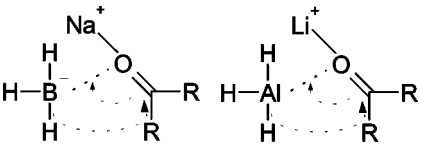
The special selectivity of hydrides toward functional groups other than C=C double bonds makes them useful in the synthesis of functionally structured molecules, e.g., reduction of amides leading to the synthesis of amines, as shown in Scheme 3.[2]

In case of an α,β-unsaturated carbonyl compound there are possibilities for variable regional selectivity: 1,2-reduction results in unsaturated alcohol; 1,4-reduction in saturated ketone, and in protonic solutions further to saturated alcohol (Scheme 4). In this case, Li^+ ion is a stronger Lewis acid than Na^+ ion, thus $LiAlH_4$ exhibits a higher selectivity toward 1,2-hydrogenation rather than 1,4-reduction. Similarly, $Ca(BH_4)_2$ can be employed, and behaves like $LiAlH_4$ owing to the stronger Lewis acidity of Ca^{2+} than Na^+ as well.[3]

Another important property of hydrides is the stereo-selectivity. This is determined by the way the

$$M^+ + H^- + H\text{-}R \longrightarrow H_2\,(gas) + M^+ + R^-$$

Scheme 1



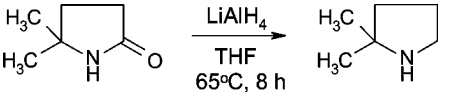
Scheme 2

bulky BH_4^- or AlH_4^- ions approaches the unsaturated bonds (Scheme 5). This kind of steric approach control becomes more propagated if the hydride ions (H^-) have been partly substituted by bulkier organic ions. For instance, $LiAlH_4$ can be mixed together with calculated amounts of proper alcohols, yielding $LiAlH_2(OR)_2$ or $LiAlH(OR)_3$. They approach the unsaturated functional groups only in particular configurations, thus elevating the stereo-selectivity. An example is shown as Scheme 6.[4]

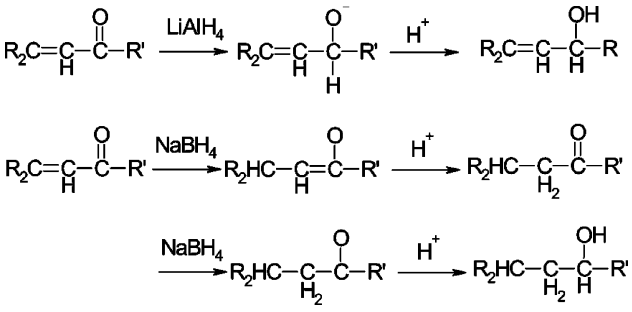
Besides the reduction of carbonyl groups, hydrides can furthermore be used to substitute halogenides, sulfonates, with hydrogen atoms, to selectively reduce epoxides to α-hydroxides, and alkynes to alkenes. The reactions are normally completed at mild conditions within a few hours, i.e., temperature ranges below 373 K and atmospheric pressure. Sometimes even lower temperatures (down to liquid nitrogen temperature) are applied to slow down the reaction rates and to suppress side reactions. Hydrides as hydrogenation agents are especially feasible for multistep synthesis of specialty chemicals such as medicines and pharmaceutically active components in laboratory or other small-scale experiments. Because the reactions are carried out homogenously in a liquid phase, all kinds of thermostatted and atmosphere-controllable batch and continuous reactor vessels are suitable. For transportation and handling, care has to be taken that contacts of hydrides with water and oxidative atmosphere, like ambient air, produce gaseous hydrogen and an enormous amount of heat, causing a disastrous explosion.

Activation of Molecular Hydrogen Using Catalysts

The history of hydrogen activation using a heterogenous catalyst (solid) dates back as early as 1823 when Dobereiner noted that hydrogen inflames spontaneously upon contact with finely divided platinum. Some 50 yr later chemists began to experiment with nickel, copper, iron, palladium, and other metals for



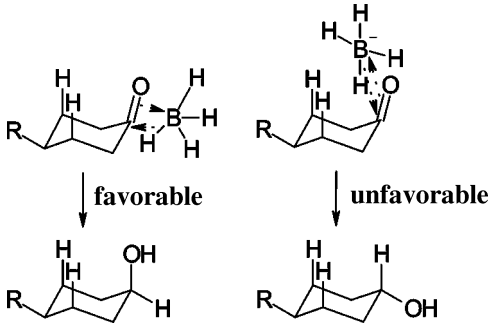
Scheme 3



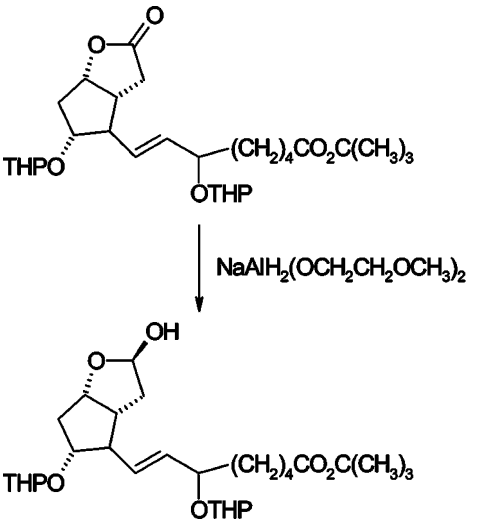
Scheme 4

hydrogenation and production of hydrogen from steam and hydrocarbons. From 1896 onward Sabatier and Senderens developed the process of hydrogenation of organic compounds in the vapor phase, including the hydrogenation of oleic to stearic acid, and nitrobenzene to aniline.[5] For years they erroneously recommended that no liquid should cover the catalyst surfaces. Nowadays by contrast most heterogenously catalyzed hydrogenation processes are performed in the liquid phase, with a solid catalyst, and in pressured H_2 atmosphere. The metal catalysts, noble metals like Pt, Pd, Ir or other metals such as Cr, Ni, Cu, and Fe are used as fine powder, porous particles, or highly dispersed nanoparticles supported on active carbons, aluminum oxides, or other oxide solids. This ensures high surface areas, thus a high effectiveness of the catalysts. Examples of common hydrogenation catalysts are the Raney Nickel, sponge-like nickel particles made by dissolution of aluminum from nickel–aluminum alloy, and Pd/C, supported palladium on high surface active carbon.

Scheme 7 sketches three possible intermediate states of the catalyst surface during a hydrogenation process. Using the concept of these intermediates the mechanism of hydrogenation can be explained: In all the three states, hydrogen molecules are dissociatively adsorbed on the metal surface as atoms. Then, the unsaturated bond of an organic compound can be either adsorbed



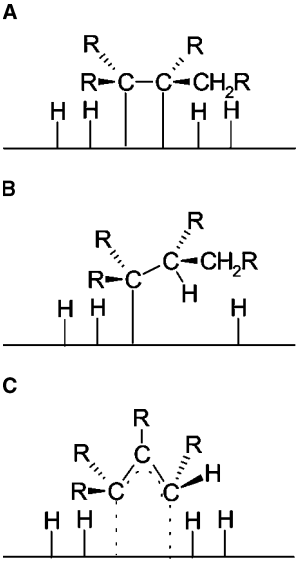
Scheme 5



Scheme 6

with its π and π^* orbitals on the metal surfaces, shown as case A, or inserted into the M–H bond, as in case B. Finally, a reductive elimination of the organics results in the hydrogenation products. Case C explains why the double-bond migration, *cis*- and *trans*-isomerization, and hydrogen exchange occur as side reactions of a hydrogenation process.

Different unsaturated bonds exhibit different reactivity toward hydrogenation. In general, alkynes are hydrogenated faster than alkenes under the same conditions. In turn, the hydrogenation of alkenes is faster than for other functional groups like carbonyls, nitrides, and nitrates. However, this chemo-selectivity is an issue to be tuned by altering catalysts. For instance, in the presence of Pd catalyst carbon–carbon



Scheme 7

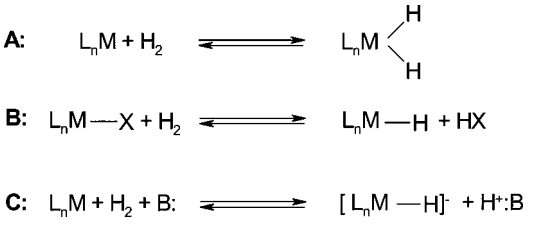
multiple bonds are reduced while C=O bonds remain. With Rh and Ir catalysts C=O bonds are more easily hydrogenated than C=C bonds.

Concerning the stereochemistry of a hydrogenation process, the adsorption of the unsaturated compound on the catalyst surface happens principally on the sterically less detained side, therefore hydrogen atoms are usually added on this side. However, this constraint is not that strict, and is easily amended through many conditional factors such as substituting groups on or close to the unsaturated bonds, solvents, and modifiers, i.e., a small quantity of a proper organic additive with particular structural features, etc. Details will be given with examples in the section Heterogenous Hydrogenation.

Beside heterogenous catalysts, there are various so-called homogenous catalysts exhibiting the function of activating molecular hydrogen, which can be employed in hydrogenation processes. These are transition metal–organic compounds, which according to the kind of hydrogen activation, can be divided into three types. The oxidative addition of hydrogen onto the metal site is the most common type of H_2 activation on a metal having d electrons (Scheme 8A). The organic complexes of early transition metals (d^0) activate hydrogen through their own hydrolysis, as shown in Scheme 8B. Lanthanides and actinides work similarly. The metal center has an orbital binding an anionic ligand, which is protonated off upon contact with hydrogen. During this process, the oxidation state of the center metal remains unchanged. In the heterolytic cleavage mode shown in Scheme 8C an external base is present to bind the proton that has been formed by the heterolytic cleavage of hydrogen on the metal center.

There are several advantages in using metal–organic compounds as hydrogenation catalysts. The catalytic activity can be varied by proper choice of the central metal species as well as the organic ligands. More significantly, the wide choice of organic ligands with a broad variety of chemical components and structural types allows very precise control of the way the unsaturated compound approaches the catalytic sites, therefore providing high chemical, regional, or stereo-selectivity. The section Homogenous Hydrogenation will be dedicated to these topics.

Hydrogen is a valuable chemical and expensive to manufacture. About 50% of commercial bulk hydrogen is currently produced by steam reforming of natural gas. Other hydrogen resources involve syn-gas, refinery side products, etc. At 973–1373 K and 0.3–2.5 MPa pressure, steam reacts with methane, yielding carbon monoxide and hydrogen over a catalyst: $CH_4 + H_2O = CO + 3H_2$. It is usually followed by the "water-gas shift" reaction, $CO + H_2O = CO_2 + H_2$, to recover additional hydrogen.[6] Electrolysis of water for hydrogen production has been discussed but no efficient method has been established yet. New methods investigated now are conversions of biomass derivatives, promising sustainable hydrogen production from renewable resources.[7]



Scheme 8

Other Reagents for Hydrogen Transfer

Both heterogenous and homogenous catalysts display the capability to activate hydrogen of a hydrocarbon or other organic compounds, and transfer it in the atomic form to another unsaturated compound by forming a more stable hydrogenated chemical. An example often used is diimine, or its derivatives, which, in the presence of Cu^{2+}, can hydrogenate alkenes, as shown in Scheme 9.

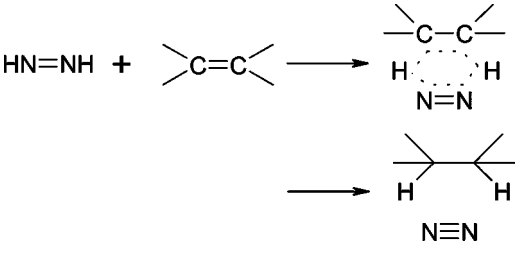
Another example is cyclohexane, which offers hydrogen in the presence of a noble metal catalyst by forming benzene.

Using these hydrogen transfer reagents to perform hydrogenation when it is not possible to employ a hydrogen atmosphere, or when high selectivity at mild reaction conditions is obliged, is a practical option. These are usually the cases of a laboratory hydrogenation experiment, or a synthesis of small-scale fine chemicals.

HETEROGENOUS HYDROGENATION

Ammonia Synthesis

The most important heterogenous hydrogenation process is probably the Haber process of ammonia synthesis, or more precisely, Haber–Bosch process.[8] It is a process of fixing air nitrogen, which is otherwise extremely unreactive. The ammonia produced is further



Scheme 9

processed into fertilizers, explosives, and polymers, on which the industrial civilization since the 20th century depends. In the production of fertilizer alone, the Haber process produces currently about 50% of all nitrogen compounds.

The Haber process is carried out at pressures of up to 20 MPa and temperatures from 623 to 723 K over a catalyst. It is an exothermic reaction ($\Delta H = -92\,\text{kJ/mol}$), thus an intermediate temperature favors the equilibrium on the product side, as does high pressure. The first Haber–Bosch reactor used a catalyst containing osmium and uranium. Current ammonia synthesis catalysts are commonly Fe catalysts with K promoters. The usual way to prepare the catalyst is to reduce magnetite, an iron oxide mineral, which is mixed with a minor amount (<1 wt%) of calcium, aluminum, and/or silicon oxides, in hot hydrogen. The resulting Fe catalyst is highly porous, whose large surface area is desirable for good activity. The potassium promoter is either added during the calcination procedure or introduced through a postsynthesis treatment with amounts around 0.5 wt%. It increases the electron density of the catalyst, and thus improves the activity. Furthermore, catalysts based on Co and some other transition metals are considered effective for ammonia synthesis as well. Corresponding processes are currently in a phase of development.

The working principal of a Haber–Bosch reactor is sketched in Fig. 1. Reactors actually used by the commercial processes, e.g., the Haber–Bosch reactor at BASF, the radial flow converter at Haldor–Topsoe bear the same working principal. This is a typical tube-bundle of fixed-bed reactors. The production volume is typically 1500 tons of ammonia per day. The feedstocks are air containing N_2 (and enriched O_2 to reach a high catalyst activity); H_2 is made from syn-gas. NH_3 leaves the reactor as liquid under the applied pressure. Unreacted N_2 and H_2 are separated from the product on-site and recycled. A new trend is to employ H_2 made from the natural gas because of its lower cost compared with the syn-gas made from coal.

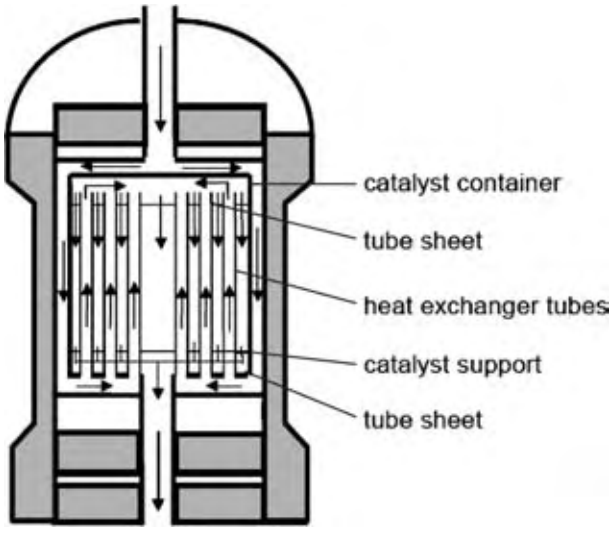


Fig. 1 Haber–Bosch reactor for ammonia synthesis.

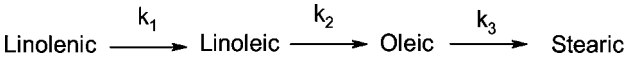
Vegetable Oil Hardening

Hardening the liquid vegetable oil to solid or semisolid, e.g., margarines, is demanded by the food industry, because the way the fat mixes with the flour produces a desired texture in baked products. The hardening is done by a partial hydrogenation process. The hardened oil is predominant in most commercial baked goods.[9]

Liquid vegetable oil is a mixture of linolenic, linoleic, oleic, and stearic esters. The hydrogenation process of these esters displays a chart of a reaction chain shown in Scheme 10. The processes of preferential hydrogenation of more unsaturated acids with minimum formation of completely saturated fatty acids are preferred by the food industry. The selectivity is expressed as the ratio $k_{\text{lino}}/k_{\text{ole}}$ or $k_{\text{lo}}/k_{\text{o}}$, where the variables k are the reaction rate constants, and the term ''lino'' represents the conversion of linolenic and linoleic compounds, while ''ole'' is for oleic. Thus, good processes have high $k_{\text{lo}}/k_{\text{o}}$ values.

Commercially available catalysts for oil hardening are mainly of two types: nickel catalysts and copper catalysts. A typical nickel catalyst contains 25 wt% Ni in hard fats as flakes. Copper catalysts for this purpose include the copper–chromium catalyst, which is a material containing 50 wt% CuO, 40 wt% Cr_2O_3, and 10 wt% BaO, and Cu dispersed on silicic acid supports with various loadings. Nickel catalysts cost less but are less selective than copper catalysts. The $k_{\text{lo}}/k_{\text{o}}$ value for a copper catalyst can be as high as 6–18. Hydrogenation can be performed on oils containing over 70% oleic acid, without increase in stearic acid.

The vegetable oil hardening processes are carried out typically in stirred tank vessels as schematically shown in Fig. 2, with units of catalyst separation and recycling. The conditional parameters are applicable at temperatures between 373 and 473 K, H_2 pressures of 1–5 MPa, and agitation rates up to 1000 rpm, typically around 750 rpm, within a time scale of a few hours, typically up to 5 hr. All these factors affect not only conversion but also selectivity, like all chain-type reactions. In terms of $k_{\text{lo}}/k_{\text{o}}$, higher temperatures have a positive effect, higher pressures and agitation rates have a negative effect, while they all increase the



Scheme 10

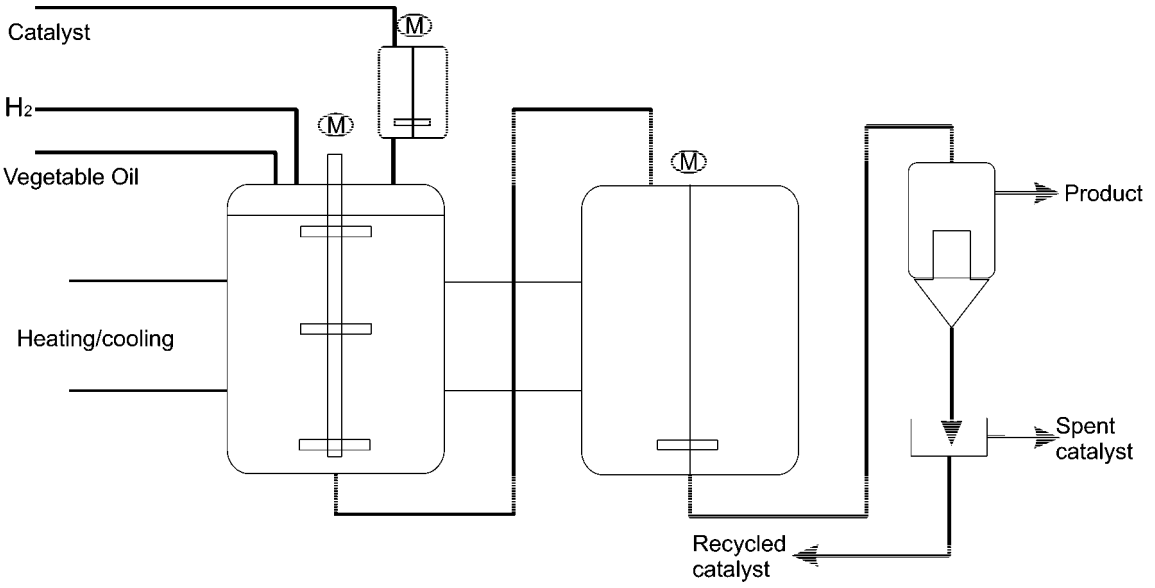


Fig. 2 Working principle of a stirred vessel usable for liquid-phase hydrogenation, e.g., vegetable oil hardening.

reaction rate. Thus, a compromise has to be found for these conditional factors.

Side reactions of a vegetable oil hydrogenation process are double-bond positional isomerization and *cis*- and *trans*-isomerization. The former type of double bond migration leads often to the formation of conjugated double bonds. The latter, because natural oil contains only the *cis*-isomers, results in the formation of an unnatural *trans*-fatty oil, with some of the remaining unsaturated bonds having transformed into the *trans*-double-bond form. While there is few concern about the double-bond migration, the formation of *trans*-fat stimulates heavy debates on its health implications. Manufacturers advertise that *trans*-fat is healthy because it is not digested and absorbed by the human digestion system. Thus, eating hydrogenated vegetable oil has the same effect as eating less fat. In contrast, other people insist that the useless *trans*-fat would deposit in blood vessels and increase the risk of heart attacks.[10]

Synthesis of γ-Butyrolactone by Hydrogenation of Maleic Anhydride

γ-Butyrolactone (GBL) is an important intermediate for the manufacture of butyric compounds and pyrrolidones used as plastilizers, polymer solvents, nylon precursors, and components of insecticides. γ-Butyrolactone is also used in photochemical etching, in vitamin and pharmaceutical preparations, and has many other applications. Synthesis of GBL by hydrogenation of maleic anhydride is a relatively new process providing a good example of studying the chemo-selectivity of hydrogenation.[11]

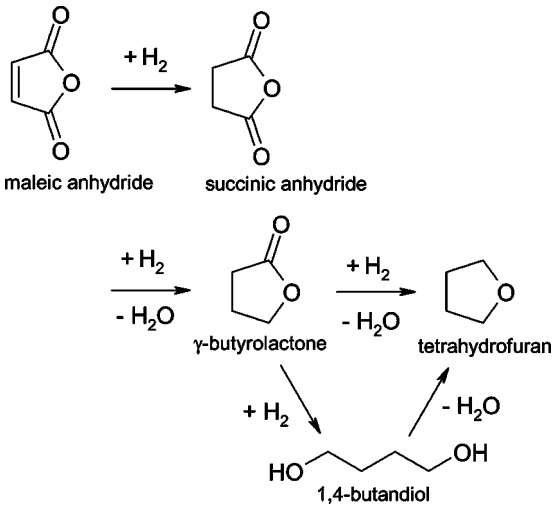
The reaction pathway, and therefore the possible side products, of maleic anhydride hydrogenation are given in Scheme 11. Because succinic anhydride is not desired, a catalyst with higher activity is needed to overcome the hurdle, leading H_2 to attack not only the C=C bond but also the carbonyl groups. Tetrahydrofuran (THF) and 1,4-butandiol (BDO) are other highly valued chemicals used as solvents and intermediate in pharmaceuticals. The production of GBL, THF, and BDO can be tuned as demanded.

The hydrogenation is carried out in a ''low-pressure vapor phase'' process, i.e., at around 473 K and under a few megapascals of H_2 pressure. Known effective catalysts include copper–chromium catalysts, and palladium–carbon catalysts, etc. The process can be coupled with maleic anhydride production units, using either benzene or butane feedstocks, and units to separate and refine GBL, THF, and BDO products. Fig. 3 shows a chart of such a process design. Other catalysts with higher activities allowing the process to be conducted at still lower temperatures in the liquid phase are under development.

γ-Butyrolactone is also the precursor to γ-hydroxybutyrate (GHB). γ-Hydroxybutyrate is a medicine with the function of a neurotransmitter. Misuse of the medical as a so-called ''date rape drug'' is dangerous. Illegal possession or sale of GHB, e.g., in the United States of America is to incur a penalty under the Texas law.

Heterogenous Asymmetric Hydrogenation

The possibility of performing enantio-selective hydrogenation over heterogenous catalysts is based on the fact that a chiral additive can govern the way a



Scheme 11

prochiral, unsaturated compound approaches the catalyst surface, and therefore the stereochemistry of its hydrogenation. Now there are two successful processes of enantio-selective hydrogenation. The first is the hydrogenation of β-ketonesters over the Raney Nickel catalyst with chiral tartaric acid and sodium bromide additives; the other is the hydrogenation of ethyl pyruvate over supported noble metals. Chiral promoters for this reaction are cinchona alkaloids. An impressive feature of these processes is that the enantio-selectivity can be switched by simple exchanges of the (*S*)-, and (*R*)-forms of the chiral additives.

Methyl or ethyl acetonacetate can be hydrogenated to (*R*)- or (*S*)-methyl- or ethyl-3-hydroxybutyrate on nickel catalysts. With (*R*)- or (*S*)-tartaric acid and sodium bromide as promoters, the hydogenation can reach enantiomeric excess (ee) values over 90%. The ee value is defined as the excess of the major enantiomer to the minor one over the total yields. The products are vitamin precursors. The function of tartaric acid is believed to form nickel(II) tartarate, which is adsorbed on the metal surface. The asymmetric site generated this way is responsible for the hydrogenation process. Naked nickel surface sites, without adsorbed tartarate, are poisoned by NaBr. The reaction is carried out at the boiling point of a solvent under a few megapascals H_2 pressure in stirred vessels.[12]

Cinchona promoted Pt or Pd (supported) catalysts are feasible for the hydrogenation of carbonyls or C=C bonds, both at the α-position of another carbonyl group. For example, ethyl pyruvate is hydrogenated on cinchonidine promoted Pt/C, producing ethyl lactate with ca. 95% ee.[13] The product is used in pharmaceuticals, agrochemicals, solvents used in the electronics industry, flavors and fragrances, health care foods, etc.

Two possible mechanisms have been proposed for this process. The first one is comparable with the Ni/tartaric acid system. Cinchonidine is adsorbed at the edges of Pt crystals or on ad-atoms on the Pt surfaces. These sites then allow the approach of ethyl pyruvate only with stereo-special configurations, resulting in enantio-selectivity. In the other mechanism a complex-like supramolecule of ethyl pyruvate and cinchonidine forms in the solution and approaches the metal surface afterward. The reaction is carried out as well in stirred vessels under a few megapascals.[14]

Asymmetric hydrogenation using modified solid metal catalysts is currently a topic under intensive research and development. In this respect, not only the reaction mechanism is studied, novel organic additives leading to more effective asymmetric hydrogenation are under consideration as well.[15]

Other Heterogenous Hydrogenation Processes

An important hydrogenation process, the Fischer–Tropsch process to hydrogenate carbon monoxide producing methanol and hydrocarbons using Fe and Co catalysts, is a stand-alone entry in this encyclopedia. Furthermore, hydrodesulfurization (HDS) has been drawing significant attention in recent years because of air pollution concerns and related legal regulations with ever more stringent limitations of

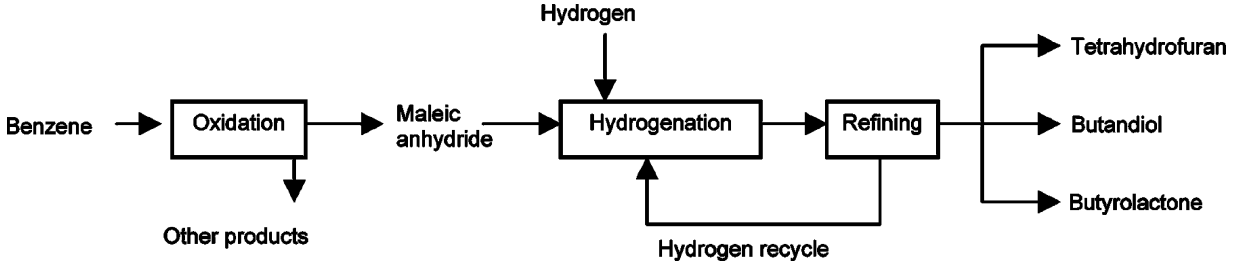


Fig. 3 Process chart for productions of tetrahydrofuran, butandiol, and γ-butyrolacton.

sulfur concentrations for transportation fuels.[16] An HDS process involves catalytic treatments with hydrogen to convert various sulfur compounds present in petroleum feedstocks. Sulfur compounds in the crude oil and various distillates include thiols, thioethers, thiophenes, polyaromatic thiophenes, and their derivatives. They are destroyed over HDS catalysts, producing hydrocarbons and hydrogen sulfide, which in turn is separated and converted to elemental sulfur via the Claus process. Currently employed catalysts are MoS_2 on γ-Al_2O_3 supports, with Co, and sometimes Ni, as promoters. Operation conditions are 673–773 K and 0.5–5 MPa hydrogen pressure, using multistage fixed-bed reactors. A key issue in the process design is the efficiency and recycling of hydrogen.[17]

Other noticeable hydrogenation processes are selective hydrogenation of alkynes, e.g., acetylene, to *cis*-alkenes, and similar partial hydrogenation processes. For partial hydrogenation, catalysts with reduced activity are required. Available catalysts include Lindlar's catalyst, a palladium catalyst partially poisoned with Pd and $CaCO_3$, and the nickel bromide catalyst, i.e., a $NaBH_4$ reduced $NiBr_2$.[18,19]

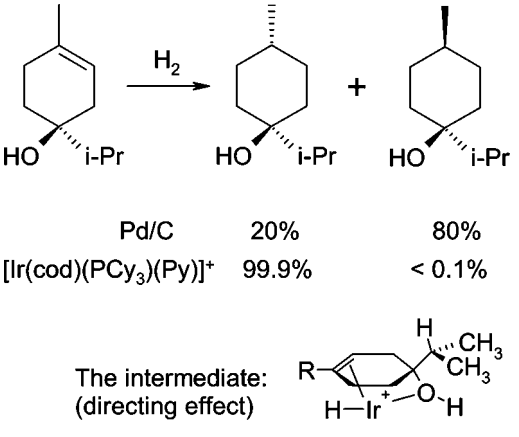
Hydrogenation using metal catalysts is a well-established method. Besides the hydrogenation of carbon–carbon unsaturated bonds, complete or partial saturations of aromatics, synthesis of fatty amines from nitriles, alcohols from ketones and aldehides can all be accomplished through heterogenous hydrogenation. Many catalysts such as Raney Nickel, copper–chromium, Pt/C, and Pd/C are commercially available in a large volume, with various modifications in metal loadings and surface areas. Chemical selectivity can usually be tuned by choosing a proper catalyst, e.g., Pd hydrogenates selectively C=C bonds, Rh and Ir hydrogenate preferentially carbonyls under suitable conditions. The choice of solvents when the process is carried out in the liquid-phase mode affects in certain circumstances the activity and selectivity because of their different polarity. EtOH, THF, dichloromethane are often used when a polar solvent is preferred, while cyclohexane is suitable as an apolar solvent. The processes can be performed either in solutions at rather low temperatures and under low H_2 pressures using a standard stirred vessel, or in the vapor phase with a fixed-bed flow-type reactor. In properly settled processes, the organics conversion can be completed without significant side products. H_2 is usually recycled.

Heterogenous hydrogenation catalysts can be combined with materials possessing other types of catalytic properties, resulting in bi- or multifunctional catalysts. For example, the catalyst used in the hydrocracking process is a combination of a noble metal, an acidic zeolite, and some other components. It leads, under the process conditions, to very effective hydrogenolysis of the long-chain components in the crude oil.[20]

HOMOGENOUS HYDROGENATION

Wilkinson's Catalysts

Wilkinson's catalyst, $RhCl(PPh_3)_3$, has been the first highly active homogenous hydrogenation catalyst. It was discovered by G. Wilkinson in 1964, and independently by R. Coffey almost at the same time.[21,22] The ligand helps the metal to be dissolvable in polar solvents and active at low temperatures. The mild condition then has an effect that the most reactive multiple bond in a molecule is hydrogenated with an extremely high selectivity. From mixtures of multiple unsaturated compounds, only the most reactive one is hydrogenated. The Wilkinson's catalyst can be simply prepared by reacting $RhCl_3{\cdot}3H_2O$ with PPh_3 in EtOH. The hydrogenation procedure over Wilkinson's catalyst follows three major steps. First, the unsaturated bond coordinates with a free orbital of the metal site, forming a π-complex. Then, this coordinated π-ligand interacts with a neighboring hydride, resulting in its insertion into the M–H bond. Finally, its reductive elimination gives a saturated product. Similar catalysts include the cationic $[Rh(cod)(PPh_3)_2]^+$, $[Ir(cod)(PCy_3)(Pyridine)]^+$, etc. They are even more active because the cationic metal sites are more electrophilic and favor the coordination of unsaturated compounds, which is often the rate determining reaction step. The stereoselectivity is determined by the way the multiple bond approaches the metal site. In certain cases, an inversed stereo-selectivity can be expected using the homogenous catalyst instead of the heterogenous catalyst, when other functional groups present in the compound offer a function to coordinate with the metal, as shown in Scheme 12 as an example. This kind of a contribution of the binding affinity of a neighboring functional group to an inversed stereo-selectivity is called "directing effect." Different functional groups in this respect



Scheme 12

display different strengths of directing effects. Generally, the order of the strength is as follows:

amide > OH > OR > ester ~ ketone

Amines and chelating ligands would bind too strongly to the catalyst, and therefore prevent hydrogenation.

The processes are carried out normally at 273 K with the Ir catalysts and 298 K with the Rh catalysts under 0.1 MPa H_2 pressure in stirred vessels. Feasible solvents are ethanol, acetone, dichloromethane, etc.

Lanthanide Hydrogenation Catalysts

$(Cp_2^*LuH)_2$ is present in solutions in its monometallic form, and is found to be the most active hydrogenation catalyst, reaching over 10 times the conversion rate as Wilkinson's catalysts.[23] Similar to Wilkinson's catalysts, the monometallic lanthanide has a free coordination site allowing the bonding of an unsaturated bond. The following hydride insertion and elimination then close up the catalytic circle. The processes are carried out at or below room temperature with 0.1 MPa H_2 pressure. This again enables the highly selective hydrogenation of the most reactive bond while other unsaturated sites remain intact.

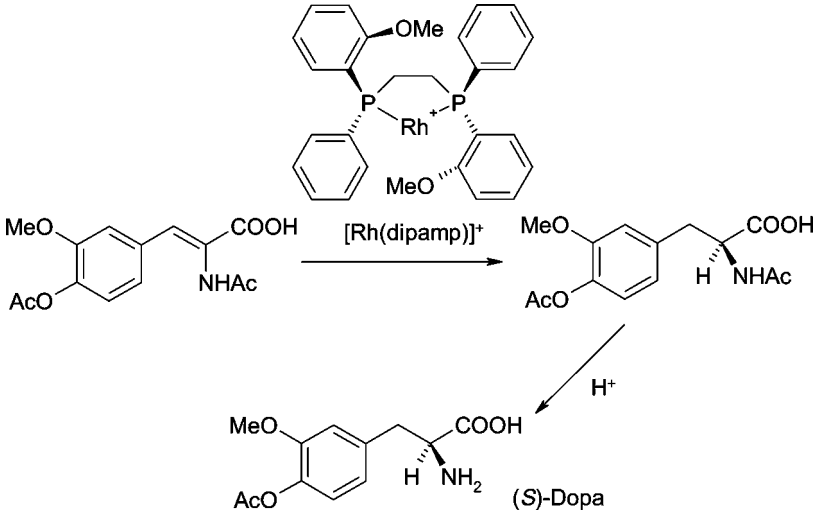
Homogenous Asymmetric Hydrogenation

About 95% of all hydrogenation processes are performed using Pd/C or Raney Nickel in the heterogenous mode.[24] The asymmetric hydrogenation, with high enantio-selectivities is the only area where the homogenous hydrogenation can predominate. The reason is that the high activity of the metal organics and the versatility of the available ligand structures provide precise controls of the coordination, H-insertion, and leaching of the unsaturated bond upon the catalytic site.

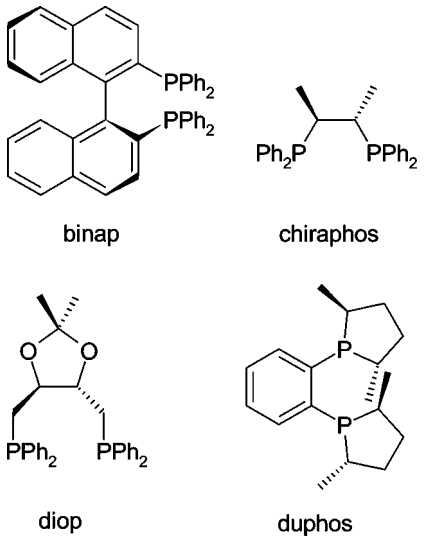
The first example has been the hydrogenation of α-acetamindocinnamatic acid producing (*S*)-Dopa, a medicine against Parkinson's disease.[25] As shown in Scheme 13, using the dipamp ligand the rhodium catalyst can achieve a 97% ee. The ligand, dipamp, is a chiral compound based on the antropisomery, i.e., the steric ligand is not freely rotational because of its bulkiness, therefore the molecule is rigid and asymmetric. The process producing (*S*) -Dopa has been commercialized at Monsanto, and won a Nobel prize in 2001 for the inventor, William Knowles, together with Ryoji Noyori for his contribution in heterogenous asymmetric hydrogenation, and K. Barry Sharpless, for chirally catalyzed oxidation.

Another often used chiral ligand is 1,1′-binaphthyl-2,2′-diyl-bis(phosphine), or binap.[26] It can be built into ruthenium catalysts, which display high activities and enantio-selectivities for the hydrogenation of alkenes, amines, allylalcohols, and unsaturated carbonyls. A directing effect is observed for an α-hydroxy group in these cases.

Besides dipamp and binap, many other effective chiral ligands, among which are mainly bi-phosphines, have been designed and are commercially available. Scheme 14 sketches a few examples in this category. There are many more chiral ligands that are obtained by connecting substituting groups to these basic structures. The chiral ligand enables a tailored design for hydrogenation of particular chemicals to the desired products. The example in Scheme 15 shows how complicated the structure of a hydrogenation catalyst can look.



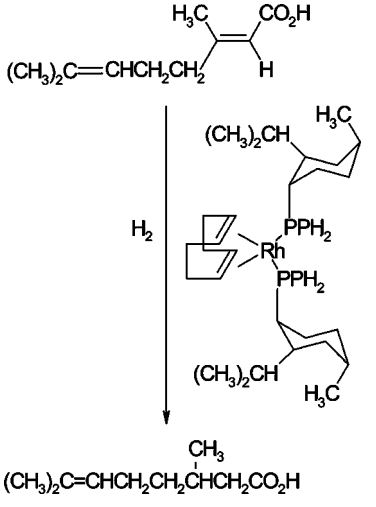
Scheme 13



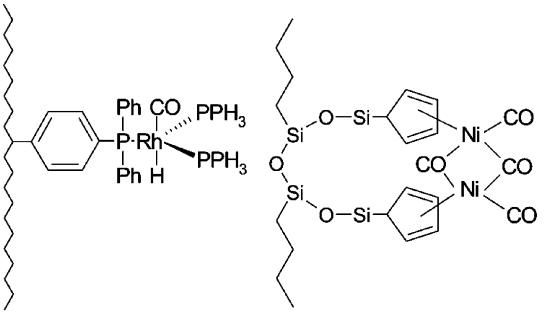
Scheme 14

Heterogenizing the Homogenous Hydrogenation

The homogenous hydrogenation processes are advantageous to the heterogenous processes in that they proceed faster and are highly selective under mild conditions. But there is a major drawback preventing their applications for large-volume productions, because the separation and recycling of catalysts from the products are tedious and cost-intensive. Therefore, methods to heterogenize the homogenous reactions are currently being developed. For the purpose of a heterogenization, the metal organic catalysts are entrapped or anchored to solid host materials, such as porous inorganic oxides, or polymers. Solid supramolecular materials are obtained through these procedures, which preserve the high activity and selectivity of the



Scheme 15



Scheme 16

metal organics. Further benefits of these materials are with respect to stability, ease of recovery, and further properties related to the porous structures such as high surface areas and the ability to diffusion control the reaction (e.g., shape-selectivity). Examples are the ''ship-in-the-bottle'' catalysts in zeolites, Wilkinson's catalysts anchored in the MCM-41 mesoporous silica through covalent bonding, and catalysts bonded to polymer backbones.[27–29]

Phosphorous is again the most common ligand element used to attach the metal complexes to inorganic or organic solid supports. Taking the organic polymers as examples, phosphorous can be bonded to the polymer chain as a dangling group in various ways. Then, these phosphorous groups can be used as ligands coordinating or chelating to the metallic catalysts. Other functionalized polymer chains or inorganic surface sites can be linked with metal sites by similar means. As shown in Scheme 16, many Ru, Rh, Ni, Ir catalysts have been heterogenized using this method. They have been proved to preserve the hydrogenation activity in various test reactions, such as saturation of acetylene, hexene hydrogenation, nitrobenzene hydrogenation, etc.[29]

Large-scale processes are yet to be developed based on these results. A major challenge is the catalyst leaching, as a heterogenized catalyst could undergo reversible or irreversible reactions forming species soluble in the reaction media, which may destroy the catalytically active species or even lead to undesired side reactions of the reactants and products. These problems have to be solved before successful processes are developed.

CONCLUSIONS

While hydrogenation using metal hydrides and other hydrogen transfer reagents offers a feasible method for laboratory experimentations, activation of molecular hydrogen with metal or metal organic catalysts is broadly employed in industrial hydrogenation processes.

Heterogenously catalyzed hydrogenation has long been established and has proved to be better than the homogenous processes in many aspects such as the stability of catalysts, the ease of separation of products from catalysts, a wide range of applicable reaction conditions, the possibility to hydrogenate hardly reducible functional groups, e.g., aromatic rings, and the ability to combine with other catalytic functions to achieve, e.g., hydrogenolysis. High selectivity of a heterogenous hydrogenation process is achieved through catalyst modifications and fine-tuning of the conditional parameters. However, homogenous hydrogenation becomes more widely applied when mild conditions, high selectivity, in particular enantio-selectivity, are required. The versatility of the structural features of usable ligands for metal–organic catalysts provides the possibility of a precise control of the hydrogenation procedure in the homogenous mode. The future development of hydrogenation processes exhibits, among all, one tendency to heterogenize the homogenously catalyzed processes by entrapping or anchoring the metal organic active species to suitable solid materials, such as porous inorganic oxides and polymers.

Hydrogenation Reactions in Dense Gas Systems

Gary Combes

INTRODUCTION

Incremental improvements across all facets of the processing industries enable companies to maintain a competitive advantage. These improvements are often driven by the need to conform to more stringent environmental standards. The substantial cost of finding alternate reaction pathways can be avoided by optimizing current synthesis processes or the product recovery stages of a process. The potential of supercritical fluids (SCFs) to reduce processing waste has been demonstrated for various commercial separation processes. More recently, SCFs have been shown to provide a suitable solvent environment for synthesis, in which reaction rates and selectivities are enhanced. With the potentially high capital costs compensated by the superior downstream separation, processing, and minimization of process waste products, the use of SCFs for integrated synthesis processes has become an attractive area of research. In this entry, recent applications of dense gases for reactions, particularly hydrogenation reactions, have been reviewed.

BACKGROUND

The major applications of dense gases, fluids above or in the vicinity of the critical point, have been for the extraction of specific compounds from solid matrices or liquid mixtures. Well-known examples include the decaffeination of coffee, extraction of olfactory compounds for the perfume and food industries, the extraction of essential oils, and the use of SCFs for the extraction of heavy fractions from distillates. These processes benefit from the selectivity of dense gases. A variety of new applications has been identified for which the properties of dense gases, other than the solvent power, are utilized. One field is the utilization of dense gases as a reactant for reactions. The dense gas processes for the production of low density polyethylene (LDPE) by free radical polymerization, and more recently, the manufacture of fluoropolymers have annual outputs measured in bulk tonnages.

Generally though, the enhanced kinetics, selectivity, and/or separation provided by a SCF process must be traded off against the generally low solubility of components in SCFs. The result is that supercritical technology is generally applied to high value, low volume products that are typical of the fine chemical industry. Potential product examples include catalysts, pharmaceuticals, food additives, electronics, specialty polymers, graft copolymers, and fluoropolymers.

Much of the focus of early reaction research centered on reactions in supercritical water ($T_c = 647.2\,K$, $P_c = 220.5\,bar$), with some promising results arising from these studies in the area of waste destruction. The major disadvantage of using supercritical water as a reaction medium is that the reaction environment strongly promotes corrosion, which combined with high temperatures and pressures, leaves only the most technologically demanding processes economically viable. Innovations in reactor design are improving the economics of supercritical water oxidation technology.

The technological challenges posed by supercritical water do not exist for many other SCFs. The critical conditions required for other SCFs are less extreme. Supercritical methanol ($T_c = 512.6\,K$, $P_c = 80.8\,bar$) has been used to break down poly(ethylene terephthalate) (PET) waste matter to its basic synthesis components for reuse in the original process. Supercritical propane is the favored solvent for hydrogenations of long chain fatty acids and oils because of its superior solvation power for large molecular weight compounds compared to carbon dioxide. As solvents, SC-CO_2, ethane, and nitrous oxide have moderate critical temperatures (i.e., 31.4°C for CO_2). The most prevalent of these solvents, carbon dioxide, is considered environmentally benign, inexpensive, nonflammable, noncorrosive, and leaves no residue after use. These characteristics, combined with the attractive mass transfer properties of SC-CO_2, present a range of opportunities for the synthesis industry.

REACTIONS IN DENSE CO_2

has been applied. Jessop and Leitner[1] and Noyori[2] provide a significant insight into dense gas synthesis chemistry. In some of the more recent works, the application of CO_2 for particle production is combined with CO_2 synthesis to obtain a process low on waste but of optimal efficiency.[3] As has been demonstrated, the unique properties of dense gases could enable the realization of a single process unit for both reaction and product separation.

Multiphase gaseous reaction systems are of prime importance in the pharmaceutical and specialty chemical industries, especially in the area of chiral synthesis. The importance of isomer-selective synthesis in the fine chemical industry is illustrated with the example of the aspartylphenylalanine methyl ester isomers. The (L,L) isomer is the common sweetening agent aspartame, whereas the (L,D) diastereoisomer has a bitter taste. In the pharmaceutical industry, thalidomide is a notable example. In the racemic or (S) isomeric form, the drug is a strong teratogen, whereas the (R) form has been claimed to possess no such side effects.[4] Enzymatic catalysis is also proving to be a significant growth area in supercritical reaction research, hence its justification in being included in the tabled survey of CO_2 reactions. A number of studies have already demonstrated that rates and selectivity for enzyme-catalyzed reactions can be enhanced in supercritical media.[5–7]

Supercritical CO_2 may not be the optimum solvent for a given reaction system. The low solubility of reaction components is perceived to be a major disadvantage of using SC-CO_2 for reactions. This limitation can be overcome through the combination of dense CO_2 and a conventional solvent. The term applied to this technique is gas antisolvent reactions (GASR) and has its origins in the gas antisolvent (GAS) particle process.[8] It is suggested that this area of reaction research offers potential for improvements in current multiphase processes without the need for considerable reengineering of the process. Evidence is provided to support this argument and its potential for future research. Finally, a consideration of some hybrid systems that incorporate not only reactions but also product separation/purification is presented to illustrate the potential for incorporating dense gases into existing processes.

Hydrogenations

Heterogeneous catalysis

The use of dense gases for heterogeneous hydrogenations is attractive given the ease of product purification and the significantly enhanced rates.[9–11] Other solvent

properties, such as viscosity, polarity, and local solvent density effects may also have an impact on kinetics. Heterogeneous hydrogenation reactions conducted in CO_2 offer the possibility of faster reaction rates through improved mass transfer and higher dissolved H_2 concentrations in reactions where the rate is greater than zeroth order in terms of hydrogen. The higher diffusivity and lower viscosity of SCFs may result in a faster removal of product from the catalyst pores, thus preventing catalyst fouling and reducing further side reactions. Improved mass transfer rates are manifest in the extended lifetime of catalysts, the enhanced product selectivity, and the reduction of residence times. The common hydrogenation catalysts of palladium and nickel exhibit very low solubility in SC-CO_2 and are suitable for continuous heterogeneous processes.

A number of heterogeneous hydrogenations have been carried out in CO_2.[12–15] Kröcher, Koppel, and Baiker[14] considered the heterogeneous catalytic synthesis of (*n,n*)-dimethylformamide (DMF) from SC-CO_2 using a variety of heterogeneous metal catalysts. From this study, silica matrix–stabilized ruthenium catalysts proved to be the most active and robust group 8 metal for the hydrogenation of CO_2 compared to metal catalysts such as iridium, palladium, rhodium, platinum, and cobalt. Turnover numbers [TON = (mole product)/(mole catalyst)] for the DMF synthesis were over three orders of magnitude greater than for the previously reported heterogeneous studies, although the TON were still less than those recorded in supercritical homogeneously catalyzed systems.

The relatively inert nature of CO_2 does not preclude it from deactivating catalysts. Minder et al. found that SC-CO_2 deactivated the platinum catalyst when used as a solvent for the hydrogenation of ethyl pyruvate.[16] Catalyst activity was maintained, however, when propane was used. The reaction rate in supercritical propane was significantly higher compared to that achieved in toluene. Tacke, Wieland, and Panster considered the hydrogenation of fatty acids in CO_2 with a variety of catalysts and reactor regimes using the commercial DELOXAN® supports.[15] The higher yield for the polysiloxane-supported 1% palladium catalyst bed compared to a 2% platinum catalyst on the same support in SC-CO_2 may have been because of catalyst deactivation by CO_2.[15] Van der Hark and Härröd observed significantly higher TON and much improved selectivities for *cis* product in the hydrogenation of fatty acid methyl esters in supercritical propane using conventional palladium or nickel catalysts.[17] These studies are evidence to show that catalyst technology plays an integral part in supercritical reactions and that CO_2 will not always be the best supercritical solvent.

The study by Hitzler et al. has illustrated the broad scope of potential hydrogenation reactions in SC-CO_2.[18] Some of the substrates investigated included *m*-cresol, benzaldehyde, acetophenone, 1-octene, and cyclohexene. Reactions were performed in 5 and 10 ml packed bed reactors and space times of up to $300\,hr^{-1}$ were achieved. Residence times of this magnitude render the issue of scale-up largely irrelevant for small (kilogram) quantities of product in a continuous process. This is advantageous for the commercialization of SCF reaction processes because it minimizes development and capital costs.

Hitzler et al. found that the product distribution could be varied by varying system parameters such as reactor temperature, hydrogen : substrate feed ratios and catalysts.[18] An example of this was the hydrogenation of acetophenone over a 5% Pd APII DELOXAN catalyst to ethylbenzene (EB), ethylcyclohexane (ECH), α-methyl benzenemethanol (MBM), and α-methyl-cyclohexanemethanol (MCH). Varying the temperature from 363 to 573 K at constant CO_2 flow (which altered the substrate : hydrogen ratio and residence time) resulted in a dramatic change in the selectivity toward the products EB, ECH, and MBM as shown in Table 2. The fact that the temperatures of these reactions were far higher than the critical temperature of CO_2 suggest that mass transfer characteristics (chiefly low viscosity) and chemical effects were significant factors.

There are few comprehensive kinetic studies included in the heterogeneous hydrogenation investigations conducted to date.[12,13] The published works by Bertucco et al.[12] and Devetta et al.[13] are notable because the investigations incorporate phase equilibria

Table 2 Conversion and selectivity for the hydrogenation of acetophenone in SC-CO_2

			Selectivity (%)			
Temperature (K)	**Sub : H_2**	**Conversion**	**MBM**	**EB**	**MCH**	**ECH**
363	1 : 2	97.5	90.0	7.5	0	0
453	1 : 5	100	14.0	41.0	28.0	17.0
473	1 : 3	91.5	0	73.0	0	18.5
573	1 : 6	94.0	0	4.5	0	89.5

(From Ref.[18].)

studies combined with equation of state (EOS) modeling to complete the kinetic studies for the system. In all cases, the reaction was the hydrogenation of an unsaturated ketone over an alumina-supported palladium catalyst. The ketone was a vitamin intermediate. The initial study was conducted in a modified internal recycle reactor to obtain perfectly mixed conditions.[12] The kinetic data were then used in subsequent modeling of a trickle-bed reactor in both two-and three-phase systems.[13] The aim of using SC-CO_2 in this instance was to enhance the solubility of hydrogen. As a consequence of the relatively extreme temperatures and pressures required to homogenize the fluids, three phases were present in the system. The results predicted by the kinetic models were in good agreement with the experimental data, largely because of the accurate quantitative evaluation of phase equilibria for the system.

Homogeneous catalysis

Supercritical media are well suited for conducting homogeneous catalytic reactions because of the absence of phase boundaries and the improved mass transfer rates. In the majority of the published kinetic works, CO_2 has been used as both the reactant and solvent to produce formic acid, methanol, formamide, and ethanol.[19–22] Jessop, Joo, and Tai[19] demonstrated the esterification of formic acid in a single stage process via the homogeneous catalytic hydrogenation of CO_2, in the presence of methanol and triethylamine using a variety of ruthenium-based catalysts. Not only was the methyl formate synthesis, a two-step reaction process, carried out concurrently in a single vessel, but the TONs were an order of magnitude higher and the equilibrium yields were greater than any reported for the ester synthesis. These results were achieved at 323 K, which is significantly lower than the 373–448 K used in prior studies.[23–25]

Novel organometallic compounds such as $Cr(CO)_5(H_2)$,[26] $(C_5R_5)Mn(CO)_2(\eta^2\text{-}H_2)$, and $(C_5H_5)Mn(CO)_2(\eta^2\text{-}H_2)$[27] have been synthesized and isolated in traditional flow reactors using SC-CO_2. Many other compounds have been identified through in situ infrared monitoring of the reactions. The work was notable because it combined synthesis and product purification in a very simple, though effective arrangement. Supercritical CO_2 was found to be a more versatile and stable environment for ligand manipulation than conventional solvents, which may allow the synthesis of further novel organometallics than predicted for conventional solvents. The reaction rate for the synthesis of $Cr(CO)_5(H_2)$ by Poliakoff, Howdle, and George was an order of magnitude faster in CO_2 than in *n*-heptane.[26] The rate enhancement was ascribed to the improved solubility of H_2 in SC-CO_2 compared to the liquid *n*-hexane and the weaker interactions between solute and reaction intermediates in the supercritical medium compared to the organic medium.

The improved reaction rates achieved in the SC-CO_2 medium combined with the variety of substrates considered so far illustrate the potential of this technology. As an indication of the economic viability of CO_2 processing in the fine chemical industry, a plant has been constructed at Thomas Swan and Co. in the UK.[28] The plant has been built for hydrogenation processes to produce fine chemicals and pharmaceutical intermediates to a rating of 1000 kg hr^{-1} of CO_2 at pressures up to 500 bar. However, the significant capital cost of supercritical processes, combined with the complex production and expensive nature of chiral products, demand that SC-CO_2 be considered for asymmetric hydrogenation.

Asymmetric homogeneous catalysis

Given the improved reaction rates of nonselective catalyzed reactions already achieved with SC-CO_2, it is not surprising that asymmetric hydrogenations have been a focal point of study. Economic and environmental regulatory guidelines are two of the major driving forces behind the efforts in the chemical industry to maximize efficiency and to minimize waste. The traditional methods for producing optically pure compounds involve preferential crystallization or diastereomeric crystallization, kinetic resolution, and catalytic asymmetric synthesis. Catalytic asymmetric synthesis has significant advantages over the other methods mentioned, including waste minimization and a reduction or elimination of separation requirements with associated savings in energy consumption. The global chiral pharmaceutical market was valued in excess of US $70 billion annually (as of 1997), making it an ideal candidate for SC-CO_2 reaction technology.[4]

Synthesis of optically pure compounds has been a long established challenge in chemistry. The focus has been on improving the catalysts involved in the reactions because of the difficult nature of separating chiral compounds.[29,30] A broad range of catalysts are available with very high selectivities in many organic solvents. The use of SCFs (in particular CO_2) as reaction media was investigated in 1995.[31] The small amount of available published data is indicative of the infancy of this research. However, a review of results to date highlights why carbon dioxide is a potential alternative to organic solvents for dissolved catalytic reactions or homogeneous catalysis.

The first published example of asymmetric hydrogenation was by Burk et al.[31] The enantioselective hydrogenation of α-enamides with cationic rhodium (R,R) Et-DuPHOS 1,2-bis(*trans*-2,5-diethylphospholano) benzene as a catalyst was investigated. To improve the

solubility of the catalyst, the very lipophilic counteranion, tetrakis(3,5-bis(trifluoromethyl)phenyl) borate (or BARF) was used. The enantiomeric excesses (e.e.) obtained were comparable to those achieved in conventional solvent systems of methanol and hexane. (Enantiomeric excess is a common measure of purity for one enantiomer over another, e.g., S over R is defined as $(S - R)/(S + R)$.) The results were catalyst and substrate selective, suggesting that steric and solvent effects were major factors.

The hydrogenation of β,β-disubstituted α-enamides by Burk et al. realized enantioselectivities that were significantly higher in SC-CO_2 than in conventional solvents.[31] The high enantioselectivities were shown not to be solely a function of the higher system pressures, but more a result of solvent effects and the improved hydrogen solubility in SC-CO_2 compared with organic solvents.[32] These observations were in agreement with the results obtained by Sun et al., who found that for H_2 limited reactions, the main kinetic factor controlling enantioselectivity in asymmetric catalytic hydrogenation was the H_2 concentration in solution.[33] Whilst the study by Sun et al. was applied to conventional solvents and not supercritical systems, it was a key factor for promoting the use of supercritical media such as CO_2.

A second investigation by Xiao et al. considered *trans*-2-methyl-2-butenoic acid as the substrate and a variety of ruthenium BINAP catalysts (BINAP is 2,2′-bis(diphenylphosphino)-1,1′-binaphtyl).[34] The results showed that the reaction in SC-CO_2 produced selectivities and yields that were comparable to those in methanol and hexane. The reaction took approximately twice as long in SC-CO_2 as in methanol, although no explanation was provided. Bonding of CO_2 to the catalyst may have inhibited, although not prohibited, the reaction. Equally, strong solvent–solute interactions may have inhibited the reaction. The presence of fluorinated alcohols enhanced the selectivity to levels above those achieved in neat methanol, possibly as a result of electronic effects and/or improved solubility. The lower pressures of hydrogen used in the SC-CO_2 trials still gave comparable yields, indicating that the miscibility of hydrogen in SC-CO_2 was not a significant factor. The limited results do not permit conclusions to be drawn on the relative rates or the true effect of hydrogen pressure.

In the work with asymmetric hydrogenation in SC-CO_2, Kainz et al. used modified iridium catalysts to hydrogenate imines.[35] The presence of BARF as a counterion provided the best results in CO_2. In comparison to dichloromethane, CO_2 gave up to double the turnover frequency (TOF = TON/time) but enantioselectivities were lower by ~10%. Again yield and selectivity were substrate specific. Lange et al. developed a chiral rhodium diphosphinite catalyst complex, which also used the BARF counterion and subjected it to a mechanistic study.[36] The hydrogenation of di-methylitaconate was conducted in both hexane and CO_2 and the results were compared. The enantioselectivity in CO_2 was comparable to that of hexane. However, the reaction was slower by a factor of five. Analysis by NMR indicated that CO_2 did not bond with the reaction intermediates. Thus, it was concluded that the solvent was either influencing the availability of the hydrogen at the reaction site or affecting specific steps in the catalytic cycle through changes in the stability of transition states.

There has been no comparative work on hydrogenation rates for solubilized compounds in CO_2 and conventional solvents to date. Most of the investigations mentioned above have shown technical feasibility, which for the synthesis of fine chemicals on the kilogram scale, is probably sufficient. An improved understanding of the reaction kinetics is necessary for the field to progress. In this respect, knowledge of catalyst solubility in CO_2 is required. An overview of work in conventional liquid solvents serves to highlight that ruthenium-, rhodium-, and iridium-based catalysts often provide improved selectivities and activities for hydrogenations. A comprehensive study along the lines of those reviewed by Jessop and Leitner;[1] Jessop, Joo, and Tai;[19] and Darr and Poliakoff[37] made on the solubility of various chelated transition metal catalysts in CO_2 and other supercritical mediums would be of immense use for future work in this area. Palo and Erkey determined the solubility of both dichloro bis(triphenylphosphine) nickel(II) and Wilkinson's catalyst in SC-CO_2 to be of the order of 0.01 mM.[38] The typical concentration used in homogeneous catalysis is about 1 mM, suggesting that catalyst development for CO_2 is essential to enhance the potential of CO_2 for selective catalytic reactions.

Hydroformylation

Hydroformylation reactions have been one of the most well researched areas of CO_2 reaction chemistry. Hydroformylation reactions are necessary for the formulation of complex chemicals. The first complete kinetic study of a hydroformylation reaction was in CO_2 and was first published in 1999.[39] Prior to this, most studies had considered the effect of dense CO_2 on linear : branch ratios or other forms of selectivity. Carbon dioxide has an effect on the selectivity of a variety of hydroformylation reactions and can enhance the rate of reaction[40] Hydroformylation is by its nature regioselective and typically the linear : branch or "*n : iso*" ratio is used as the measure of selectivity. The use of asymmetric catalysts to achieve chiral products has introduced a second degree of selectivity to catalyst design. Advancements in catalyst design, together with solvent selection, are expected to make

larger gains in selectivity, and thus simplify the separation and purification steps downstream.

Palo and Erkey determined a kinetic expression for the hydroformylation of 1-octene in SC-CO_2.[39] The ''CO_2'' phyllic catalyst developed was *trans*-RhCl(CO)$(P(p\text{-}CF_3C_6H_4)_3)_2$, which obtained an estimated solubility of at least 7.6 mM in SC-CO_2.[39] The observed solubility was a 100-fold improvement on that achieved with nonfluorinated catalysts. A half order dependence on the hydrogen concentration was observed, which contrasts markedly with results in conventional solvents, where the order with respect to hydrogen has always been one or greater.[41] The result suggests that either the improved hydrogen solubility or the suspected improved mass transfer rates had altered the rate-limiting step. Conversely, solvent effects such as higher local densities or the weaker solvent cage may have contributed to a change in the rate-limiting step in the mechanism. The evaluation and comparison of the Arrhenius equation for this reaction in CO_2 and conventional solvents would assist in determining the principal factor.

The work also revealed that unlike in conventional systems, there was no substrate inhibition and no critical catalyst concentration loading, which is often brought about by the formation of an inactive catalytic dimer species. The novel catalyst or the presence of CO_2 was suggested to be the cause of this effect. Carbon monoxide was found to have a strong effect on the selectivity of linear vs. branched product in the supercritical environment.

A comparison with other literature results highlighted the solubility issues that arise when comparing CO_2 with conventional solvents. As shown in Table 3, the concentrations of the gases are higher in CO_2 than in organic solvents. The substrate concentration in CO_2 is almost an order of magnitude lower than those in conventional solvents. The fine chemical and pharmaceutical industries, where this technology will be most applicable will obtain typically lower substrate solubility because the substrates will be far more complex CO_2-phobic molecules.

The improved catalytic efficiency of homogeneous hydroformylation reactions in CO_2 has been proven experimentally. The studies by Koch and Leitner of the homogeneous hydroformylation of 1-octene with the catalyst [(cod) Rh(hfacac)] (cod = cyclo-octadiene and hfacac = hexafluoroacetylacetonate) produced TON in CO_2 that were three times higher than those in toluene.[42] The addition of perfluoralkyl-substituted triarylphosphine and triarylphosphite ligands to the system produced improved regioselectivities of *n* : *iso* product compared to those achieved in conventional solvents. The side reaction of olefin isomerization that occurs in phosphite-modified systems in conventional solvents was totally suppressed in the dense gas environment. In addition, the work demonstrated catalyst activity for a number of substrates in liquid CO_2. The relative rates for the hydroformylation of the sterically hindered *trans*-3-hexene were at least five times greater in CO_2 than toluene under the same conditions. The results clearly indicate that the dense gas media can effect beneficial changes to the reaction chemistry.

Further catalyst development has occurred based on the improved regioselectivity of the perfluoroalkyl-substituted ligands for use in homogeneous hydroformylations in CO_2.[43,44] Kainz et al. developed a perfluoroalkyl-substituted arylphosphane ligand that achieved solubility improvements in CO_2 of several orders of magnitude.[43] A high degree of conversion and a high selectivity for *n* : *iso* product with no hydrogenation side reaction characterized the successful catalyst development. Franciò, Wittmann, and Leitner used the (R,S)-3-H_2F_6-BINAPHOS ligand complexed to [Rh(acac)] to perform the catalyzed hydroformylation of vinyl arenes in SC-CO_2.[44] Regioselectivity of 93% and enantioselectivity in excess of 90% were consistently attained at temperatures ranging from 308 to 333 K and pressures of 115–242 bar. The yields and rates were comparable to those in benzene and proved to be far superior than the results achieved in hexane. The yields in CO_2 systems were comparable with benzene at high substrate : catalyst loadings of 2000. The acceptance of CO_2 as a replacement solvent is more likely in this case given the environmental and health issues that benzene presents and the absence of solvent residue in the product. These studies indicate

Table 3 Comparison of concentrations used in hydroformylation experiments in CO_2 and conventional solvents

		Concentrations (10^{-3} mol dm^{-3})			
Solvent	**Substrate**	**H_2**	**CO**	**Catalyst**	**Substrate**
CO_2	1-Octene	130–2600	130–2200	0.63–0.25	0.04–0.96
Ethanol	1-Hexene	21.4–62.1	6.2–153	0.33–1.2	0.20–1.56
Toluene	1-Dodecene	8.9–30.8	8.4–121	1.0–8.0	0.18–2.2
Toluene	Ethylene	2.7–44.7	14.0–149	0.5–4.0	0.045–1.45

(From Ref.[72].)

that the considerable potential for homogeneous hydroformylation chemistry in CO_2 requires the concurrent development of catalyst technology.

Phase Transfer Reactions

Phase transfer catalyzed (PTC) reactions consist of two immiscible phases with the transfer of catalyst between the two phases such as liquid–liquid or solid–fluid phase. The reaction has been known to occur in a catalyst rich third phase. The PTC reactions are acknowledged as being a significant subset of reaction chemistry. The PTC industry is estimated to generate products worth billions of dollars annually in areas such as polymers, pharmaceuticals, and agrichemicals, although this value is not yet reflected in the degree of supercritical research into this area. The higher diffusion rates of solutes (both catalysts and reactants) through the dense CO_2 and the suspected improved mass transfer rates across the phase boundaries are features of PTC reaction that could benefit from the utilization of CO_2. The significantly lower solubility in CO_2 for both reactants and catalysts will impact on its overall economics.

The use of ionic liquids in combination with CO_2 has the potential to produce cleaner processes with improved selectivity.[45–48] The negligible miscibility of the ionic liquid in CO_2 compared with appreciable amounts of CO_2 that can be found in the liquid phase make the use of CO_2 as a ''green'' solvent attractive for continuous reaction processes. Sellin, Webb, and Cole-Hamilton[45] conducted a hydroformylation of hex-1-ene and 1-octene catalyzed by rhodium based catalyst in 1-butyl-3-methylimidazolium hexafluorophosphate (BMIMHF) in contact with CO_2. Improved *n* : *iso* product selectivity was obtained, compared with that using toluene with similar selectivity, but substantially lower yield (40% compared to >99%). Using 1-octene as a substrate and $[Rh_2(OAc)_4]$/[1-propyl-3-methylimidazolium] $[PhP(C_6H_4SO_3)_2]$ as catalyst, over 20 hr of continuous operation was achieved with minimal catalyst leaching at 373 K.

Brown et al. have conducted asymmetric hydrogenations of tiglic acid with $Ru(O_2CMe)_2$((R)-toluene BINAP) in BMIMHF with water using CO_2 to extract the product.[49] Catalyst activity and enantioselectivity were maintained through five sequential experiments. Liu et al. studied the hydrogenation of CO_2 with the catalyst $RuCl_2(Ph_2PCH_2CH_2PPh_2)_2$ in the presence of dialkylamines to produce *N,N*-dialkylformamides in the system of SC-CO_2/BMIMHF.[50] The results indicated that the selectivity for amines other than dimethylamine was higher in the SC-CO_2/BMIMHF system compared to conventional solvent systems. It was determined that CO_2 offered no advantage in terms of reaction rate for simple hydrogenations over hexane as a solvent. However, the separation step of the product from the solvent would be simpler and considerably less expensive using CO_2.

Reactions in a CO_2-Expanded Phase

The replacement of conventional solvents with CO_2 for hydrogenation reactions theoretically promises improved reaction rates with the improved gas miscibility. It is a different case when the optimum temperature lies below the critical temperature of CO_2. The solubility of gaseous hydrogen in a liquid phase increases with increasing temperature. If a reaction produces a higher selectivity for the desired product at lower temperatures, then the efficiency of the process becomes more complex. A conundrum exists whereby the reaction rates may be increased at the expense of selectivity, or the purification steps downstream are minimized but at the cost of a considerably slower reaction rate.

When phase equilibria are considered together with kinetic rate expressions, a dense gas expanded medium can be a viable alternative compared to SCF technology. There is a strong case that dense CO_2-expanded solvents may enhance the gas solubility in the liquid phase at temperatures below the critical point of CO_2. The issue that has been the commercial downfall of many potential CO_2 applications remains the poor solubility of most potential reactants in CO_2. It is possible that by using CO_2 in conjunction with conventional solvents, the solubility issue can be addressed. A significant advantage is also realized when it comes to product recovery and purification compared with the use of nonexpanded solvent. An added benefit is the reduction in organic solvent requirements that results through the use of CO_2-expanded media.

Given that the dense gas is miscible with the solvent, the degree of expansion has been found to be a function of the fraction of CO_2 in the liquid phase as shown in Fig. 1.[51] An arbitrary minimum for the amount of CO_2 required in a GASR system is defined by the fact that appreciable expansion is only gained at mole fractions beyond 60% of CO_2. The use of CO_2-expanded solvents theoretically provides the optimum tuning medium for reaction rates. The benefit of large scale operation is that it potentially affords the fine chemical industry the means to combine reaction chemistry together with simpler separation techniques. Significant improvements in processes, both current and new, can be achieved at significantly milder conditions than those required for homogeneous supercritical reactions.

The hydrogenation of CO_2 to form formic acid serves to illustrate the potential of expanded systems. Jessop et al. found that whilst the rate of hydrogenation

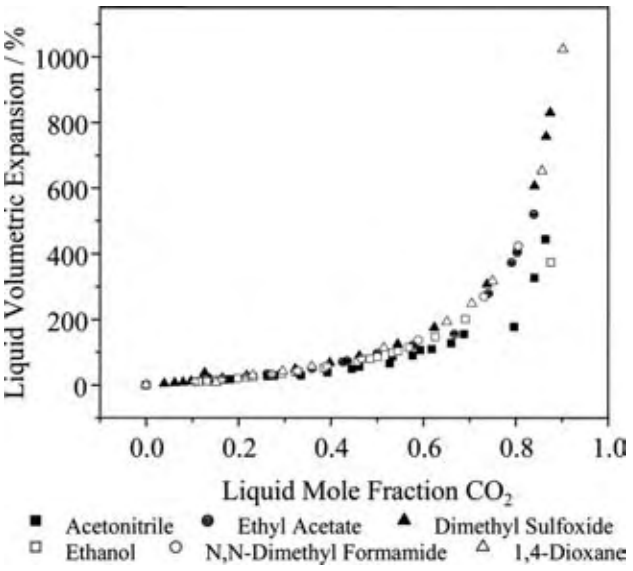

Fig. 1 Expansion curves of a variety of organic solvent/CO_2 systems at 298 K. (From Ref.[51].)

was fastest in the homogeneous phase, the TOF for the hydrogenation reaction in a two-phase mixture of methanol and CO_2 was still significantly faster than neat methanol.[19,20] The TON and TOF for the production of formic acid from CO_2 are shown in Table 4. Other solvents including dimethylsulfoxide (DMSO), acetonitrile, and tetrahydrofuran (THF), all of which expand with the addition of CO_2 were considered for the same reaction. The initial rate of hydrogenation in the two phase CO_2/DMSO system was comparable to that of the single CO_2/DMSO phase and CO_2/methanol system.

There have been few instances where a study has been focused on an expanded solvent as a reaction medium.[52–54] Kerler et al. reported that oxidations in a CO_2-expanded environment were more efficient than the corresponding reaction in SC-CO_2.[53] Kayaki, Naguchi, and Ikariya investigated the arylation of ethylene with iodobenzene using $PdCl_2\{P(OC_6H_5)_3\}_2$ and base.[55] The reaction was run over 18 hr at 403 K. The selectivity for styrene was increased from 57% in the absence of CO_2 to 83% in CO_2 at 101 bar. Selectivity increased at the expense of conversion as the CO_2 pressure was increased from 101 to 151 bar, which corresponded to the progression of the system from a binary mixture to a supercritical phase. Further studies with catalysts of higher solubility in the supercritical phase failed to provide higher TONs. The conclusion was drawn that the CO_2 was extracting the styrene from the liquid phase, thus preventing further reaction with the styrene. These studies were conducted at low concentrations and hence the true effect of the CO_2 on the reaction was not determined.

Combined Reaction and Separation Using Dense CO_2

The synthesis and purification processes are often numerous and complex. Dense gases present the possibility of combining the reaction and separation operations into a single integrated process and may provide a convenient way of removing the impurities through improved reaction control.

Darr and Poliakoff conducted one of the first studies where SC-CO_2 was used in a two-stage continuous reaction and purification process to form pure organometallic products.[55] The *cis*-$W(CO)_4$(pyridine)$_2$ or novel *cis*-$W(CO)_4$(3,5 lutidine)$_2$ were formed in a continuous flow reactor at 488 K and were then removed from solution via precipitation, with a second flow of CO_2 used to remove the excess solvent and reactant for reclamation and recycle. The benefits of this system, aside from the production of novel materials, include reduction of organic solvent consumption, decrease in number of stages and time, and production of 100% purity product.

The asymmetric catalytic hydrogenation of 2-(6′-methoxy-2′-naphthyl)propenoic acid to (S)-naproxen was monitored in both methanol- and CO_2-expanded methanol.[8] The catalyst used was [dichloro-(S)-(-)-2,2′-bis(diphenyl-phosphino)-1,1′-binapthyl]ruthenium(II). Addition of CO_2 to the methanol produced strong retardation of the reaction rate. An average reduction in enantioselectivity of 6% was observed compared to that in methanol. The enantioselectivity was found to increase as the temperature decreased in both neat methanol and CO_2-expanded methanol systems, indicating that the underlying mechanisms were similar. Insufficient oxygen removal may have prevented the

Table 4 Relative rates for the hydrogenation of CO_2

Catalyst precursor	Additive	No. of phases	TON	TOF (hr^{-1})
$RuH_2[P(C_6H_5)_3]_4$	H_2O	1	80	80
$RuH_2[P(C_6H_5)_3]_4$	Methanol	2	770	1500
$RuH_2[P(CH_3)_3]_4$	H_2O	1	1900	630
$RuH_2[P(CH_3)_3]_4$	Methanol	2	760	1500

(From Ref.[19].)

reaction from progressing to complete conversion and also retarded the reaction rate. Spectroscopic studies indicated that the effect of local density enhancements on the thermodynamic state of reaction components contributed to the retardation of the reaction in the expanded solvent media as well. While low enantioselectivity and reaction rate were achieved for this hydrogenation reaction in the CO_2-expanded methanol, the study does not close the avenue for further research in the area of hydrogenation reaction in gas expanded solvent systems.

Recent work by Warwick et al. for an alternate synthesis and purification process for a novel pharmaceutical have built upon the concept.[3] Warwick et al. investigated the effect of dense CO_2 as an antisolvent for improving yields of the synthesis of the nonsteroidal anti-inflammatory drug, copper indomethacin. The conventional synthesis is currently performed by dissolving reactant, copper acetate, and indomethacin in dimethylformamide (DMF) followed by using ethanol as an antisolvent to precipitate the product, including copper indomethacin and removing acetic acid as a by-product. It is important to remove the residual of indomethacin (reactant) from the product (i.e., copper indomethacin) because of the noted side effect of the former. The replacement of ethanol with CO_2 decreases dramatically the volumetric requirements of antisolvent and cuts processing time by 80%. The recovery of the antisolvent is considerably simpler using CO_2 compared to ethanol. By considering the solubilities of the individual components and utilizing the optimum reactant ratio, the yield can be improved to almost 100% whilst simultaneously achieving improved purity of product. The use of CO_2 also produced a significant reduction in residual solvent levels.

The combination of reaction and product separation into the desired micronized form is desirable from a processing view. Warwick[56] extended this work to using an aerosol solvent extraction system (ASES) arrangement. It was highlighted that for very fast reactions, ASES is a viable process for synthesizing and separating product in the single vessel. Using the component solubility of the system and a dense CO_2-based ASES arrangement, the product was synthesized and micronized in one vessel. Little or no solvent residue was realized by repeated washing of the micronized product.

CONCLUSIONS

It is clear that there is a wide scope for performing reactions in CO_2 and expanded solvents. An improved knowledge of solvent effects on reaction rates and selectivity at high pressure will enable targeted research to be applied to specific reactions to achieve improvements in synthesis processes.

The application of CO_2 to the considerably larger body of catalyzed reactions provides a greater challenge to our understanding of CO_2 chemistry. In many studies, technical feasibility of the reactions has been established and in several, complete investigations of the kinetics have been conducted. Utilizing dense gases for reactions often provides an advantage with the subsequent separation and purification processes being more efficient than the conventional solvent systems. In many cases, reaction rates and selectivity in a dense gas environment were improved compared to the conventional synthesis process conducted in an organic solvent. Most reaction investigations using CO_2 have typically been performed at dilute conditions to avoid solubility issues. The limits of a reaction system are rarely explored and hence the boundaries of a process (which include not only the reaction steps but the product recovery and purification) are never completely defined. Using dense gases for reactions should always be evaluated from the perspective of the complete process, rather than for just one stage.

Hydrophilic Polymers for Biomedical Applications

Frank Davis
Séamus P. J. Higson
Cranfield University, Silsoe, U.K.

INTRODUCTION

The production of polymeric materials is one of the world's major industries. Polymers are utilized in many applications because of their processability, ease of manufacture, and diverse range of properties. Many of the commonest polymers such as polyethylene, polystyrene, and polytetrafluoroethylene (PTFE) are highly hydrophobic materials rendering them unsuitable for many biomedical applications. For applications that require contact with body fluids such as blood or urine, it is necessary for the materials to be hydrophilic and to be capable of maintaining intimate contact with the fluid in question for prolonged periods of time without significant loss of functional performance.

This entry begins by describing the nature of hydrophilic polymers and structures, together with properties of some of the most commonly encountered materials. Details are then given of some applications that require the use of polymers and how they can be applied. The entry finishes with a brief synopsis of the work in this field and possible future research and applications.

STRUCTURE AND PROPERTIES OF HYDROPHILIC POLYMERS

Polymeric materials made from simple hydrocarbon monomers such as polyethylene are extremely hydrophobic in nature. There is very little in the way of interaction between the polymer backbone and water, which means that these polymers will not adsorb water and their surfaces are not wettable. For a polymer to be hydrophilic, functional groups capable of undergoing interactions with water such as hydrogen bonding are usually required. Such groups include, but are not limited to, alcohols, ethers, esters, carboxylic acids, amines, and amides. These can interact with water via hydrogen bonding or dipolar interactions; such polymers can vary from just being wettable at their surfaces to being permeable to water, and in some cases are capable of adsorbing many times their own weight in water. Some of the most widely used polymers are discussed later. The properties and use of these materials in biomedical applications can only be summarized within the limits of this entry; however, several other works have been written on this subject.[1–3]

Hydrogels

Many of the polymers mentioned within this work exist as hydrogels. In essence, a hydrogel is a polymer that would normally be soluble in water but has been cross-linked to form a polymer network. The cross-linking process renders the polymers insoluble but does not remove their affinity for water. Therefore, the network can adsorb water with consequent swelling of the polymer. The nature of the polymer and the degree of cross-linking affect the swelling behavior; highly hydrophilic polymers containing few cross-links will tend to adsorb large amounts of water with a high degree of swelling. Less hydrophilic monomers, incorporation of hydrophobic comonomers, or a high degree of cross-linking, all act to reduce water adsorption, usually leading to a more rigid and firmer gel. Hydrogels often show high biocompatibility, usually because they have a high water content, within either a bioinert or a biodegradable polymer network.

Synthetic Hydrophilic Polymers

The structures of a number of synthetic hydrophilic polymers as a representative range of those commonly used are shown in Fig. 1. Many common hydrophilic polymers are based on methacrylate or acrylate backbones. One of the most common is polyacrylic acid, which forms the basis of many hydrogel materials (Fig. 1A). Although simple polyacrylic acid is water soluble, it can be easily cross-linked to form an insoluble network polymer that still, however, retains high affinity for water and is capable of adsorbing large amounts of water to form hydrogels; these are discussed later. Polymethacrylic acid-based polymers are similar in nature (Fig. 1B). One of the most commonly used polymers for contact lenses, polyhydroxyethyl methacrylate, is based on a similar backbone (Fig. 1C).

Polyvinyl alcohol is another widely used material, often as a surface coating because of its high biocompatibility (Fig. 1D). Usually, it can be obtained by the hydrolysis of polyvinyl acetate, with varying amounts

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120023855

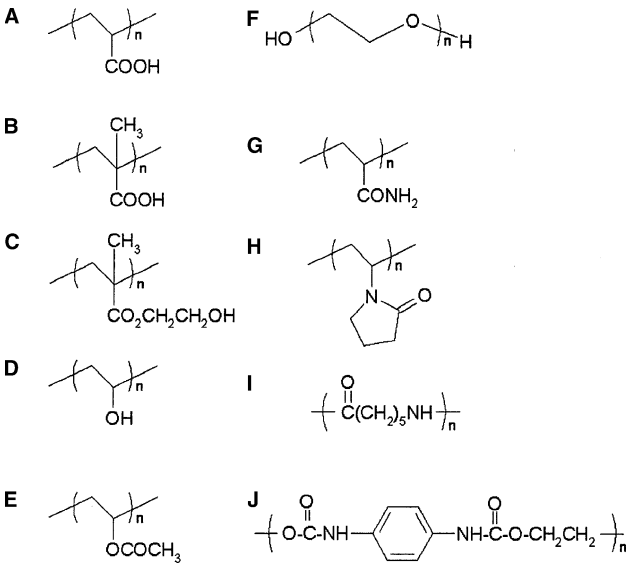

Fig. 1 Structures of some common synthetic hydrophilic polymers: (A) polyacrylic acid, (B) polymethacrylic acid, (C) polyhydroxyethyl methacrylate, (D) polyvinyl alcohol, (E) polyvinyl acetate, (F) PEG/PEO, (G) polyacrylamide, (H) polyvinylpyrrolidinone, (I) Nylon 6, and (J) a simple polyurethane.

of hydrolysis (Fig. 1E). Direct synthesis from the monomer is not possible because vinyl alcohol does not exist but tautomerizes to acetaldehyde. The solubility and physical properties of this polymer are highly dependent on its molecular weight and degree of hydrolysis. Cross-linking of the polymer leads to a variety of hydrogels.

Polyethylene glycol (PEG) and the very similar polyethylene oxide (PEO) are used as biocompatible coating agents and hydrogel forming materials, often as block or graft copolymers with other materials (Fig. 1F). They are often bound to polyurethanes to form hydrophilic foams such as Biopol® (Metabolix Inc.).

Polyacrylamides are also suitable for a variety of biomedical uses; the structure of polyacrylamide is shown in Fig. 1G, although the use of acrylamides in copolymers is much more common. Polyvinylpyrrolidinone has also found use as a biocompatible coating material (Fig. 1H). Polyacrylonitrile, though not suitable in itself, can be hydrolyzed to form some hydrophilic polymers such as the Hypan® (Hymedix Inc.) series of hydrogels.

Condensation polymers have been used although they are often not sufficiently hydrophilic enough to be considered within this entry. Typical polymers such as Nylon 6 and a typical polyurethane are shown (Figs. 1I and 1J). Some of these have been incorporated into composites with more hydrophilic materials; Biopol, for example, is formed from a copolymer of a polyurethane and PEG.

Natural Hydrophilic Polymers

Besides the synthetic materials, there are a variety of hydrophilic polymers obtained from natural sources. Some examples include collagen, alginate, and carrageen, all of which are obtained from natural sources.[1] Collagen is widely used in implants and many other possible uses and applications have been studied for this material.

A series of materials have been made by derivatizing cellulose (Fig. 2a). This naturally occurring polysaccharide contains reactive hydroxyl groups, which can be easily substituted, normally to form ethers. Typical materials include sodium carboxymethylcellulose, hydroxyethyl, and hydroxypropyl cellulose (Figs. 2b–2d). The properties of these polymers depend greatly on the molecular weight and degree of substitution; they have found uses both as gels and as coatings.

Hydrophilic Polymers: Use as Contact Lens Materials

The use of contact lenses, initially made from glass, to correct vision has been known since the 19th century. The first polymeric contact lens was a ''hard'' contact lens made in 1936 from polymethylmethacrylate (PMMA).[4] However, these lenses had to be taken out at night to prevent eye irritation and much research has been directed to making those that could be worn for much longer periods of time. This led to the development of the so-called ''soft'' lenses.

To be suitable for long-term wear, a contact lens material has to satisfy several criteria. It must be hydrophilic enough to maintain a stable, continuous tear film on its surface, resist fouling by tear components, not irritate the eye, and be comfortable to wear. It should also be realized that the metabolism of the cornea is highly dependent on dissolution and adsorption of atmospheric oxygen and therefore any lens material must have sufficient oxygen permeability to maintain this, else corneal anoxia will set in.

Hydrogels were the first polymers to be used for this application because of their favorable physical properties and compatibility with the ocular environment.

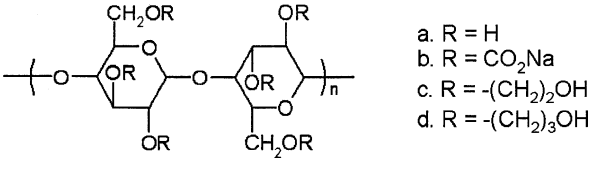

Fig. 2 Structures of some common cellulose-based hydrophilic polymers: (a) cellulose, (b) sodium carboxymethyl cellulose, (c) hydroxyethyl cellulose, and (d) hydroxypropyl cellulose.

The first commercial product, Polymacon® (Bausch & Lomb), was based on polyhydroxyethyl methacrylate (Fig. 1C).[5] The materials did suffer somewhat as they did not offer sufficient oxygen mass transport across the lens for prolonged use; hence, much further work has been devoted to developing materials with higher oxygen permeability. Organosilicon-based polymers such as polydimethylsiloxane have high oxygen permeability; however, most of these are very hydrophobic (Fig. 3A). They have, therefore, been incorporated into lenses along with hydrophilic materials in an attempt to make a material with the required properties. Early studies utilized copolymers containing dimethylsiloxane groups along with hydrophilic monomers such as hydroxyethyl methacrylate or *n*-vinyl pyrrolidinone.[6] Fluoroethers also have high oxygen permeability and a copolymer of a perfluoroether with methyl methacrylate was briefly marketed under the name Fluorofocon A® (3M); however, the relatively high cost of the fluorocarbon monomers eventually led to their withdrawal from the market (Fig. 3B).[7]

Most soft contact lenses commercially available are based on polyhydroxyethyl methacrylate; however, there are a few materials available, such as Lotrafilcon A® (Ciba Vision) and Balafilcon A® (Bausch & Lomb), based on siloxane or fluorosiloxane copolymers, that offer good oxygen permeability and so allow up to 30 days' continuous wear for contact lenses.[4] A survey of the patent literature shows that much interest is still being shown in the field of siloxane-based hydrogels in general and also in improving manufacturing processes for contact lenses formed from such hydrogels.

Besides external contact lenses, there are surgically implanted intraocular contact lenses that are usually used to replace the eye's natural lens after cataract surgery; these lenses are normally based on silicone or PMMA and lie outside the scope of this entry.

Implantable Membranes

Postsurgical adhesions are a common problem following major abdominal, gynaecological, and other forms of surgery. Adhesions are scars that form abnormal connections between tissue surfaces. Postsurgical adhesion formation is a natural consequence of surgery, resulting when tissue repairs itself following incision, cauterization, suturing, or other forms of trauma. This can lead to complications such as bowel obstruction and infertility. Implantable materials are in this case sometimes placed directly between tissue surfaces, for instance, between organs and the abdominal wall, to prevent adhesion formation.

A suitable membrane must be sterile, noninflammatory, and nontoxic, and because these cannot be removed from the body without further surgery, they are often also designed so as to be bioresorbable. A variety of polymers have been studied for this purpose. Typical materials available commercially include Seprafilm® (Genzyme Corp), which is based on a sodium hyaluronate/carboxymethyl cellulose composite, and Oxiplex® (Fziomed Inc.), which is based on a PEO/carboxymethyl cellulose composite.[8] Products designed for similar use but marketed in gel form include Oxiplex-SP®, Spraygel® (Confluent Surgical Inc.), and Resolve® (Life Medical Sciences Inc.). These can be applied directly to the site, rapidly form a solid hydrogel film to prevent adhesions, and are designed to be reabsorbed by the body after approximately 1 week.[9]

Sutures and Implants

Sutures are used to close wounds or incisions made during operations. If the material used for the suturing is bioresorbable, then this eliminates the need for removal of any stitches. Polymers such as polyglycolide [first marketed as Dexon® (Bayer Corp) in the 1960s] and polylactide are commonly used for this purpose, although a wider range of polymers are now available and have been recently reviewed elsewhere (Figs. 4A and 4B).[10]

Besides sutures, other medical devices such as orthopedic fixation devices are of interest because the use of biodegradable polymers means that not only does the device not require removal (a process that can cause refracture of the bone), but because if it degrades it will also slowly transfer stress over time to the damaged area, allowing healing of the tissues. At the time of writing, bioresorbable polymers that offer the necessary strength for use as bone plates for long bones are yet to be developed, although they have

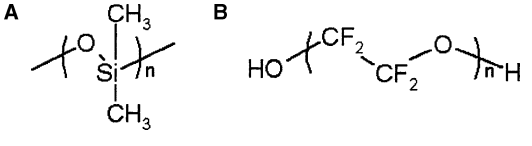

Fig. 3 Structures of some polymers used in contact lens formulations: (A) a typical polysiloxane and (B) a typical polyperfluoroether.

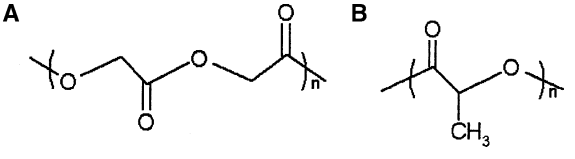

Fig. 4 Structures of some bioresorbable polymers: (A) polyglycolide acid and (B) polylactide.

found use in the manufacture of rods and pins for fracture fixation.[10]

Natural polymers have also been studied for cosmetic implants such as collagen. Bovine collagen implants have become increasingly popular for use in dermal augmentation of the skin since their introduction in the 1980s. They can be used either to remove unwanted wrinkles or to augment features such as collagen lip injections, which are gaining in popularity.

Burn and Wound Dressings

Many burn dressings are based on keeping a burn site moist while protecting it from the environment as well as helping in pain relief. Because hydrogels contain such a high water content, they have been investigated for use as burn and other wound dressings.[11] They have many desirable properties; for example, imposing the soft, moist texture can alleviate some pain; they also adhere to the wound but not so tightly that they cannot be easily detached from the wound for replacement; and finally, they are also transparent, allowing visual inspection of the healing process. Also, hydrogels prevent dehydration of the wound, have good oxygen permeability, and yet provide a barrier against bacteria. Finally, they can be easily manufactured with coadsorbed drugs for aiding in pain control, promotion of healing, and/or administration of antibiotics.

Materials are based on cross-linked hydrophilic polymers and are manufactured under a variety of trade names such as Spyroflex® (AGS Labs Inc.), Burnfree® (Burnfree Products), and Burnshield® (Levtrade International Ltd). Usually, they contain the hydrogel attached to an impermeable backing sheet and are currently available in up to blanket sizes. Typical polymers used include polyvinyl alcohol, PEG, and polyvinyl pyrrolidinone together with combinations of these materials. Irradiation is often used both to cross-link and to sterilize the hydrogel after it has been formed into the dressing. Collagen hydrogels are also being researched for their ability to allow cell migration and inhibit wound contraction because of their high tensile strength and low extensibility.[12]

Coatings

One major problem with inserting any type of biomedical device into the body that comes into contact with blood or other body fluids is that of biofouling. Both proteins and cells can adhere strongly to many foreign surfaces. In the case of devices such as contact lenses, for example, lipids and tear proteins can adsorb onto the surface of the lens. This can cause clouding of the lens, rendering it unsuitable for use, or lead to irritation. The irreversible adsorption of proteins and cells on synthetic surfaces has adverse effects on a variety of devices. Adverse biological reactions include fibrous encapsulation and blocking of small artificial blood vessels. Other devices, such as heart valves, can give rise to the formation of thromboses. This can cause either arterial blocking or the clot can detach from the surface, leading to the possibility of a stroke or heart attack. The application of hydrophilic polymer coatings has been widely studied to help render many surfaces biocompatible to minimize such risks.

Although a wide variety of polymeric materials have been utilized in the attempted prevention of biofouling as described in the extensive review by Kingschott and Grieser, by far the most popular materials have been ones based on PEG/PEO.[13]

The theoretical considerations of the causes of biofouling and why a PEG/PEO surface should resist the process so well is a topic for a complete review article in itself; however, it is widely reported that the lowest adsorption of proteins occurs for these materials.[13] One factor is thought to be the fact that the PEG/PEO chains are usually highly solvated, meaning that incoming protein molecules experience a surface that is largely composed of water. This surface mimics the typical conditions found within biological systems.

Several different approaches have been used to attach PEG/PEO coatings to a variety of surfaces. Among the simplest is the physical adsorption of Pluronic surfactants, which consist of PEO–polypropylene oxide (PPO)–PEO block terpolymers (Fig. 4A).[14] The more hydrophobic PPO section of the chain is absorbed onto the substrate being treated with the more hydrophilic PEO blocks stretching out into the aqueous phase. These materials display a variety of biocompatibilities depending on the makeup of the surfactant. Interestingly, increasing the length of the PPO section appeared to have a larger repulsive effect than doing so of the PEO section. This indicates that perhaps only short PEO chains are necessary for effective protein repulsion and the beneficial effect of increasing the PPO section is because of better anchoring of the surfactant and prevention of displacement by protein molecules.[14]

Other methods of attachment have been studied. Alkyl thiols are known to form well-packed chemically bound monolayers on noble metal surfaces and so this method has also been used to attach PEG chains to surfaces. A variety of thiol-substituted PEG oligomers were synthesized and spontaneously assembled onto gold and silver surfaces (Fig. 5B).[15] Quite short PEG chains were found to be sufficient to induce biocompatibility. It was found that the packing arrangement of the PEG derivatives was important in determining the surface properties with the resultant biocompatibility not simply being a direct function of packing density. Thiols pack more tightly on silver

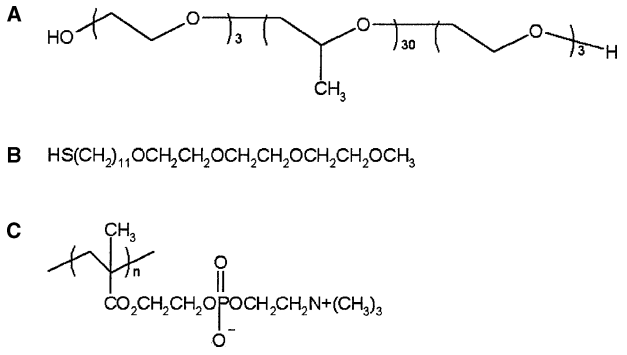

Fig. 5 Structures of some common synthetic polymers used in coatings: (A) a typical Pluronic surfactant, (B) a thiol-substituted PEG derivative, (C) a polymer containing a phospholipid head group analog.

than on gold; yet some treated silver surfaces showed higher levels of fibrinogen adsorption than the corresponding treated gold surface. This was attributed to the PEG chains being in different conformations and showed that simply increasing the surface packing density does not necessarily increase repulsion.

Plasma deposition has also been utilized to deposit PEO-like materials from volatile precursors onto a variety of subjects.[13] This technique involves generating a reactive plasma containing PEO-like monomers, which polymerize and deposit, often with chemical grafting, onto any surface within the plasma.[16] The availability of large-scale vacuum apparatus makes this technique feasible on an industrial scale. The materials deposited by this technique were often shown to contain only short PEO segments; yet greatly reduced protein deposition was observed and the small amounts (ng/cm) that did deposit were easily eluted.[16]

Other materials have also been studied for their ability to reduce protein adsorption onto surfaces. Because many cell membranes are based on phospholipids, polymers containing phospholipid-type head groups have been utilized for this purpose. Poly(2-methacroylethyl phosphoryl choline) could be plasma deposited onto silicone rubber and the adhesion of albumin reduced by factors of up to 80 (Fig. 5C).[17]

Polysaccharides have also been studied for this purpose, although generally they are not as effective as PEG/PEO systems.[13] Polymers based on dextran substituted with thiol groups could be adsorbed on gold surfaces and have been shown to significantly repel protein deposition, with the degree of repulsion being dependent on both the polymer molecular weight and the amount of thiol substitution.[18]

An additional benefit of coating samples with hydrophilic polymers is their ability to act as a lubricant. Lubrication of a device surface improves device insertion and manipulation; however, traditional treatments that include coatings with low-friction materials such as PTFE or silicone fluid, while improving slip in the body, are difficult for the physician to handle. Incorporation of hydrophilic polymers leads to the adsorption of water molecules in the presence of water or body fluids. This creates a sheath of water at the surface of the device. This watery interface causes the decrease in wet friction, achieving lower friction when wet, while still being easy to handle when dry.

Biosensors

Biosensors are devices that use the unique recognition qualities of biological molecules to selectively detect the presence of desired analytes within complex mixtures such as blood and serum. They generically offer simplified reagent less analyses for a range of biomedical and industrial applications, and for this reason the field has continued to develop into an ever-expanding and multidisciplinary one during the last couple of decades. The world market for biosensors is approximately $5 billion, and at the time of writing, approximately 85% of the world commercial market for biosensors is for blood glucose monitoring.[19] Biosensors can be used as in vivo devices, as in the simple glucose test where a drop of blood is extracted and tested; however, much research is now taking place on implantable, in vivo continuous reading biosensors.[19]

Sensors containing biomolecules such as glucose oxidase suffer from problems such as stability because the enzyme can denature upon storage or use. Also, the testing of complex mixtures infers the danger of unspecific adsorption of interferents or simple blocking of the sensor by protein or cell deposition. Hydrophilic polymers have been utilized in an attempt to solve some of these problems. The use of hydrophilic polymer membranes within biosensors has been recently reviewed.[20] The highly hydrated environment of a swollen hydrogel is a simple analog of conditions found within the biological environment. In this context, the trapping of active ingredients in a hydrogel has been utilized to improve the stability of the biomolecule.[20] Also, a thin hydrophilic polymer coating, such as PEO, can minimize biofouling while also helping to exclude common interferents such as ascorbate ions.[20]

Drug Delivery

The pharmaceutical industry has shown great interest in the development of controlled release systems based on hydrophilic polymers. Many drugs are most efficient when released into the body at a constant rate, rather than in individual doses. For example, a drug could be incorporated into a hydrogel either as it is synthesized or postsynthesis. This can then be ingested

by, implanted within, or be simply placed in contact with the patient, e.g., upon the skin. Once in vivo, the drug is released into the environment by diffusion or by the polymer being eroded or dissolved in some way, for example, by digestion. Ideally, this process will occur at a constant rate, thereby continually releasing controlled amounts of the drug. If the polymer is surgically implanted close to an affected site, it means the drug is delivered where it is most needed.

For a polymer to be suitable for this purpose, it must display several properties. First, it must be biocompatible and must biodegrade within a reasonable period of time. Both the polymer itself and its degradation products must be nontoxic and must create neither an allergic nor an inflammatory response. The nature of the drug itself can also affect the method of release; low molecular weight drugs are capable of diffusing out of the polymeric matrix, and if water soluble will be rapidly released. Larger molecules such as proteins tend to be trapped within the matrix until the polymer itself degrades and releases them. The rates of release are dependent on several variables, including the quantity/dosing of drugs within the composite, the rate of degradation of the polymer, the amount of water present (if it is a hydrogel type polymer), and the presence and degree of cross-linking. The application of a wide variety of hydrophilic biodegradable polymers to delivery of proteins has been extensively reviewed.[21] Typical polymers include hydrogels based on polyvinyl alcohol, polyvinylpyrrolidinone, or cellulose, and natural polymers such as alginase or collagen. Besides enabling the controlled release of the active material, the polymer can also be exploited as a stabilizing medium for what are often unstable biological agents.

The polymer-based delivery device can be used to apply the active agent in many ways, including ingestion, suppositories, skin patches, ocular and subcutaneous methods. The treatment of cancer is a field in which these methods are being widely researched, for example, ara-C, a treatment for acute leukemia has the least side effects when introduced subcutaneously. As an alternative to continuous infusion, the drug can be incorporated into cross-linked polyhydroxyethyl acrylate disks, which displayed steady controllable drug release.[22] A polycaprolactone/PEG composite was similarly used as a matrix for the anticonvulsant drug clonazepam and displayed long-term (>45 days) constant release properties.[23] Nitroglycerin is a problematic drug owing to its loss of tablet activity, often by volatilization of the active component.[24] This can be avoided by incorporation of the nitroglycerin into an acrylic-based hydrogel, which is then incorporated into a transdermal patch, as exemplified by products such as Deponit® (Schwarz Pharma), Minitran® (3M Pharma), and Nitrodisc® (G.D. Searle Company).

These products are usually based on simple polymeric systems; however, more complex architectures are known. Insulin can be contained within a ''smart'' porous membrane containing glucose oxidase encapsulated within a polymethacrylic acid/PEG copolymer. High levels of glucose interact with the glucose oxidase, causing a pH drop and shrinkage of the membrane, which leads to the release of insulin.[25]

Apart from drug delivery, recent work has focused on the use of hydrophilic polymers in gene therapy and has shown that encapsulation of the DNA inside a hydrophilic polymer can increase the transfection efficiency.[3]

Artificial Organs

In the human body, the kidneys remove toxic wastes such as urea from the blood for excretion via the bladder. When they fail to perform this function, it leads to the condition known as uremia, which if not addressed will ultimately lead to death. To prevent this, hemodialysis must be performed, usually by a kidney dialysis machine, which can be thought of as an artificial organ external to the body. A semipermeable membrane based on the hydrophilic polymer cellulose is an integral part of this process. Hemodialysis uses a cellulose membrane tube that is immersed in a large volume of fluid. Blood is first removed from the patient, pumped through this tubing, and then back into the patient intravenously. Cellulose membranes contain pores that allow passage of most solutes in the blood while retaining the proteins and cells.

As blood passes through the membrane, free exchange of the solutes occurs between blood and the external isotonic solution—a salt solution with ionic concentrations near or slightly lower than the desired concentrations in the blood. This means that the two solutions are in dynamic equilibrium, and so the concentration of these species within the blood does not change. Compounds such as urea that are present in the blood in excess pass, however, into the external solution and are thereby removed from the bloodstream.

Hydrophilic polymers are used as major components of artificial internal organs. The physical properties of these materials and, in particular, their high water content, soft texture, and consistency, give them a strong resemblance to actual living soft tissues. A possible application, for example, in the case of organ failure, would be to incorporate living cells from a donor into these hydrogels and then implant them in the patient. The high biocompatibility of the hydrogel would prevent rejection and help to keep the implanted cells viable. For example, hepatocytes could be encased inside highly permeable hydrogel (83% water) tubes

with a survival rate in vivo of 85% after 45 days.[26] The tubes maintained viability, prevented rejection, and allowed the passage of albumin from the encapsulated cells. A similar principle using membranes of calcium alginate hydrogel was used to encapsulate hepatocytes. Experiments showed that these units had the ability to replace liver function.[27]

Polymer-based heart valves are widely used as replacements for diseased or damaged human heart valves. Most mechanical heart valves are made from metals, silicone, or polyesters, although some work has gone into incorporating biocompatible coatings such as PEO into these systems.

Tissue Engineering

Biocompatible hydrophilic polymers, both natural and synthetic, can be used to promote tissue repair and regeneration. For example, gelatin scaffolds can be constructed by glutaraldehyde cross-linking, followed by freeze drying of the solution to give a porous matrix. This material can be specifically shaped to provide a support for tissue growth and organization over long periods.[28]

Coronary artery bypass grafting is commonly used to relieve conditions such as angina. Usually, the graft is taken from the patients themselves—a section of vein from the patient's leg being the most common. However, should there be a shortage of supply of this native material, the use of an artificial analog becomes necessary. Synthetic materials have been developed based on Dacron® (Dupont) or PTFE, although these are satisfactory only when used in large arteries; in smaller vessels they tend to cause thrombosis.[29] Current research includes the use of hydrophilic polymers as scaffold materials for the growth of cells with anticoagulatory properties, as recently reviewed elsewhere.[29,30] Both natural polymers such as collagen and synthetics such as biodegradable polyesters have been used.[29,30] The advantages of the polyesters are that not only are they stronger than many of the natural materials, but that over a period of time they are also reabsorbed by the body to be replaced with endogenous endothelial cells.[30]

CONCLUSIONS

The primary focus of this entry has been to provide a basic understanding of the field of hydrophilic polymers and their uses. These materials have a range of applications both in the bulk and as thin films. For example, hydrogel membranes are used as inhibitors of postsurgical adhesion formation and also as coatings. Dispensing these polymers onto the surface of medical devices can confer desirable surface properties that the substrate material lacks. Hydrogel coatings especially can result in vast improvements in biocompatibility or reduction in surface friction. In the bulk, their predictable and controllable diffusivity can lead to their use as drug delivery agents. Both natural and synthetic polymers have been utilized for these purposes.

The present polymer technology has resulted in improvements in several different medical fields, including drug therapy and surgical procedure. It is always difficult to predict future developments, but it appears likely that hydrophilic polymers will help further the development of more viable localized drug delivery, implantable sensors, and artificial organ substitutes than currently exist. Much research is being carried out worldwide in these fields, making this both an interesting and a fast moving field.

Hydrotreating Catalysts and Processes: Current Status and Path Forward

Arunabha Kundu
Nishith Dwivedi
Azad Singh

Department of Chemical Engineering, Indian Institute of Technology, New Delhi, India

INTRODUCTION

The reaction of any petroleum fraction with hydrogen in the presence of a catalyst is commonly known as hydroprocessing. Depending on the purpose it serves, a hydroprocessing process can be broadly classified as hydrotreating, hydrorefining, and hydrocracking. Hydrotreating (HDT) processes remove the undesirable impurities such as sulfur, nitrogen, unsaturated molecules, and metals. It is a refining process for treating petroleum fractions from atmospheric or vacuum distillation units (e.g., naphthas, middle distillates, reformer feeds, residual fuel oil, and heavy gas oil) and other petroleum fractions (e.g., catalytic cracked naphtha, coker naphtha, gas oil, etc.) in the presence of catalysts and substantial quantities of hydrogen. Hydrotreating includes desulfurization, removal of substances (e.g., nitrogen compounds) that deactivate catalysts, conversion of olefins to paraffins to reduce gum formation in gasoline, and other processes to upgrade the quality of the fractions. Hydrorefining is a refining process similar to HDT that uses higher temperatures and pressures than HDT. The purpose of hydrorefining is to treat heavier molecular weight petroleum fractions. The fragmentation of heavy molecules into desirable ones is carried out during hydrocracking. All these processes have been widely used by petroleum refiners in the past and will also find continuous growth. The increasing importance of hydroprocessing has spurred research interest to develop more efficient catalysts and processes for commercial applications.

Hydrotreating reactions are generally carried out at high pressure (100–3000 psig) and temperature (270–350 °C) in trickle-bed reactors (TBRs) in which the liquid hydrocarbons and gaseous hydrogen are passed in a cocurrent downward flow through a fixed bed of solid catalysts. The following reactions take place during HDT:

- Hydrodesulfurization (HDS) (i.e., the conversion of organo-sulfur compounds to H_2S and similar molecular weight organic compounds).
- Hydrodenitrogenation (HDN) (i.e., the conversion of organo-nitrogen compounds to NH_3 and similar molecular weight organic compounds).
- Hydrodemetallization (HDM) (i.e., the precipitation of metal on catalyst in sulfide form).
- Hydrodeoxygenation (HDO) (i.e., the removal of –OH from molecule).
- Hydrogenation (HYD) (i.e., the hydrogenation of olefins to aliphatic compounds).

Environmental concerns are forcing drastic changes in motor fuel specifications. It is clear today that motor fuel quality will continue to be modified to improve both combustion quality and postcombustion gas clean-up performance. Regulations are becoming increasingly more stringent to minimize air pollution. For instance, 500 ppm S has been a common world specification; the Swedish Class 1 limit is 10 ppm S; in the United States, most refiners are designing for 5–8 ppm of the hydrotreaters; present EC regulations for the sulfur content of diesel fuels is 350 ppm and is expected to be below 50 ppm in 2005 and 10 ppm around 2008. In India, the sulfur specification will be 500 ppm by 2005 and 350 ppm by 2010 throughout the country. To eliminate sulfur compounds in fuels to get the very low value required by the new regulations, several proposals can be made. For example, to reduce the concentration from 500 to 10 ppm of sulfur in gas oil, it is necessary to do one or more of the following:

- To enhance the activity of the present catalysts considerably, by a factor of 4–5, which would correspond to very high conversion (higher than 99.9% for many gas oils).
- To increase the process severity, especially to increase the hydrogen pressure (from 1.5 to 2 times).
- By a better knowledge of the reactions in the process conditions, to find new catalyst combinations and synergism with noncatalytic processes by a better knowledge of the reactions involved in the process.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120008052

In the second point, it means that refiners are faced, at a minimum, with revamps of their existing hydrotreaters, and possibly even reconfiguration of refineries. In some cases, especially where cracked stock feeds must be processed for on-road diesel, new grassroots, high-pressure hydrotreaters are being contemplated. These new units will be very expensive, with capital costs of the order of $1600–$2400 per barrel of the installed capacity, and they will be stretched near their technical limits to achieve ultralow sulfur levels. Hydrotreating process represents some of the most important catalytic processes and the annual sales of HDT catalysts represent close to 10% of the total world market for catalysts.[1] Cobalt–molybdenum and nickel–molybdenum are the most commonly used catalysts for this process. Both types of catalyst remove sulfur, nitrogen, and other contaminants from petroleumfeed. Cobalt–molybdenum catalysts, however, are selective for sulfur removal, while nickel–molybdenum catalysts are selective for nitrogen removal. CoMo catalysts showed a much better sulfur tolerance than NiMo catalysts in the HDS of dibenzothiophene.

HYDROTREATING REACTIONS

Hydrodesulfurization

Sulfur compounds are one of the most important heteroatoms or impurities present in petroleum crudes in varying amounts. Some crudes contain as low as 0.05 wt%, while some sour crudes have as high as 5 wt% sulfur. In addition to these organic sulfur compounds, some hydrogen sulfide can also be found. The distribution of sulfur compounds with respect to boiling range also changes from crude to crude, but generally the content of sulfur (in wt%) increases with the boiling range.

The types of sulfur compounds present in the petroleum fraction also change with the boiling range. Organic sulfides, disulfides, mercaptans, and thiophenes are found in the lighter boiling fractions. Different derivatives of thiophenes, e.g., benzothiophenes, dibenzothiophenes, are predominant in the heavier fractions.

Chemistry and Kinetics of Desulfurization

Hydrodesulfurization reactions occur when hydrogen reacts with the sulfur atom and forms hydrogen sulfide. The rate of the reaction depends on the type of sulfur compounds present, namely, aliphatic and aromatic thiols, sulfides, disulfides, various thiophenes and thiophene derivatives. The order of reactivity among these compounds decreases in the following order:

$$\text{RSH (thiols)} > \text{R–S–S–R}^1\text{(disulfides)} > \text{R–S–R}^1\text{(sulfides)} > \text{thiophenes}$$

Aliphatic and aromatic thiols have high reactivity and the sulfur atom can be removed easily. Aliphatic thiols may react through elimination and HYD:

$$\text{R–CH}_2\text{–CH}_2\text{–SH} \rightarrow \text{R–CH=CH}_2 \rightarrow \text{R–CH}_2\text{–CH}_3$$

or through hydrogenolysis, if a β-H atom is present

$$\text{R–CH}_2\text{–CH}_2\text{–SH} + \text{H}_2 \rightarrow \text{R–CH}_2\text{–CH}_3 + \text{H}_2\text{S}$$

The elimination takes place via acid–base catalysis and can be catalyzed by metal sulfide. Hydrogenation and hydrogenolysis take place on metal sulfide surface.

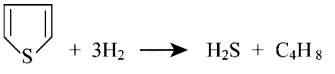
Sulfides and disulfides also react similarly to form hydrogen sulfide and hydrocarbons:

$$\text{RSSR}^1 + 3\text{H}_2 \rightarrow \text{RH} + \text{R}^1\text{H} + 2\text{H}_2\text{S}$$
$$\text{RSR}^1 + 2\text{H}_2 \rightarrow \text{RH} + \text{R}^1\text{H} + \text{H}_2\text{S}$$

Thiophene derivatives are slower to react and their reactivity decreases in the following order:

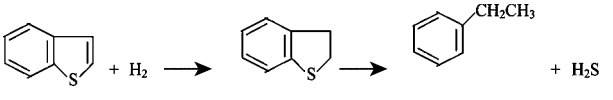
Thiophenes > benzothiophenes
> dibenzothiophenes
> alkyl substituted dibenzothiophenes.

Among the different isomers of alkyl substituted dibenzothiophenes, reactivity varies with the location of alkyl groups. The thiophenes react with hydrogen to form mixed isomers of C_4H_8 and H_2S.



The thiophene ring is not saturated prior to removal of sulfur atom. The first step may be involved with the simultaneous removal of a sulfur atom and the saturation of the hydrocarbon. Studies show that HDS and subsequent HYD reactions occur on separate sites.[2] In case of benzothiophene, however, the thiophene ring is hydrogenated to thiophene before sulfur atom is removed and this is in contrast with thiophene desulfurization.

The primary product from the desulfurization of dibenzothiophene is biphenyl with some amount of phenyl cyclohexane.



The actual mechanisms for all the above reactions are much more complex and involve a series of steps. The low reactivity of dibenzothiophenes is explained by their steric hindrance. When the sulfur atom is covered by two benzene rings on both sides, the benzene rings hinder the adsorption of the sulfur atom onto the catalyst surface. Transformation rates for the conversion of substituted dibenzothiophenes on a $NiMo/Al_2O_3$ catalyst are given in Table 1.[3]

Hydrodenitrogenation

In petroleum fractions, nitrogen is present as organonitrogen compounds. They are present in smaller concentrations than sulfur compounds. The ratio of nitrogen to sulfur varies from 1 : 2 to 1 : 10 depending on the origin of the crude. Normally, the nitrogen content in crude varies from 0.1 to 2 wt%. Nitrogen compounds found in petroleum are principally of the following two types:

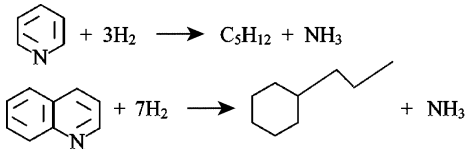
1. Basic nitrogen
2. Nonbasic nitrogen

The basic nitrogen compounds, which are mainly pyridine homologous, occur throughout the boiling ranges, but tend to concentrate in the higher boiling fractions. The nonbasic nitrogen compounds are usually of pyrole, indole, and carbazole types, and also occur in the heavier fractions.

Nitrogen compounds poison catalysts used in secondary processing. Basic nitrogen is a major source of coke formation in catalytic cracking and neutralizes the acid sites in the catalyst. They are also a source of instability in fuels and a source of NO_x emission on burning of heavy fuels. The only industrial method for removing nitrogen from petroleum fractions is HDN.

Chemistry of HDN

Nitrogen compounds are less reactive than sulfur compounds. These compounds are largely present in the form of heterocyclic compounds having five-membered pyrolic rings or six-membered pyridinic rings. The nonheterocyclic compounds, which include aniline, nitriles, and aliphatic amines are easily convertible and therefore are of little concern in industrial HDN. The reactions with pyridine and quinoline during HDN are given below:



In general, the hydrocyclic rings must first be saturated before ring breakup occurs at a C–N bond unlike HDS, which may not require complete HYD. Nitrogen is removed from the resulting amine or aniline as ammonia. Aliphatic amines react readily, but aromatic amines are more refractory. Hydrogenation of the aromatic ring is a prerequisite for the removal of nitrogen atom not only from pyridine, but also from aniline. Because of this, much higher H_2 pressures are required to obtain substantial conversions in HDN than in HDS.

Under the high pressure typical of industrial processes, HDN reactions are not limited by equilibrium. The reaction order for HDN of naphtha, kerosene, gas oil, and vacuum gas oil (VGO) streams is taken as 1 and activation energies are 10, 15, 23, and 25 kcal/mol, respectively.[2]

Hydrodemetallization

The occurrence of metallic constituent in crude oil is of great importance to the petroleum industry even though they are present in small amounts. Even very minute amounts of iron, copper, and particularly nickel and vanadium in the feedstock to the catalytic secondary processing units can affect the activity of the catalyst. These metals are present in the form of high molecular weight organometallic compounds. The concentration of nickel and vanadium can vary from 6 and 33 ppm, respectively, in light Arabian crude to 114 and 387 ppm, respectively, in Venezulean crude. A portion of the metal atom is surrounded by four pyrole-type rings. The nonporphyrinic structures comprise a wide variety of organo-metallic compounds. The principal method

Table 1 Transformation rates for the conversion of substituted dibenzo-thiophenes on a $NiMo/Al_2O_3$ catalyst

	Molecule			
	4,6-DMDBT[a]	**4,6-DEDBT**[b]	**4,6-DiBuDBT**[c]	**4,6-DiPrDBT**[d]
Transformation rate (relative to 4,6-DMDBT)	100	75	40	1.5

[a]4,6-Dimethyldibenzothiophene.
[b]4,6-Diethyldibenzothiophene.
[c]4,6-Dibutyldibenzothiophene.
[d]4,6-Dipropyldibenzothiophene.

of removing these metals is HDT in the presence of catalysts at elevated hydrogen pressure.

Chemistry of HDM

$$\text{M–P} + \text{H}_2 \leftrightarrow \text{M–PH}_2 \text{ reversible HYD}$$
$$\text{M–PH}_2 \rightarrow \text{breakup and deposition}$$
$$\text{irreversible hydrogenolysis}$$

Metal removal rates have generally been interpreted using a single kinetic rate expression of the form:

$$\text{Rate} = kP_{\text{H}_2}{}^m C^n$$

where C = concentration of organometallic compound, $m = 1$, and $n = 1$–2.

Unlike the other HDT reactions, in HDM reactions, metal sulfides are deposited on the catalyst causing permanent fouling leading to replacement of catalysts once their activity is exhausted. Consequently, the catalyst should be designed in such a way that a uniform deposit of metals is obtained throughout the catalyst and the catalyst has high metal retention capacity. Hydrodemetallization catalyst should also have large pore volume with macropores so that large reactant molecules can diffuse in and out of the pores. Ni–Mo catalysts are normally used for their high HYD activity. However, natural materials, e.g., manganese and bauxites have also been considered for HDM catalysts, especially as sacrificed catalyst to absorb metal deposition.

Hydrodeoxygenation

Hydrodeoxygenation involves the removal of oxygen from various oxygen containing compounds in petroleum feedstocks. The oxygen content in petroleum crudes is very low, typically of the order of less than 0.1 wt%. Carboxylic acids and to a lesser extent phenols are found in low- and medium-boiling fractions. However, fuels derived from tar sands, shale oils, and coal have a substantial amount of oxygen compounds. These may include ethers, furan, carboxylic acids, and phenols.

Hydrogenation

Hydrogenation processes are employed to remove unwanted olefins, diolefins, and polycyclic aromatics from various refinery streams. Hydrogenation of olefins takes place at atmospheric pressure, with the reactivity generally decreasing with increasing chain length and substituent groups adjacent to the double bond. Hydrogenation of aromatics requires high pressures of hydrogen for saturation of the double bond. This is partially due to low reactivity of resonance stabilized aromatic structures and partly to equilibrium constraints of pressures and temperatures employed. The relative activities of sulfided $NiMo/Al_2O_3$ for HYD of one ring of various multiring aromatic model compounds are found to be of the following order:[2]

$$\text{Benzene} < \text{phenanthrene} < \text{napthalene} < \text{anthracene}$$

CATALYSTS USED IN THE HYDROTREATING PROCESS AND ITS RECENT DEVELOPMENT

Composition of Catalysts

Supported metal sulfide constitutes the most important catalyst in the HDT process. Industrial HDT catalysts are composed of a molybdenum sulfide (or tungsten sulfide) phase promoted by cobalt or nickel and usually supported on alumina. This combination has the pivotal property in hydroprocessing to convert organosulfur compounds to clean hydrocarbons in the abundant presence of fouling molecules such as H_2S and NH_3. Hydrogen sulfide generally decreases reaction rates owing to competitive adsorption with sulfur containing molecules. However, the behavior is more complex as dissociative adsorption may alter the nature of the active sites. For instance, Leglise et al. pointed out that sulfhydryl species play a positive role in the catalytic mechanism of thiophene conversion at very low hydrogen sulfide partial pressures.[4] High conversion levels imply high hydrogen sulfide partial pressures, and hence the necessity for sulfur-tolerant catalysts. Generally, CoMo catalysts are preferred when a high HDS duty is required, whereas NiMo based materials, which have better HYD activity than CoMo catalysts, are used when nitrogen removal is the major goal. The HDN and HDS reactivity of pure sulfides and sulfide pairs can be ranked as below:

Pure sulfides:

$$\text{Mo} > \text{W} > \text{Ni} > \text{Co} \quad \text{for HDS and HDN}$$

Sulfide pairs:

$$\text{CoMo} > \text{NiMo} > \text{NiW} > \text{CoW} \quad \text{for HDS}$$
$$\text{NiMo} \cong \text{NiW} > \text{CoMo} > \text{CoW} \quad \text{for HDN}$$

Al_2O_3 is the only support that is being used in most commercial HDS catalysts. Before the 1980s, the alternative supports other than Al_2O_3 that were used in most of the investigations were SiO_2 and SiO_2–Al_2O_3. The use of carbon-supported catalysts

that showed outstanding activities for HDS reaction at the laboratory level stimulated some research interest in such systems because it allows easy metal recovery. A major drawback is its low density. Availability of methods to prepare oxides such as ZrO_2, TiO_2, MgO with high surface area generated more interest in these materials as supports. These materials when used as supports could impart four to five times higher activities in Mo and W catalysts. To take advantage of their high intrinsic activities, mixed oxides such as TiO_2–Al_2O_3, ZrO_2–TiO_2 supports figured in many investigations.[5,6] In recent years mesoporous materials such as MCM-41, zeolite supported catalysts, and hydrotalcite derived catalysts received considerable attention because of their potential for possible application in ultradeep desulfurization.

A large number of elements in the periodic table (I, Cl, F, B, P, As, Cs, Na, Ca, Mg, Ga, Li, K, Rb, Zn, Ti, Si, etc.) are used as additives for HDT catalysts. Among all these elements, phosphorous is mostly used as a third element in commercial catalysts. Although it is frequently used, its role is still unknown. Various researchers have reported the following explanations for its role:[7]

1. Phosphorous is generally used to enhance HDN activity by modifying Lewis acidic sites of alumina support.
2. The addition of P into $NiMo/Al_2O_3$ catalyst increases hydrocracking activity. It indicates that P has also an indirect effect on Bronsted acidity.
3. Phosphorous leads to increase in the size of MoS_2 slab and the number of MoS_2 stacking.
4. Phosphorous decreases the metal–support interaction.
5. Phosphorous inhibits the formation of $NiAl_2O_4$, to increase the amount of a P–Ni–Mo heteropoly compound or to form Mo–P tetrapoly and Co–phosphate-like compound.
6. The increase in the dispersion of Co and Mo species is also reported in the literature.
7. Phosphorus increases the sulfidability of molybdenum.
8. Phosphorous can increase the amount of octahedrally coordinated Ni in the polytungstate structure at the expense of Ni in tetrahedral sites.
9. Phosphorous has also been reported to affect the deactivation of HDT catalysts.

Structure of Chemical Components in a Catalyst

Structural information of HDT catalysts has been explained in terms of several models. These models are monolayer model, intercalation model, contact synergy model, and the Co–Mo–S model. In the monolayer model, the molybdenum species was assumed to be bonded to the surface of the alumina forming a monolayer. Interaction of the Mo^{+6} with the alumina was believed to occur via oxygen bridges resulting from reaction with surface OH groups. Cobalt (Co^{+2}) was assumed to be in tetrahedral positions in the surface of the alumina, replacing Al^{+3} ions, which is explained by the promotional effect of Co. In the intercalation model, it is assumed that MoS_2 (WS_2) is on the surface of the alumina carrier where a plane of Mo(W) atoms is sandwiched between two hexagonal, close-packed planes of sulfur atoms. The Co(Ni) ions are then believed to occupy octahedral intercalation positions in the van der Waals' gap between the layer. In the contact synergy model, the presence of Mo as MoS_2 and Co as Co_9S_8 has been proposed. In the Co–Mo–S model, the Co–Mo–S phase was shown to be MoS_2-like structures with the promoter atoms located at the edges in fivefold coordinated sites (tetragonal pyramidal geometry) at the (1010) edge planes of MoS_2.

Pretreatment of Catalysts

Hydrotreating catalysts are supplied in an oxidic form. During the operation, the oxidic form is converted to a sulfided form. In this case, the sulfur present in the feed is converted to H_2S, which subsequently reacts with the metal oxide to form sulfides. A significant operating time can be gained if the catalyst sulfiding is performed prior to HDT. This results from the decreased catalyst deactivation of the presulfided catalyst compared with that of the oxidic catalyst. Presulfiding of the catalyst can be performed either in situ or ex situ. It is evident that at least 40 hr of the operating time can be gained by using the ex situ presulfided catalyst.[8]

During the in situ presulfiding, the catalyst bed is contacted with a sulfur containing liquid or H_2S containing sour gas and H_2. This results in the conversion of metal oxides to the corresponding sulfides, e.g., MoO_3 is converted to MoS_2. Liquid phase sulfidings are preferred because of the better distribution of sulfur across the bed. Also, the liquid acts as a sink of heat generated by the exothermic sulfidation reactions. An example of the procedure used for the in situ presulfiding of the catalyst was published by Gorra et al.[9]. In this case, a hydrogenated diesel fraction was used, thus eliminating the risk of catalyst deactivation by aromatics in the untreated fraction. The fraction was spiked with dimethyldisulfide to give 1 wt% sulfur. An optimal presulfiding was achieved at about 350°C. Fundamental aspects of presulfiding were discussed by Zeuthen et al.[10].

The ex situ presulfiding, perhaps more accurately termed as presulfurizing, comprises wetting of the

oxidic catalyst with an alkylpolysulfide, e.g., ditertiononyl pentasulfide containing about 37 wt% sulfur.[11] Usually, a stoichiometric amount of sulfur is added, i.e., in the case of CoMo catalysts, the added amount should be sufficient to convert all MoO_3 and CoO to MoS_2 and Co_9S_8, respectively. After a thermal treatment, the active oxides of the catalyst are converted to the oxysulfides. In this form, the catalyst is ready to be loaded in the reactor. The final conversion of the oxysulfides to sulfides is completed in situ during the start-up in the presence of H_2 and the feed. The Sulficat and Acticat are perhaps the best-known ex situ presulfiding processes available commercially.[12,13]

DIFFERENT HYDROTREATING PROCESSES

Hydrotreating processes are carried out for different product streams, namely, naphtha, fluidized catalytic cracking gasoline, kerosene/aviation turbine fuel, diesel, and on feed streams to other secondary processes, namely, VGO, atmospheric resid, and vacuum resid. Different HDT processes and their characteristics with respect to operating pressure, temperature, liquid hourly space velocity, and hydrogen consumption are reported by Nigam.[14] The operating pressure and H_2 consumption in four main HDT processes are given in Fig. 1.

REACTORS USED IN HYDROTREATING AND COMPARISON OF THEIR PERFORMANCE

Fixed-Bed Reactor—Cocurrent and Countercurrent Operation

Two types of fixed-bed reactors are used in HDT processes. Fixed-bed reactors having randomly packed catalyst in tubular devices traversed vertically downward by a gas–liquid stream are mainly used and generally known as TBR. Depending on the capacity of the plant, the reactor may vary from 1 to 6 m in diameter. The TBR reactor configuration ensures flexibility of operation and high throughputs of gas and liquid. Owing to a motionless catalyst bed, nearly plug flow is achieved in TBRs and in that respect they are superior to other three-phase reactors where the catalyst is either slurried or fluidized.[15,16] Trickle-bed reactors are usually operated at elevated pressures of about 2–30 MPa to slow down catalyst deactivation, increase the concentration of the gaseous component in the liquid phase, attain high conversion, achieve better heat transfer, and handle large volumes of gas at less capital cost. The other fixed-bed reactor configuration with countercurrent flow of gas and liquid has been proposed by Kundu et al.[17]. Though it has advantages with respect to lower H_2S and NH_3 concentration in the major part of the bed and better axial temperature profile compared to conventional TBR, the countercurrent configuration is limited to low velocities far below those of industrial interest because of excessive pressure drop and flooding problem. This problem has been minimized by incorporating structured catalytic packing by sacrificing the volume of the reactor in an optimized way between the reactor volume and the rate of conversion (details are in Kundu et al.[18]).

Ebullated Bed Reactor

This reactor is used for feeds having high metal or when higher conversion is required. The catalysts are in suspension and the option for the addition and removal of catalysts is present. It is most applicable in highly exothermic reactions. The expansion rate of

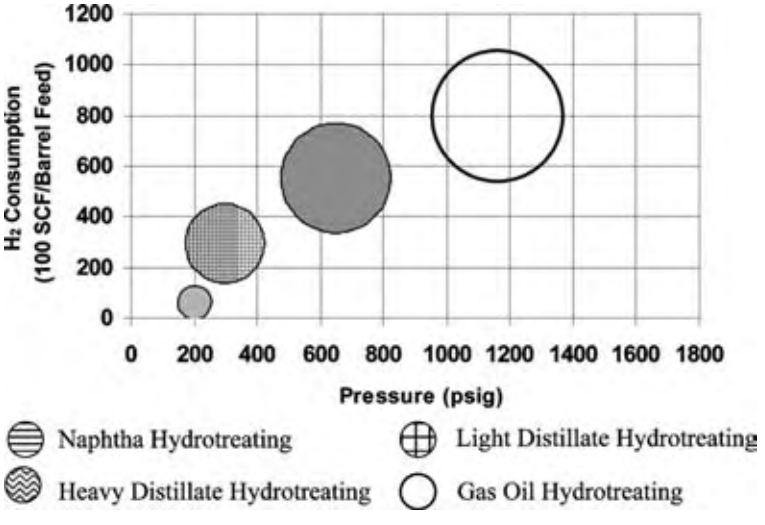


Fig. 1 Applications of hydrotreating processes and operating conditions.

the bed is kept at 1.3–1.5 under normal conditions. The advantages of the reactors are 1) high heat transfer rates; 2) uniform temperature; 3) catalyst replacement; and 4) much lower pressure drop. The disadvantages are 1) backmixed flow and the volume of the reactor not being fully utilized; 2) catalyst attrition due to motion; and 3) higher consumption of catalyst.

Moving-Bed Reactors

In moving-bed reactors, both the feed and the catalyst move in cocurrent downflow and the catalysts are continuously renewed. The metal content increases along the bed and metal-rich catalysts are withdrawn from the bottom. It can handle the feed having higher metal content. The moving-bed reactor can be used as a first reactor for demetallization and asphaltene disaggregation. Other conversions (HDN, HDS) can take place in a fixed bed downstream.

SELECTION OF A PROCESS FOR CATALYST DEVELOPMENT

There were basically two approaches, which were used in the past for HDT process development studies using catalyst in the commercially applied size and shape. The first one, which was followed 30–40 yr ago in various industrial research and development centers, was to test the commercial catalyst in large pilot plants. The second approach was to use a smaller pilot plant and simulate the data generated in these units, applying a suitable hydrodynamic model to predict the performance of a commercial unit. These are generally known as small-scale TBRs. Because of the presence of a liquid phase, the problems in these small TBRs are more complex as compared to those present in other small-scale fixed-bed catalytic reactors handling only vapor phases.

The catalysts are made in small quantities and to avoid the complexity of preparing shaped catalysts, it is common to test catalysts in the form of powder or fine particles. This also helps to compare the intrinsic reaction rates of various catalyst formulations. Because the number of catalyst samples to be tested are many, the testing method needs to be simple and fast. However, this should not compromise with the reliability and meaningfulness of the data generated. Because of the small amount of catalyst available, slurry reactors using batch autoclave or fixed-bed continuous microreactors are typically used for this stage of initial catalyst screening. A description of these two reactors for the purpose of initial screening of the catalyst is available in Bej.[19]

Reactors for Process Development and Optimization Studies

The best catalyst selected through previous screening tests is formed into a shape (cylindrical or multilobe) and undergoes further experimentation for process development and optimization. Some additional experiments are needed at this stage to select the proper size and shape of the catalyst and also to determine the effect of other ingredients such as binders and additives used in forming. Two points are very important in selecting an appropriate reactor at this stage of research. First, the catalysts need to be tested in their commercially applied size and shape. Second, the objective at this stage of research is to predict the full performance of the catalyst for a commercial operation rather than simple preliminary screening. The diameter of a small-scale (bench- or microscale) TBR is much smaller than those of a commercial reactor. Hence, the ratio of the reactor diameter to catalyst particle diameter is very low (<100). The ratio of the catalyst bed height to the particle diameter is also low in these reactors. Because of the smaller volume of catalyst used, the liquid flow rate is also lower. The values of these parameters along with the Reynolds number for various sizes of the reactors are given in Sie and Krishna.[20] Because of the low values of these factors, a number of problems such as incomplete wetting of catalyst and backmixing of liquid are observed in these small-scale reactors.[21]

Dilution Technique

The theories of dilution techniques have been explained in detail by various researchers.[20,22,23] The selection of the proper size of diluent is very important. Equal volumes of diluent and catalyst were used for this comparison. For the case of an undiluted bed, only commercial size catalyst is packed in a small-scale reactor. The wall effect is very significant and in this case causes channeling of liquid. Because of the high void space inside the catalyst bed, the liquid holdup in the catalyst bed is also very low. As a whole, there is incomplete wetting of catalyst and only partial utilization is achieved in this case. Besides this, an appreciable amount of axial backmixing is present in the undiluted catalyst bed. When a larger size of diluent is used, it cannot enter the void space between the catalyst particles. Thus, it does not increase liquid holdup and hence only partial utilization of catalyst is also obtained. However, the addition of diluent increases the bed height, which in turn reduces liquid axial dispersion to some extent. When the diluent size is smaller, it can enter the narrow void space between the catalyst particles and can increase the liquid holdup

of the bed. Thus, almost complete wetting of catalyst is achieved by using a fine size of diluent. The use of fine size of diluent also reduces the axial dispersion in a significant way.

In essence, diluting the catalyst bed with appropriate size of inert particles increases liquid holdup, improves catalyst wetting, and reduces liquid backmixing. The selection of diluent size depends on several factors such as the length and inner diameter of the reactor, the size, shape and amount of catalyst, and the flow rate of reactants. Therefore, there is a lot of research interest to determine the appropriate size of the diluent for various sizes of small-scale reactors to overcome their limitations.

Operating in Upflow Model

Sometimes, the researchers used upflow mode for the catalyst development in a bench-scale TBR for overcoming the partial wetting and wall flow. The upflow mode of operation suffers from the serious drawback of nonideal flow of liquid and the formation of stagnant zone inside the catalyst bed. A large difference in hydrodynamics for cocurrent downward flow and cocurrent upward flow was obtained when using a large size of diluents. This difference can be minimized by using higher liquid flow rates and smaller size diluents. The comparison of upflow and downflow operation with and without diluents was carried out by Chander et al., De wind et al., Khadilkar et al., and Dudukovic et al.[23–26].

COMMERCIAL HDT PROCESSES

Different commercial HDT processes using TBRs are available. For diesel hydrotreatment process, IFP's technology, and UOP's unionfining process is widely used in the petroleum refining industry. ABB Lummus in association with Criterion catalysts offers different HDT processes for upgradation of diesel quality under the family of technologies called SynSat Technology. The process uses intermediate by-product gas removal and optional countercurrent gas flow in addition to the conventional cocurrent downward mode of gas and liquid flow (Fig. 2). The HDT processes using licensed ebullating bed processes include:

- LC-Fining. Licensed by ABB Lummus Global Inc., Oxy Research and Development Co., and BP Amoco Corporation.
- H-Oil. Licensed by IFP North America and Texaco.
- T-Star. Licensed by IFP North America and Texaco.

These LC-Fining and H-Oil both use similar technologies but offer different mechanical designs.

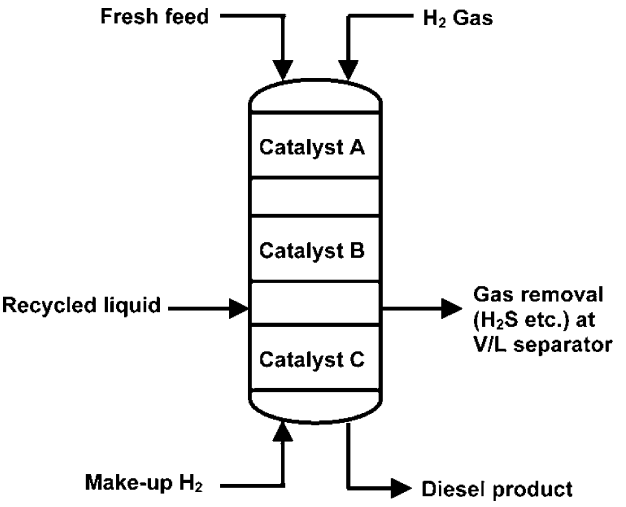

Fig. 2 SynSat process with Criterion/Lummus catalytic HDT reactor technology.

LC-Fining system consists of three sections, i.e., fresh catalyst handling, daily addition/withdrawal of catalyst to and from the reactors, and a spent catalyst handling system. The advanced design of the H-Oil reactor incorporates an improved internal recycle cup enabling a complete separation of the recycle liquid from the gas.[8] With this improvement the throughput of the feed was increased.

CONCLUSIONS

Hydrotreating is very important in petroleum refining industries and is an essential process for treatment of petroleum products owing to the stringent environmental regulations imposed on the world. The appropriate catalyst and reactors are necessary for getting deep conversion (e.g., deep HDS). Apart from the elementary composition of the catalyst, different types of catalyst supports and additives are used to get better performance of the catalyst. The development of the catalysts is still a result of trial-and-error experiments and empirical knowledge rather due to the desired fundamental understanding. Regarding the selection of reactors, countercurrent operation has been tried to commercialize for getting high conversion. There is a necessity to optimize the reactor volume utilization vs. the conversion for this reactor. Countercurrent TBR will also help to handle easily the heavy fraction of the oil.

INTRODUCTION

Enzymes are proteins employed by Mother Nature to catalyze the chemical reactions necessary to sustain life in plants and animals. As catalysts, enzymes may influence the rates and/or the directions of chemical reactions involving an enormous range of substrates (reactants). Enzymes function by combining with substrates to form enzyme–substrate complexes (reaction intermediates) that subsequently react further to yield products while regenerating the free enzyme.

The region of the enzyme that interacts with substrates is referred to as the active site. For reaction to occur there must be an appropriate fit between the three-dimensional structure of this site and the geometry of the reactant molecule so that an enzyme–substrate complex may form (Emil Fischer's ''lock and key'' hypothesis). Enzymes are relatively labile species and when subjected to unfavorable conditions of temperature, pH, pressure, chemical environment, etc., they can lose their catalytic activity. In these situations, deactivation of the enzyme can usually be attributed to changes in the geometric configuration of the active site.

Enzymes are characterized by unusual specific activities and remarkably high selectivities. They are effective catalysts at relatively low temperatures and ambient pressure. The primary driving force for efforts to develop immobilized forms of these biocatalysts is cost, especially when one is comparing process alternatives involving either conventional inorganic catalysts or soluble enzymes. Immobilization can permit conversion of labile enzymes into forms appropriate for use as catalysts in industrial processes—production of sweeteners, pharmaceutical intermediates, and fine chemicals—or as biosensors in analytical applications. Because of their high specificities, immobilized versions of enzymes are potentially useful in situations where it is necessary to obtain high yields of the desired product to minimize downstream processing costs and the environmental impact of a process.

Because the costs of isolation and purification of soluble enzymes are high and it is often both technically difficult and costly to recover an active form of the enzyme from product mixtures when the reaction of interest is completed, soluble enzymes are normally employed only in batch operations in which the enzymes are removed from the liquid product by precipitation. Thermal deactivation may be used instead to destroy the catalytic activity of the enzyme. Immobilization of the enzyme circumvents these difficulties because the solid phase containing the enzyme is easily recovered from the product mixture. Use of immobilized enzymes makes it possible to conduct the process in a continuous flow mode, thereby facilitating process control via manipulation of the flow rate of the process stream. One can offset losses in enzyme activity as time elapses by reducing the flow rate to maintain a constant product composition. Operation in this mode permits one to obtain more product per unit of enzyme employed.

TECHNIQUES FOR IMMOBILIZATION OF ENZYMES

A variety of physical and chemical methods have evolved for immobilizing enzymes on or within solid supports. Kennedy and Cabral employed a variation of the scheme in Fig. 1 to classify techniques for immobilization of enzymes.[1] Judicious choice of the support is essential not only for the stability of immobilized enzymes, but also for the operational characteristics of the device containing the immobilized enzyme and the economic viability of the intended application. The discussion below and the information in Table 1 indicate some of the criteria employed in selecting a mode of immobilization.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120018070

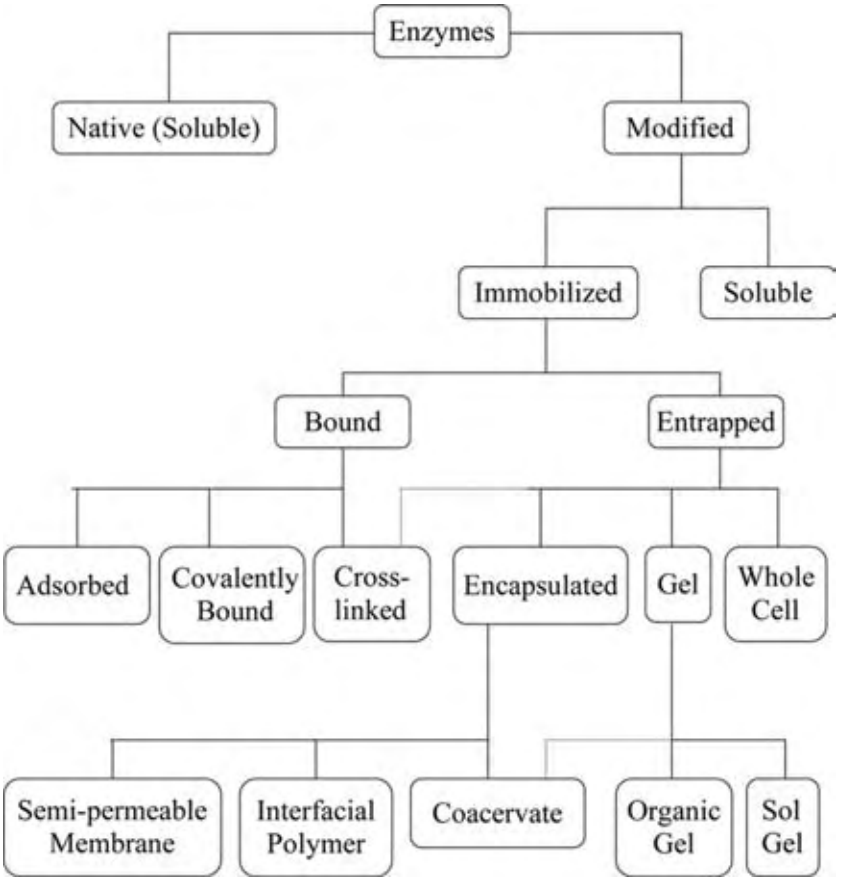

Fig. 1 Schematic representation of modes of immobilization of enzymes. (Dotted lines indicate potential alternative uses/classifications.)

Enzyme Carriers—Particulate Supports

Industrial scale processes involving immobilized enzymes are normally carried out in fixed-bed reactors. Hence, the desired characteristics of the catalyst support are closely akin to those for the heterogenous catalysts commonly employed in the chemical industry, namely:

- Chemical, mechanical, and thermal stability.
- Resistance to both microbial degradation and swelling or dissolution in the reaction medium.
- High permeability to reactant and product species (and to the enzyme during the immobilization process) (pore diameters in the 10–50 nm range and porosities of ~50% or better).
- The requisite hydrophobicity or hydrophilicity for the intended application.
- A moderately high specific surface area (~50 m^2/g) and a pore size distribution that provides adequate capacity for adsorption of the enzyme.
- A suitable shape and particle size (to minimize pressure drop), typically greater than 0.5 mm in diameter.
- Relatively low cost.
- Regenerability.
- Inertness with respect to both the enzyme-mediated reactions of interest and reactions leading to deactivation of the enzyme.

Because naturally occurring materials do not meet the morphological specifications, most carrier materials are synthesized via routes that produce the desired characteristics. Boller, Meier, and Menzler have indicated that although immobilization of enzymes on solid supports has been studied for half a century, there are no generally applicable rules for selecting the proper support for a specific application.[2] Nonetheless, they also indicate that microporous and mesoporous epoxy-activated acrylic beads with particle diameters in the 100–250 μm range (pore radii in the 10–100 nm range) are popular supports for the preparation of multiton quantities of catalysts for industrial biotransformations.

Methods of Immobilization

Several physical and chemical methods can be utilized to immobilize an enzyme on a solid support (Fig. 1).

Physical adsorption

The simplest method of immobilization is physical adsorption of the enzyme on the carrier. The procedure consists of contacting a solution of the enzyme with the support material under appropriate conditions, and

Table 1 Comparison of different modes of immobilization of enzymes

	Modes of immobilization							
Characteristic	**Physical adsorption**	**Ionic binding**	**Chelation**	**Covalent bonding**	**Cross-linking**	**Physical entrapment**	**Membrane entrapment**	**Whole cells**
Ease of preparation	Simple	Simple	Simple	Difficult	Intermediate	Difficult	Simple	Intermediate
Binding force	Weak	Intermediate	Intermediate	Strong	Strong	Intermediate	Weak	Intermediate
Fraction of original enzyme activity	Intermediate	High	High	High	Low	Small	High	High
Ease of regeneration	Possible	Possible	Possible	Rare	Impossible	Impossible	Possible	Impossible
Cost of immobilization	Low	Low	Intermediate	High	Intermediate	Intermediate	Intermediate	Intermediate
Stability	Low	Intermediate	Intermediate	High	High	High	Intermediate	Intermediate
General applicability	Yes	Yes	Yes	No	No	Yes	Yes	Some
Protection of enzyme from microbial attack	None	None	None	None	Good	Some	Some	Some

after allowing sufficient time to elapse, separating the solution from the now insoluble enzyme preparation by filtration, centrifugation, or other means. Because no chemical interactions are involved, there is little or no conformational change in the enzyme. Thus, the impact on the geometry of the site at which the biocatalyst interacts with substrates is minimal. The forces binding the enzyme to the carrier are relatively weak and may involve hydrogen bonding and hydrophobic interactions in addition to conventional van der Waals forces. The extents of adsorption and retention of activity are dependent on experimental parameters such as the pH of the solution/suspension, temperature, ionic strength, species concentrations, and the chemical nature of the solvent.

It is important to allow sufficient time for diffusion of the enzyme into the pore structure of the support to maximize the extent of physical adsorption of the enzyme. Surface coverages of the support by adsorbed enzymes may range from a fraction of a monolayer to multiple layers. Because the forces binding the enzyme to the support are relatively weak, enzymes immobilized by physical adsorption are susceptible to desorption during use. Shifts in microenvironmental conditions, such as changes in pH, ionic strength, temperature, composition of the solvent, etc., can lead to desorption with concomitant apparent loss of activity of the biocatalyst. On the other hand, these characteristics can sometimes be advantageous in protocols used to regenerate a fixed bed of immobilized enzyme, once it has lost a significant fraction of its original activity. In some cases, it may be appropriate to use a multifunctional cross-linking agent such as glutaraldehyde to chemically bind the adsorbed protein molecules to one another or to the underlying surface of the support. This approach minimizes the potential for loss of activity by desorption of the enzyme, but renders the task of regeneration of the activity of the biocatalyst much more difficult.

Ionic bonding and chelation

A useful variation of the physical adsorption method involves adsorption of the enzyme on carriers whose structures contain anion or cation exchange residues. Unless the pH of the system corresponds to the isoelectric point of the enzyme, the interactions of the net charge on the protein with opposite fixed charges on the solid support enhance the strength of adsorption of the enzyme on the support. In practice, both ionic bonding and physical adsorption occur simultaneously; the main difference is that when ionic forces are present, the strength of the interaction is greater. An alternative to employing charge bearing carriers is to enhance the strength of the adsorbate–adsorbent interaction by taking advantage of the ability of some transition metal compounds to form chelate structures with enzymes.

Covalent bonding

Stronger bonds between the enzyme and the carrier can be formed when covalent bonding is employed. Enzymes are copolymers (proteins) composed of a variety of amino acid monomers. They possess a number of reactive side chains that can be utilized for the purpose of forming covalent bonds with solid supports, whose surfaces contain appropriate functional groups. The functionalities present in the side chains of the protein typically include amino, carboxylic acid, sulfydryl, hydroxyl, imidazole, disulfide, indole, and phenol groups. The particular chemistry employed in forming covalent bonds between the enzyme and the carrier is selected on the basis of the chemical nature of the support and the intended application. The range of potential coupling processes is vast for both inorganic and organic supports, and methodologies based on several different types of chemical reactions are described in Refs.[1,3–5]. A sample of some of the most commonly employed types of reactions is presented in Table 2.

If the enzyme is to retain significant catalytic activity after being covalently bound to the support, immobilization should occur via functional groups that are not associated with the active site of the enzyme. This limitation may be difficult to surmount, and enzymes immobilized via covalent bonding may thus suffer significant losses of activity relative to the activity of the soluble precursor. Nonetheless, the wide variety of supports with functional groups capable of reacting (or susceptible to appropriate functionalization) via a range of chemistries with enzymes makes covalent bonding a generally applicable route for immobilization of enzymes. Enzymes bound to supports in this manner are not susceptible to desorption from the surface during use.

Cross-linking

Enzymes can be readily cross-linked using a bi- or multifunctional reagent, such as glutaraldehyde, bis-diazobenzidine-2,2-disulfonic acid, or toluene diisocyanate, which can react with free amino or carboxyl groups or with other functional groups that might be present in the enzyme. Cross-linking of proteins results in an insoluble polymer that may not possess appropriate physical properties for the intended application. Cross-linking is often used in combination with other techniques (especially physical entrapment and physical adsorption) to obtain a material that has enhanced stability.

Table 2 Examples of reactions commonly used for covalent bonding of enzymes to solid surfaces

Functional group of the support	Functional group of the enzyme	Coupling reagent
Amine, $-NH_2$	$-NH_2$	Glutaraldehyde
Hydroxyl, –OH	$-NH_2$	$(CH_3O)_3$ Si $(CH_2)_3$ NH_2 + glutaraldehyde
	$-NH_2$	Cyanogen bromide or tresyl chloride
Aldehyde, 	$-NH_2$	None
Acid anhydride, 	$-NH_2$	None
Imidocarbonate, 	$-NH_2$	None
Cyclic carbonate, 	$-NH_2$	None
Triazinyl 	$-NH_2$	None
 (X = NH, O, S)	$-NH_2$,-OH, -SH	None
$-COOH$	$-NH_2$	Carbodiimide (RN=C=NR)

Physical entrapment of enzymes

Enzymes can also be immobilized by physical entrapment, either in a solid matrix or encapsulated by a membrane that is permeable to low-molecular-weight species, but not to high-molecular-weight species. These membranes may be fabricated from polymers or formed by interfacial polymerization of appropriate monomers. The membranes may also be parts of living cells that have the capacity for bringing about the desired chemical transformations as part of the metabolic processes required for their existence. In addition, the membranes can consist of the walls of cells subjected to lysis.

Gel Formation. Entrapment of enzymes in solid matrices composed of synthetic or natural polymers or inorganic gels is a relatively simple process. The basic technique involves occlusion of the enzyme within the lattice of a solid matrix as the matrix is formed by polymerization, precipitation, or coacervation. Gels

formed from polysaccharides, especially those derived from cellulose and algae, have often been used in combination with cross-linking agents to immobilize enzymes. Both anionic polymers (e.g., carrageenan, carboxymethylcellulose, and sodium alginate) and cationic polymers (e.g., chitosan) have been used to form ionotropic gels within which enzymes or whole cells can be entrapped. This approach leads to a product that is not robust with respect to changes in ionic strength or pH, but it is usually the method of choice for immobilizing whole cells. Gels formed by polymerization of acrylic and methacrylic acids can be activated using a soluble carbodiimide as a precursor to production of covalently bound enzymes. In addition to the organic gels noted above, it is also possible to employ sol–gel techniques based on hydrolysis of metal alkoxides to produce inorganic polymeric structures within which enzymes can be physically entrapped.

A major disadvantage of the gel entrapment route to immobilization is the potential for physical loss of the enzyme as time elapses. To circumvent this problem, cross-linking agents, such as *N,N′*-methylene-bis-acrylamide or glutaraldehyde, may be used to more firmly immobilize the enzyme or to provide mechanical stability. However, the more rigid the matrix the greater is the possibility that diffusional resistance to transport of reactants (substrates) to the site of the enzyme and of products out of the gel will limit the reaction rate.

Encapsulation. Immobilization of enzymes by encapsulation within semipermeable structures dates back to the 1970s.[6] There are three fundamental variations of this approach. In coacervation, aqueous microdroplets containing the enzyme are suspended in a water-immiscible solvent containing a polymer, such as cellulose nitrate, polyvinylacetate, or polyethylene. A solid film of polymer can be induced to form at the interface between the two phases, thereby producing a microcapsule containing the enzyme. A second approach involves interfacial polymerization in which an aqueous solution of the enzyme and a monomer are dispersed in an immiscible solvent with the aid of a surfactant. A second (hydrophobic) monomer is then added to the solvent and condensation polymerization is allowed to proceed. This approach has been used extensively with nylons, but is also applicable to polyurethanes, other polyesters, and polyureas.

A third general approach to encapsulation involves the use of permselective membrane devices of the types employed in ultrafiltration and nanofiltration of aqueous solutions, especially those devices that employ the membrane in the form of hollow fibres. In effect, the enzymes are retained within a macrocapsule. An aqueous solution of the soluble enzyme or whole cells is contained on the retentate side of the membrane, while a solution containing the substrates is supplied to the permeate side of the membrane. The reactants are transported across the membrane to the retentate side where they undergo reaction. The products then diffuse out of the retentate zone across the membrane to the permeate side where they can be removed by convective transport. Throughout, the enzyme is retained on the retentate side provided that one employs a membrane whose molecular cutoff value is significantly below the molecular weight of the enzyme. An advantage of this approach is that this apparatus permits periodic replacement of the biocatalyst.

Reactions mediated by enzymes immobilized by coacervation, interfacial polymerization, retention by semipermeable membranes, or gelation are particularly susceptible to mass transfer/diffusional limitations on the rate.

Immobilized Cells. Instead of immobilizing individual enzymes in molecular form, one can elect to immobilize whole (living) cells containing the enzymes of interest. Many of the techniques employed for immobilization of enzymes are readily extended to immobilization of whole cells, especially those methods involving physical entrapment of the enzymes. In essence, immobilization of whole cells is just another means of physically encapsulating the enzyme(s) of interest. Furthermore, immobilization of whole cells circumvents the need for the multiplicity of processing steps involved in isolating and purifying intracellular enzymes with concomitant reductions in cost. The stability of the desired enzyme(s) is usually enhanced by virtue of the fact that its natural environment is maintained during both immobilization and use. This advantage is of particular benefit in the case of membrane-bound enzymes and for enzyme-mediated reactions involving the participation of either cofactors or multiple enzymes. The necessity for purification of multiple enzymes is avoided and the optimal spatial location of these enzymes within various compartments of the cell remains intact, as do the sites for regeneration of cofactors. Hence, the structural integrity of the catalytic complex is retained. Moreover, the enzymes present in immobilized cells are much more robust with respect to local perturbations in pH, temperature, ionic strength, and the presence of substances that cause deactivation of the enzyme (e.g., toxic metal ions).

On the other hand, use of whole cells as the vehicle for immobilization of enzymes is not without problems. These disadvantages include the susceptibility to mass transfer/diffusional limitations on reaction rates and possible losses in the yield of the desired product as a consequence of unwanted side reactions. In addition, there are potential problems associated with maintaining the integrity of the immobilized cells—supplying the nutrients, energy sources, or cofactors necessary to maintain the cells in a sufficiently viable condition to mediate the reaction(s) of interest.

Comparison of immobilization techniques

Table 1, an extension of the work of Kennedy and Cabral, is a concise summary of important characteristics of different immobilization techniques.[7]

APPLICATIONS OF IMMOBILIZED ENZYMES

Industrial Applications

In spite of the high expectations generated by immobilized enzyme technology in the last third of the 20th century, only a limited number of reductions to industrial practice have been accomplished. Very few large-scale immobilized enzyme processes can successfully compete with processes based on either free enzymes or more conventional catalysts. Some of these are indicated below.

Applications in the Food Industry

Immobilized glucose isomerase for the production of high-fructose corn syrup

A major shift in the technology employed for the production of sweeteners began in the early 1960s with the introduction of soluble enzymatic methods for the production of dextrose syrups from starch. (In commercial practice, the term dextrose is used instead of glucose.) This seminal change was followed about a decade later by utilization of immobilized glucose isomerase for the production of high-fructose corn syrups (HFCS) for use as sweeteners in the manufacture of soft drinks and other foods and beverages. Glucose and fructose have the same molecular formula ($C_6H_{12}O_6$), but differ in geometric configuration (Fig. 2) and sweetening power. Schenck has reviewed the technology for production of high-fructose syrups.[8]

Starch, a polymer formed from glucose monomers, is the principal storage carbohydrate of plants and commercially is obtained primarily from corn. The industrial process involves, first, acid or enzyme (soluble bacterial α-amylase) catalyzed hydrolysis of aqueous suspensions of gelatinized starch to obtain a product with a low dextrose equivalent (DE) of 5–12 and sugars such as glucose and maltose. (The DE is the percentage of the dry matter that consists of reducing sugars expressed as dextrose. This parameter indicates the percentage of the glycosidic linkages in the starch precursor that have been cleaved by hydrolysis.) This hydrolysis dissolves the starch. Further hydrolysis with soluble α-amylase yields a product with a DE in the range of 8–15. This product is then saccharified using one or more soluble enzymes. Fungal α-amylase and fungal glucoamylase (GA) are utilized either separately or in combination (and sometimes in combination with pullulanase) to produce a dextrose syrup with a typical DE of 42. Soluble enzyme preparations from *Aspergillus niger, A. oryzae*, or *Rhizopus oryzae* are then employed for additional saccharification to obtain the 95–98 DE feedstock necessary for the production of HFCS. The resulting products are sweeteners whose compositions and applications depend on the extent of hydrolysis mediated by the enzymes in question. Yields of glucose may be as high as 95–97%. However, the sweetening power of glucose suffers by comparison to that of fructose, and it is the subsequent conversion of glucose to fructose for which immobilized glucose isomerase (xylose isomerase) is an effective biocatalyst. This isomerization reaction constitutes the heart of the technology that brought about a revolution in the manufacture of sweeteners. The resulting syrups compete successfully with sucrose (cane sugar) in many food applications. Virtually all manufacturers of soft drinks use HFCSs in their formulations.

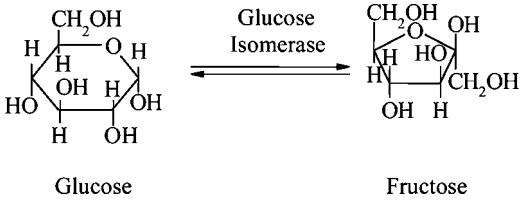

Fig. 2 Isomerization of glucose to fructose over an immobilized glucose isomerase.

Production of fructose from glucose became commercially viable only after adequate procedures for immobilization of glucose isomerase were developed, so that the same quantity of enzyme could isomerize large quantities of substrate in a packed-bed reactor fed continuously with a solution of maltodextrins. Process conditions (typically 55–65°C and pH 7.5–8.5) depend on the particular form of the immobilized enzyme. Reactor diameters are typically between 0.6 and 1.5 m, with corresponding heights of 2–5 m. Initial residence times are less than 1 hr, but to compensate for the loss of enzyme activity as time onstream elapses it is necessary to increase the residence time by reducing the flow rate of the feed stream so as to maintain the composition of the effluent constant. Manufacturers frequently employ large numbers of reactors in tandem to maintain constant production rates. After several months when the activity of a particular packed bed decreases to about 10% of its initial value, that bed can be removed from the reactor network and the biocatalyst replaced by a new charge of enzyme.

Because glucose isomerase is formed intracellularly in many bacterial strains of commercial interest, some industrial processes have utilized immobilized cells,

rather than isolated enzymes, in this application. In whole-cell processes the microbial cells are recovered from the fermentation broth and treated to maintain both enzymatic activity and particle integrity. For the biocatalysts derived from soluble enzymes, the enzyme is separated from the cells and purified prior to immobilization. Relatively few organisms (*Actinoplanes missouriensis, Bacillus coagulans, Streptomyces rubiginosus, S. olivochromogenes, S. murinus, and Microbacterium arborescens*) have been used to generate the glucose isomerase used in commercial operations. Although the equilibrium yield of fructose for the typical operating conditions cited above corresponds to 50–55% on a dry basis (db), the reactors are normally operated to obtain yields of 42–45% db to circumvent the limitations on the rate imposed by the approach to equilibrium and to obtain an economically viable reactor size. The effluent from the reactor is then polished to remove color and salts using a combination of activated carbon and ion exchange resins and then concentrated to ca. 71% (w/w) solids. This 42% HFCS product can be used directly in formulating some food products, but manufacturers of soft drinks who desire to effect complete replacement of sucrose in their formulations require that the 42% HFCS be fractionated (for example, by a continuous chromatographic technique) to obtain a product enriched in fructose and a raffinate enriched in glucose. The latter can then be recycled to the immobilized enzyme reactor (IMER) for further conversion to fructose. One possible mode of operation to produce the three fructose-rich syrups of commercial interest and crystalline fructose is shown in Fig. 3. Data provided by the USDA Economic Research Service indicates that in 2002 U.S. production of HFCS corresponded to 9.3 million short tons (db) of fructose.

Other food-related applications

Swaisgood has reviewed applications of immobilized enzymes in the food industry during the past 40 yr.[9] He discusses not only the HFCS application, but also a variety of others, some of which are no longer employed commercially. Table 3 contains a summary of these applications.

Applications Involving Fine Chemicals–Chiral Synthesis and Chiral Separations

In the mid-1980s researchers in the pharmaceutical industry demonstrated that single enantiomers of pharmaceutical compounds often functioned better as therapeutic agents than racemic mixtures. There are many examples for which one particular chiral form (enantiomer) of a compound demonstrated therapeutic efficacy, while the other chiral form was ineffective or produced deleterious effects. (For example, dextromethorpan is commonly used as a cough suppressant, while its enantiomer, levomethorphan, is a powerful narcotic.) By 2002 annual sales of the top 10 single-enantiomer drugs totaled $34.2 billion.[10]

In the pharmaceutical industry, immobilized enzymes (especially lipases) are used to mediate reactions of two general types: reactions involving prochiral substrates and kinetic resolution of racemates.

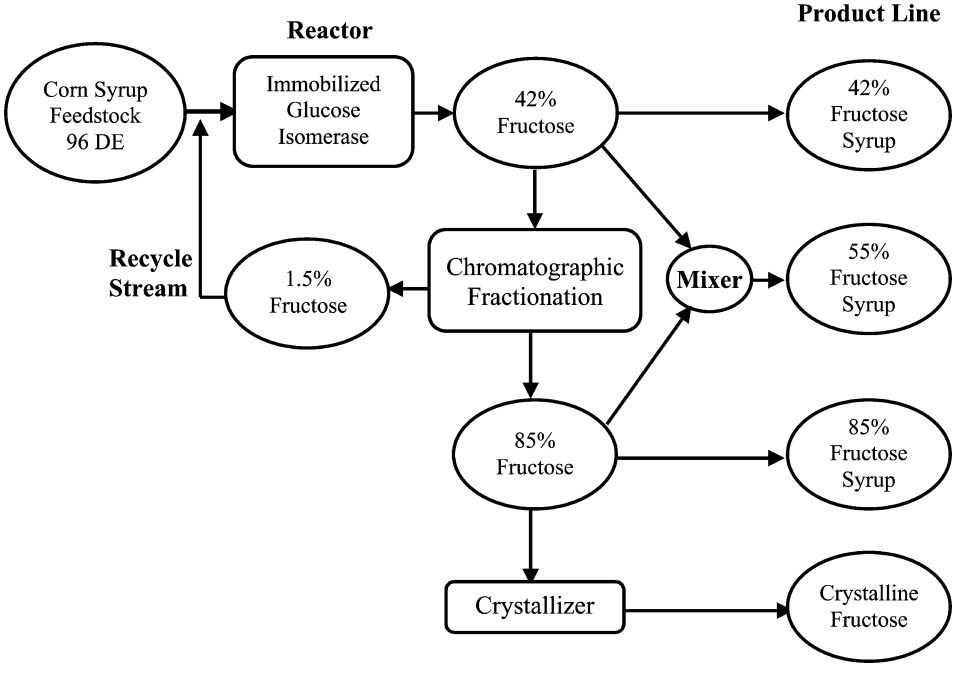

Fig. 3 Flow diagram for production of HFCS products.

Table 3 Applications of immobilized enzymes in the food industry

Product	Immobilized enzyme (application)	Countries	Half-life of enzyme	Productivity (wt/wt of enzyme)
Whey hydrolysate	β-Galactosidase (hydrolysis of lactose)	Finland, Norway, France, and U.K.	20 mo	2000
L-Amino acids	Aminoacylase (resolution of optical isomers)	Japan	65 days	n.a.
L-Phenylalanine	Transaminases (production of aspartame)	Japan	>8 mo	n.a.
5′-Ribonucleotides	5′-Phosphodiesterase (chemical synthesis)	Germany	>500 days	n.a.
Isomaltulose	Isomaltulose synthase (chemical conversion)	U.K., Germany, Japan	1 yr	1500
Invert sugar	Invertase (hydrolysis of sucrose)	Europe	n. a.	6000
Modified fats and oils	1,3-Specific lipases (migration of acyl groups)	Japan, U.K.	n. a.	1100

n.a., not available.

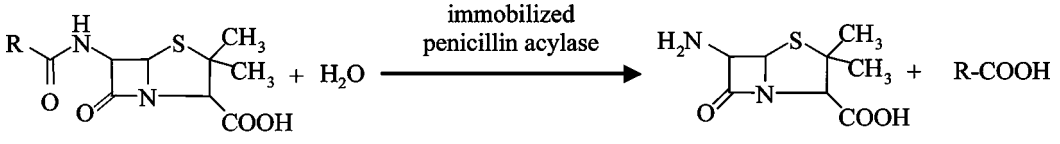
Although prochiral or chiral alcohols and carboxylic acid esters initially served as the primary classes of substrates, compounds susceptible to processing via these two routes now encompass diols, α- and β-hydroxy acids, cyanohydrins, chlorohydrins, diesters, lactones, amines, diamines, amino alcohols, and α-and β-amino acid derivatives. Gotor and Arroyo have reviewed the use of biocatalysts for the preparation of pharmaceutical intermediates and fine chemicals.[11,12] Some specific examples are indicated below.

Penicillins and cephalosporins are characterized by β-lactam structures and are the antibiotics that have traditionally been those most commonly used in the treatment of infections. Pharmaceutical companies have synthesized a variety of semisynthetic β-lactam compounds for use as oral antibiotics, for example, ampicillin and amoxicillin. These penicillin derivatives are prepared by acylation of 6-amino-penicillanic acid (6-APA) derived from penicillin G (benzyl penicillin) or penicillin V (phenoxymethyl penicillin). An immobilized penicillin amidase (penicillin acylase) from *Escherichia coli* or *Bacillus megaterium* is used to prepare the 6-APA in nearly quantitative yield (Fig. 4). This substance is used as the starting material for the production of a number of other penicillins. The immobilized enzyme can be reused more than 600 times in the batch reactor used to accomplish this transformation.

A similar reaction scheme can be used to produce derivatives of cephalosporin via acylation of 7-amino-cephalosporamic acid or 7-amino-desacetoxycephalosporamic acid. These compounds could be produced from a natural cephalosporin using an immobilized cephalosporin acylase, but alternative routes to these compounds are more cost-effective.

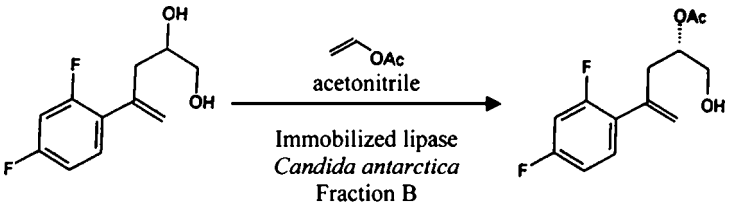
Immobilized forms or reticulated crystals of *Candida antarctica* lipase are effective biocatalysts for the synthesis of pure enantiomers utilized as anti-inflammatory agents. For example, one route for production of the *S*-isomers of 2-aryl propionic acids (ibuprofen, naproxen, ketoprofen, and flurbprofen) involves enantioselective hydrolysis of the corresponding racemic esters. Arroyo has indicated that an immobilized form of *C. antarctica* lipase (fraction B) is used to mediate the selective acetylation of a diol to form the *S*-enantiomer of a monoacetate (Fig. 5), which is further processed to obtain an antifungal agent.[12]

Analytical chromatographic separation of enantiomeric acids and N-substituted amino acids has been effected using immobilized α-chymotrypsin supported on activated silica.[13] Similarly, cellulase immobilized on silica gel can bring about chromatographic



natural penicillin 6-amino penicillanic acid

Fig. 4 Conversion of natural penicillin to 6-APA over an immobilized penicillin acylase.



diol S-monoacetate

Fig. 5 Generation of the *S*-enantiomer of the monoacetate precursor of an antifungal agent from a diol as mediated by an immobilized lipase from *Candida antarctica*, fraction B.

separation of enantiomers of propanolol.[14] This approach can be employed in industrial separation of racemic mixtures using simulated moving-bed chromatography as in the production of naproxen, warfarin, propanolol, and ephedrine.

Biosensors and IMERs

A biosensor is a sensing device consisting of a recognition element (enzyme or cell) in intimate contact with an appropriate transducer that is able to convert the concentration of a species involved in the recognition reaction into a measurable electronic signal. Biosensors based on immobilized enzymes have been employed for decades in analyses for solutes present in either aqueous solution or biological fluids. Fabrication of these biosensors frequently involves immobilization of an enzyme on a membrane electrode that is capable of donating electrons to (or accepting electrons from) species participating in an enzyme-mediated reaction. The substrate to be quantified diffuses to this surface where the biocatalytic reaction occurs. Electrochemical (potentiometric or amperometric) measurements are then employed to monitor changes in the concentration of the analyte of interest. In many applications, the transducer element is located downstream from an IMER that converts the substrate into a chemical form that stimulates the response of the transducer.

Analytical applications

Schuhmann has reviewed amperometric biosensors and indicated that these sensors can be categorized as devices employing: 1) direct electron transfer between redox proteins and electrodes modified with self-assembled monolayers; 2) anisotropic orientation of redox proteins at monolayer-modified electrodes; 3) electron transfer cascades via redox hydrogels; and 4) electron transfer via conducting polymers.[15] These biosensors are employed to quantify the concentrations of a wide variety of substrates. For these determinations, the choice of the support material and the method of immobilization are tailored to the particular application. Gupta and Mattiasson have described several unique applications of enzymes in bioanalytical systems.[16]

Physical entrapment of an enzyme in a gel or polymeric matrix is often employed in analytical applications of biosensors because much of the original activity of the free enzyme is retained. However, this approach is limited to relatively small analytes that can readily penetrate the solid matrix. For in vivo measurements, heparin may also be employed to coat the sensor to create a biocompatible nonthrombogenic surface. A technique for reversible binding of enzymes in biosensors involves use of antibodies raised against enzymes (antigens). For reversible immobilization of glycoenzymes one can utilize lectins (carbohydrate binding proteins). Novel protein structures (sequences) including one partner of an affinity pair can be constructed using recombinant DNA technology. These tagged enzymes can subsequently be immobilized to complementary ligands bound to the support for use in enzyme purification and in ELISA.

Analytical protocols based on the use of immobilized enzyme-mediated reactions that are highly specific to the analyte require little, if any, manipulation of the sample (extraction, addition of reagents, dialysis, filtration, etc.). The sensing element is normally reusable and has the great advantage that it does not require consumption of reagents during the reaction. Thus, a single biosensor may often be utilized to make hundreds or thousands of measurements so that the resulting cost per assay is low. In other cases, the biosensor involves a dipstick that undergoes a color change as the enzymatic reaction proceeds.

The most widely employed types of biosensors are those that employ an oxidase to generate hydrogen peroxide. A classic example is the electrode containing an immobilized glucose oxidase that generates an amperometric signal related to the concentration of glucose present in the sample. However, biosensors of these types are often susceptible to interference from other electrochemically active solutes in the sample. A wide variety of techniques have been developed to circumvent or minimize this problem, for example, application of a semipermeable membrane above the

enzyme matrix, use of enzyme field effect transistors, etc. For analytes that are not susceptible to quantitation by simple electrochemical methods, it may be necessary to employ coupled enzyme reactions or optical modes of detection, perhaps taking advantage of optical fibers. Other biosensors may utilize field effect transistors, thermistors, bioluminescence, or chemiluminescence for detection of the analyte.

The IMER approach does not require that the enzyme be placed in close proximity to the detector if the transducer signal is generated by a soluble product or cosubstrate of the enzymatic reaction. In the latter case, a variety of flow systems and postreactor detectors can be utilized to produce simultaneous determinations of the concentrations of several analytes. For example, an IMER can be combined with a high-performance liquid chromatography (HPLC) instrument (perhaps also in combination with mass spectroscopy) for purposes of both qualitative and quantitative analysis. The chemo-, stereo-, and regioselectivities of enzymes facilitate separation and/or identification of analytes that may be present as different isomers (e.g., in peptide analysis based on use of peptidase IMERs in combination with these techniques to obtain structural information about the sequence of amino acids in peptides).

In some cases, coimmobilization of multiple enzymes is required, especially when successive use of two or more enzymes is employed to convert the original substrate to a final product that is easier to detect or that permits one to drive an unfavorable equilibrium situation to completion by consumption of the initial product in a detection reaction yielding the product that serves as the actual analyte.

Two important general categories of biosensor applications are discussed below.

Detection and Analysis of Sugars. Because the refractive index detectors used in HPLC are not very selective and are characterized by low sensitivities for different sugars and their various isomers, reactors containing immobilized enzymes are often coupled to the corresponding chromatographic columns to obtain significant improvements in selectivity and sensitivity. Examples include:

1. Separation and determination of glucose and lactose in a penicillin fermentation broth using a glucose dehydrogenase (GDH) to catalyze oxidation of the β-anomeric form of aldoses to lactones in the presence of NAD^+. The analysis is based on amperometric detection of the NADH formed. The enzymatic reactor is packed with silanized porous glass beads activated with glutaraldehyde as a support for immobilization of GDH from *Bacillus megaterium*.[17]
2. Determination and quantification of sugars in the discharge from the sulfite pulping of lignocellulose using coimmobilization of a mutarotase (MT), from porcine kidney that converts all of the aldoses to their active β-anomers, with a xylose isomerase from *Streptomyces* sp. (that produces the detectable ketoses), a galactose dehydrogenase (from a recombinant *Escherichia coli*), and GDH from *Bacillus megaterium*.[18]
3. Detection of glucose and malto-oligomers (G2–G10) in corn syrup. This assay employs the selective hydrolysis of α-(1,4) and α-(1,6) linkages of malto-oligosaccharides to glucose by GA with amperometric detection at a gold electrode. Glucoamylase from *Aspergillus niger* is supported on Nucleosil 300 previously silanized with (γ-glycidoxypropyl) trimethoxysilane and activated with 1,1′-carbonyldiimidazole.[19]
4. Detection of oligosaccharides (e.g., stachyose, raffinose, sucrose, and fructose) in a soybean extract using invertase hydrolysis of β-D-fructofructoside to fructose, and further oxidation of this sugar by hexacyanoferrate (III) ion in the presence of fructose dehydrogenase (FDH). This analysis is based on a coimmobilization of invertase from *Candida utilis* and FDH from *Gluconobacter* on poly(vinyl alcohol) (PVA) beads and coulometric quantification of the hexacyanoferrate(II) ions formed.
5. Analysis of malto-oligosaccharides using an IMER containing GA, MT, and GDH coimmobilized on an aminated porous silica matrix. This analysis has been used for quantification of sugars in soft drinks, beer, and fermentation broth containing *Penicillium* and *Fusarium sysporum s.*

Analysis of Amino Acids. Differentiation of the L- and D-forms of amino acids is essential because they differ in their biological and physiological properties. Although chromatographic columns that effect separations of chiral compounds could be used for analysis of solutions of these acids, a combination of a reactor containing a stereoselective immobilized enzyme and a chromatographic system provides the necessary selectivity for such analyses.

1. Immobilized L-amino acid oxidase catalyzes the oxidation of L-amino acids to 2-oxo acids. Detection of the hydrogen peroxide product is accomplished using a fluorometric or chemiluminescent assay subsequent to the reaction in the packed bed. L-Amino acids can also be quantified amperometrically using a platinum electrode Ag/AgCl on which the enzyme is

immobilized. L-Lys, L-His, L-Cys, L-Arg, L-Met, L-Leu, L-Ile, L-Tyr, L-Phe, and L-Trp can be quantified by this procedure.

2. Branched-chain L-amino acids can be analyzed using leucine dehydrogenase immobilized on aminated PVA activated with glutaraldehyde. This enzyme catalyzes the deamination of L-Leu, L-Ile, and L-Val to 2-oxo acids in the presence of NAD^+.

There are many instances where it is helpful to use biosensors for the detection of contaminants and monitoring of air and water quality. In some cases, appropriate biosensors exist. Generally speaking, development of such biosensors is a demanding task because of the wide range of potential substrates (including such hazardous substances as chemical and biological warfare agents) and the associated problems of interference effects, the necessity for unattended operation, and the need for robust sensors in harsh environments. Analyses for aldehydes produced in industrial plants, incinerators, automobile exhausts, or foodstuffs (aroma and storage controls) are based on oxidation of aldehydes to carboxylic acids by immobilized aldehyde dehydrogenase in the presence of a thiol, K^+, and NAD^+. Determinations of some metals (e.g., zinc) via IMERs are sensitive, specific, fast (minutes), and do not require chromatographic separations.

Medical/Clinical Applications

Liang, Li, and Yang have reviewed biomedical applications of immobilized enzymes with emphasis on the use of biosensors for the diagnosis of disease states.[20] Electrodes containing immobilized enzymes constitute the primary technology used in this application. Table 4, adapted from Liang, Li, and Yang, contains a summary of applications of enzyme-based sensors in clinical diagnosis.[20]

Diagnosis of renal problems, xanthinuria, and toxemia of pregnancy via determination of the ratio of hypoxanthine to xanthine in plasma is facilitated by the use of biosensors. Xanthine oxidase immobilized on aminopropyl-CPG (controlled pore glass) activated with glutaraldehyde oxidizes hypoxanthine first to xanthine and then to uric acid. Use of an IMER with biosensors for hypoxanthine, xanthine, and uric acid provides the necessary data. Pre- or postcolumn enzymatic reactions catalyzed by creatinine deiminase, urease, alkaline phosphatase, ATPase, inorganic pyrophosphatase, or arylsufatase facilitate analysis of uremic toxins (simultaneous detection of electrolytes, serum urea, uric acid, creatinine, and methylguanidine).

Analysis of steroid hormones for control of endocrine functions by radioinmmunoassay fails for homologous steroids. Instead, one can employ highly specific steroid dehydrogenases to mediate oxidation of the hydroxy functions of hydroxysteroids. Then, highly sensitive fluorescence detection is used to determine specific positions of OH groups and α and β configurations with HPLC systems combined with an appropriate postcolumn enzymatic reactor. Similarly, one can determine serum bile acid concentrations as an indicator of liver disease by combining an IMER containing 3α-hydroxysteroid dehydrogenase with gas or liquid chromatography.

In addition to the steroid hormones, the steroids utilized for pharmaceutical applications can be selectively determined using appropriate immobilized enzymes in an IMER. Use of α-, β-, and/or stereoespecific dehydrogenases permits one to enhance the selective

Table 4 Applications of biosensors containing immobilized enzymes for clinical analyses

Substrate (analyte)	Immobilized enzyme(s)	Linear range (approximate)
Glucose	Glucose oxidase/GDH	50 mM
Lactate	Lactate oxidase	27 mM
Oxalate	Oxalate oxidase	1 mM
Urea	Urease	100 mM
Glutamate	Glutamate oxidase	200 μM
Carnitine	Carnitine dehydrogenase and diaphorase	1 nM
Theophylline	Theophylline oxidase	30 μM
Creatine and creatinine	Creatininase, creatinase, and sarcosine oxidase	30 mM
Cholesterol	Cholesterol oxidase	3 mM
Amino acids	Amino acid oxidase	10 mM
Acetylcholine and choline	Acetylcholine esterase and choline oxidase	100 μM
Bilirubin	Hemoglobin and glucose oxidase	
γ-Aminobutyric acid	Catalase and γ-glutamate oxidase	10 nM

detection and chiral resolution of steroids. Detection of anabolic steroids in urine by these methods is employed in sports medicine as a means of controlling illicit use of these drugs by athletes.

Flow injection analysis (FIA) for ethanol can be utilized for blood alcohol determination in drunken driving situations.

One can also envision applications involving the use of encapsulated or entrapped enzymes in bioreactors for therapeutic applications involving detoxification of deleterious substances or correction of metabolic deficiencies. In these applications, the enzymes could be contained within artificial cells [e.g., modified red blood cells (erythrocytes) or liposomes]. Liang, Li, and Yang have reviewed biomedical applications of immobilized enzyme bioreactors.[20]

SUMMARY

Techniques for immobilization of enzymes and applications of immobilized enzymes are discussed.

Both chemical and physical methods may be used to immobilize biocatalysts while retaining or modifying their activity, selectivity, or stability. Among the techniques used for immobilization of enzymes are physical adsorption, covalent bonding, ionic binding, chelation, cross-linking, physical entrapment, microencapsulation, and retention in permselective membrane reactors. The mode of immobilization employed for a particular application depends not only on the specific choice of enzyme and support, but also on the constraints imposed by the microenvironment associated with the application.

Commercial uses of immobilized enzyme technology are limited in scope, but encompass industrial production of HFCS, biosensors, clinical diagnostic procedures, chemical analyses, chiral syntheses, and therapeutic applications.

CONCLUSIONS

Immobilized enzyme technology is not a stagnant technology. It has evolved in recent decades to the point where it can be employed for select industrial processes and, more importantly, for rapid analyses of significant import in both clinical and analytical situations. The analytical applications also have important implications for monitoring air and water quality in support of environmental regulations, as well as in analyses of process effluents and industrial wastewaters. Biosensors based on immobilized enzyme technology offer significant commercial potential for detecting food spoilage and chemical and biological warfare agents, as well as for monitoring food storage conditions.

One of the areas in which immobilized enzymes are expected to have major impact is in the biocatalysis of reactions in organic media, for example, in the synthesis of chiral compounds as intermediates in the manufacture of pharmaceuticals and in the modification of naturally occurring fats and oils to produce value-added products targeted at the nutraceuticals market.

Use of recombinant DNA technology, other means of genetic engineering, and enzymes obtained from thermophilic and halophilic organisms can be expected to produce novel enzymes with enhanced selectivity, activity, or stability. These novel enzymes may be utilized to effect reactions at elevated temperature, in organic media, and in other harsh environments where stringent requirements must be met. In addition, further advances in permselective membrane technology and/or affinity separation media may facilitate improvements in the biosensors employed in analytical applications as a result of immobilization of both enzymes and cofactors in a manner that minimizes leakage problems.

Advances in the understanding of structure–activity/selectivity relations for enzymes evolving from the use of x-ray, NMR, and other instrumental methods for characterization of enzyme structures should contribute to the development of improved immobilized enzyme systems for both analytical and industrial applications. Immobilized enzyme technology has enormous potential, but significant advances on several fronts are necessary prior to widespread industrial use of this technology. Katchalski-Katzir has discussed this problem in a review of past successes and failures in efforts to employ immobilized enzymes in the food, pharmaceutical, and chemicals industries.[21]

From an industrial perspective, economic considerations are paramount when deciding whether or not to adopt a new technology. A crucial consideration for future development of large-scale industrial processes employing immobilized enzyme technology is that they be cost-effective relative to alternative technologies. To date, immobilized enzyme technology has, in most instances, failed to pass the test of economic viability for chemical, pharmaceutical, and food processing applications. On the other hand, this technology has found increasing numbers of applications in clinical and analytical applications, where it proves to be cost-effective. Indications are that in the future, novel and better commercial IMERs will be utilized more extensively and routinely in FIA systems in analytical applications.

Incineration and Combustion

I

Selim M. Senkan
Department of Chemical Engineering, University of California, Los Angeles, California, U.S.A.

INTRODUCTION

Incineration is the thermal treatment of wastes generated as by-products of our technological society, and as such represents an important application of combustion.[1] Incineration not only reduces the volume of waste generated, but also results in the detoxication, decontamination, and sterilization of waste, while allowing the recovery of substantial amounts of energy and to a lesser extent materials. Although the prevention of waste generation in the first place is the most desirable option, our societal concerns for safety, security, and health, as well as simple processing inefficiencies inevitably results in the creation of some waste, which must be dealt with efficiently and effectively. Incineration provides an effective and efficient solution to these waste products.

The primary thermodynamic products of waste incineration, like any combustion process, are CO_2 and H_2O. When wastes contain chlorine and sulfur compounds, their combustion products include HCl and SO_x.[2] Incinerator exhausts may also contain unburned principle organic hazardous compounds (POHC) that was fed, particulate matter (PM), such as soot and fly ash; oxides of nitrogen (NO_x); products of incomplete combustion (PIC) that include carbon monoxide (CO), volatile organic compounds (VOC) such as methane, acetylene, 1,3-butadiene, and benzene; polycyclic aromatic hydrocarbons (PAH) such as anthracene, pyrene, and benzo(a)pyrene; chlorinated aromatics, including polychlorinated di-benzo dioxins (PCDD) and furans (PCDF); and metals, such as lead, arsenic, and mercury, and their oxides. Incineration also produces a residue (bottom ash) of incombustible and partially combusted waste that must be properly disposed in a secured landfill. As a result of several unfortunate and highly publicized incidents involving dioxin exposure in the past, little public support exists today for the broad utilization of incineration. This is regrettable because steadily increasing waste generation coupled with rapidly diminishing secured landfills call for the larger scale implementation of the versatile incineration technology.

One of the most extensive fundamental information sources on combustion and incineration is the *Proceedings of the International Symposium on Combustion*, which is regularly published by the Combustion Institute. In addition, selected books listed at the end of this entry provide information on combustion processes. In particular, the books by the National Academy of Engineering, *Waste Incineration and Public Health,*[3] *Pollutants from Combustion*: *Formation and Impact on Atmospheric Chemistry*,[4] and *Gas-Phase Combustion Chemistry*,[5] represent some of the more recent compilations. Information on federal government regulations pertaining incinerators and emissions from these devices can be found at the US Environmental Protection Agency (EPA) internet site http://www.epa.gov/epaoswer/hazwaste/combust/newmact/hazmact.htm. This web site provides information both on incinerator standards as well as the data EPA used to establish these standards. The industrial perspective on government regulations as well as technological issues facing incinerators can be obtained from the internet site of the Coalition for Responsible Waste Incineration (CRWI, www.crwi.org).

WASTE GENERATION

The waste generated can be categorized into three groups:

1. Municipal solid waste, defined to be nonhazardous, is widely generated by households, commercial establishments such as restaurants, public, private, and government facilities.
2. Hazardous waste, which is defined under the EPA's Resource Conservation and Recovery Act (RCRA) as potentially dangerous to human health or the environment on the basis of being flammable, toxic, corrosive, or reactive, are generated by manufacturing companies, universities, hospitals, government facilities, as well as to a smaller extent by households.
3. Medical waste is separately categorized because of its infectious or toxic characteristics, and is generated primarily by hospitals, medical laboratories, and offices.

As shown in Fig. 1, the amount of municipal solid waste generated in the United States steadily increased

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120037169

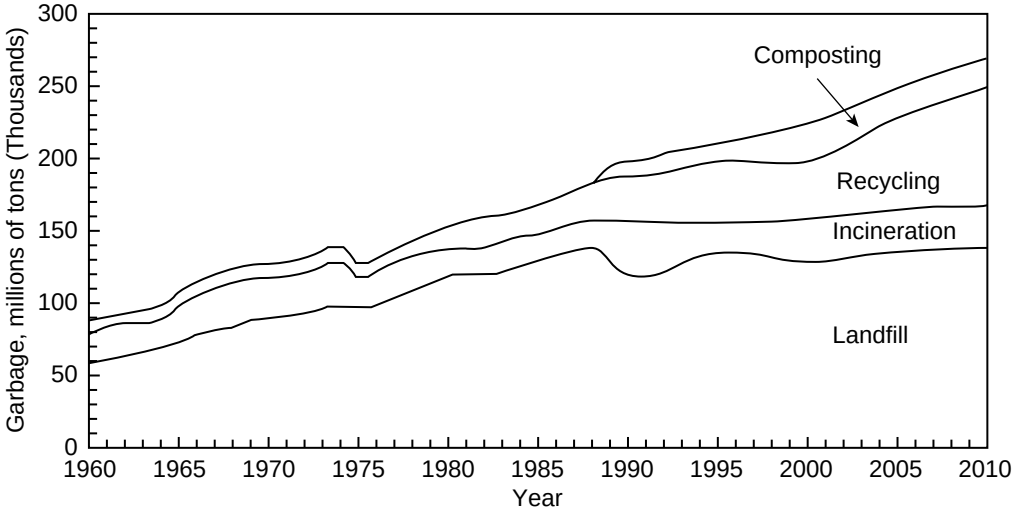

Fig. 1 Trends in municipal solid-waste generation and management in the United States, 1960–2010. (From Ref.[3].)

over the past four decades in spite of incentives for source reduction and recycling. Nearly, 80% of this waste is combustible (Fig. 2), thus can be disposed of by incineration. Yet, only 10–15% of municipal waste is incinerated (Fig. 1). This is because of: 1) the availability of lower-cost disposal alternatives, such as landfilling; 2) the opposition from local advocacy groups; and 3) the politically popular recycling programs, which decreased the public support for incineration. Clearly, as landfills become unavailable and exporting wastes are no longer feasible, we must rely on incineration technology to provide a more permanent solution to our growing waste disposal problems.

Municipal waste incinerators typically are large, state-of-the-art facilities where volume reduction and power and/or steam generation are often accomplished simultaneously. Owing to the presence of a large combustible fraction, municipal wastes can be incinerated directly with little use of an auxiliary hydrocarbon fuel.

Our estimates of the amount of hazardous wastes generated are less certain because of the inconsistent use of the definition of ''hazardous waste.'' Consequently, it has been difficult to obtain reliable historical data on generation and to determine the amount of waste reduction attained. For example, according

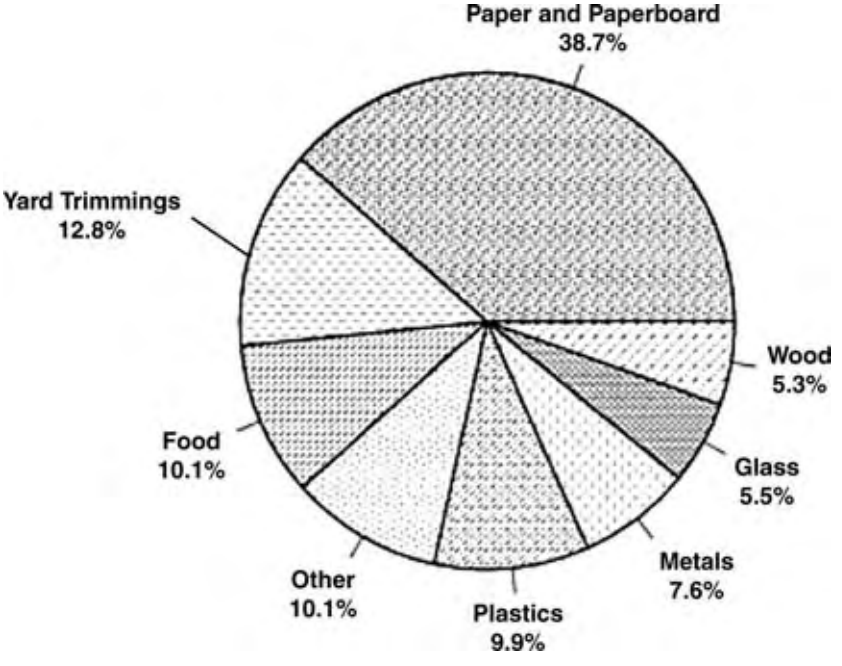

Fig. 2 Municipal solid-waste composition by weight. (From Ref.[3].)

to EPA estimates, over 264 million metric tons of hazardous wastes were managed in the early 1980s.[3] In contrast, the Chemical Manufacturers Association reported over 600 million metric tons of hazardous wastewater and about five million metric tons of hazardous solid waste during the same period.[3]

Rotary kilns (e.g., cement kilns), metal-recovery and smelting furnaces, mobile incinerators, and industrial boilers are primarily used to incinerate hazardous wastes. The obvious benefits of combustion of waste as fuel are the recovery of energy from the waste and the conservation of fossil fuels. Because the kiln and furnace operators are paid to take in the waste, rather than having to pay for fuel, also create economic incentives. Mobile incinerators are most commonly used for soil decontamination projects, and can be moved from site to site once the job is completed.

Medical wastes are generated in quantities significantly lower than the municipal and hazardous wastes, yet their infectious nature causes them to be the focus of significant attention. Typical composition of medical waste is shown in Fig. 3. As over 70% of the medical waste is combustible, incineration again represents an effective management tool. Because medical wastes consistently contain chlorinated plastics, e.g., polyvinyl chloride (PVC) gloves, as well as human tissue and organs, their incineration products can contain significant levels of chlorinated dioxins and furans.[6]

WASTE INCINERATORS

In Table 1, waste generation in the United States, the number of incineration facilities, and the amount of waste combusted are summarized. As seen from this table, the most prevalent incinerators are the medical waste incinerators. Industrial boilers and furnaces were the next most abundant type of incineration facilities, followed by municipal waste incinerators.

HEALTH EFFECTS OF INCINERATION

The adverse health effects of incineration by-products, or any combustion process, can be acute or long term. In Table 2, the acute toxicities of selected PIC are presented together with some other reference materials, where the toxicities are expressed in terms of LD_{50} (Lethal dose that kills 50% of laboratory animals).[7] As evident from this table, tetrachloro di-benzo dioxin (TCDD) has been shown to be extremely toxic with LD_{50} of 0.001 mg/kg, to guinea pigs. However, it is important to note that this extreme toxicity was not seen in other laboratory animals, as well as in humans. The latter was determined as a result of several tragic accidents in which large populations were exposed to dioxins (Seveso, Italy, Times Beach Missouri, U.S.A.). Unfortunately, LD_{50} values do not truly reflect the full adverse impact of a chemical or their mixtures.

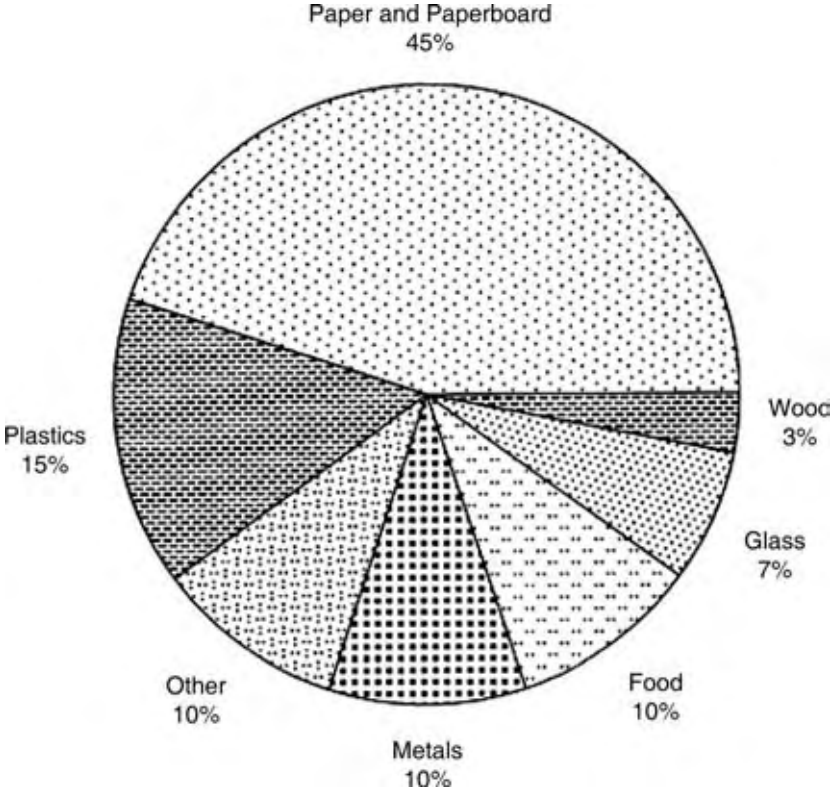

Fig. 3 Typical medical waste composition. (From Ref.[3].)

Table 1 Waste generation in the United States, number of incineration facilities, and amount of waste combusted

Type of waste	Amount generated (million tons/yr)	Number of incineration facilities	Amount of waste combusted (million tons/yr)
Municipal solid waste	209	122	36
Hazardous waste	276		3
On-site incinerators		129	
Commercial incinerators		20	
Industrial boilers and furnaces		950	
Cement kilns		18	
Light weight aggregate kilns		5	
Medical waste		1655	0.8

(From Ref.[3].)

Chronic exposure to some chemicals, such as some isomers of PAH, at doses that do not show any acute toxicities are well known to induce cancer, cause mutations, or are teratogens.[7] Complex mixtures present challenges even far greater than individual molecules.

In Fig. 4, the relative contribution of individual airborne hazardous pollutants to lung cancer rates are presented.[8] The results presented in Fig. 4 were obtained after removing cancer incidents that are directly attributable to tobacco smoke which primarily is an indoor pollutant. As seen from this figure the PIC (which includes PAH), 1,3-butadiene, benzene, and formaldehyde, which are produced by all combustion/incineration processes, were the largest contributors to lung cancer, representing in excess of 50% of the risk, far more than dioxins. However, because different chemicals target different parts of the body, it is important to consider other organs and types of cancer in assessing the full impact of chemicals on human health.[7]

Table 2 Approximate acute LD_{50} values for some chemicals for laboratory animals

Chemical	LD_{50} (mg/kg)
Ethanol	10,000
Sodium chloride	4000
Benzene	930
Phenobarbital sodium	150
Formaldehyde	100
Picrotoxin	5
Strychnine sulfate	2
Nicotine, arsenic	1
D-Tubocurarine	0.5
Hemicholinium-3	0.2
Tetrodotoxin, mercury	0.1
TCDD	0.001
Botulinum toxin	0.00001

INCINERATION TECHNOLOGY

Today waste incinerators can be designed and operated to achieve better than 99.999% destruction and removal efficiencies (DRE) of the waste compounds and to only emit extremely low concentrations of the pollutants of concern under normal operating conditions. In addition, operator training can help ensure that an incinerator facility is run at its peak combustion efficiency and the emission-control devices are operated optimally for maximum pollutant capture or neutralization. However, as with all types of facilities, there exist off-normal (upset) operating conditions that might result in the temporary increase in the emissions of pollutants. Such conditions occur during incinerator startup or shutdown or when the composition of the waste being burned changes sharply. Upset conditions can also be caused by malfunctioning equipment, operator error, or inadequate maintenance. Continuous monitoring of the combustion chamber and incinerator emissions can provide useful feedback and help control the incinerator operations.

Proper design and operation of an incinerator require attention to *temperature*, *turbulence* of the mixture being combusted, and residence *time* at the incineration temperature, generally referred to as the 3*T*s of combustion. To achieve efficient combustion, every part of the waste stream must reach an adequately high temperature for a sufficient period of time, and there must be adequate mixture of waste and oxygen. Cool spots can occur next to the furnace's walls where heat is extracted such as in boiler-type furnaces. Cold spots are less likely in refractory lined furnaces, such as in cement kilns.

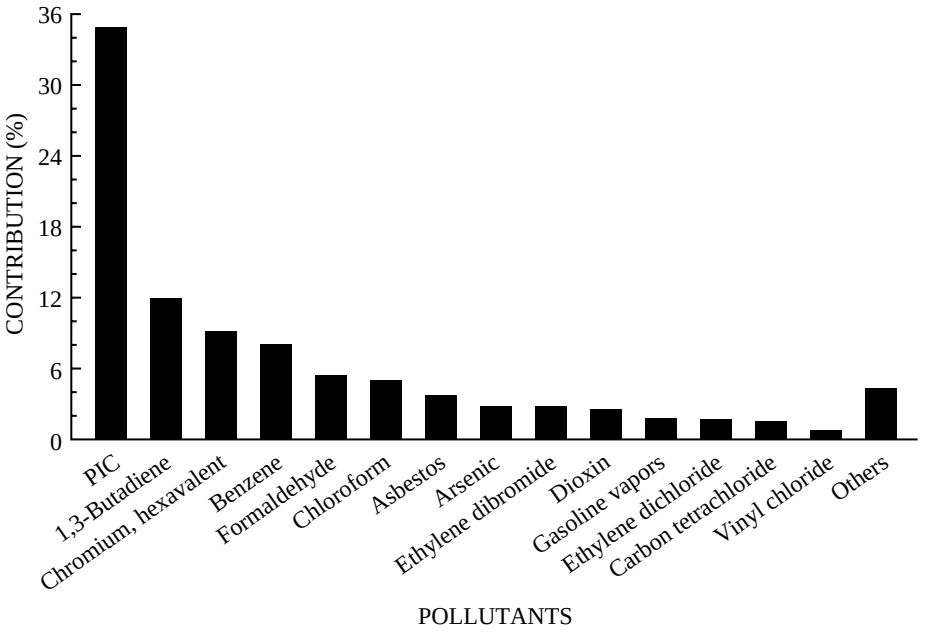

Fig. 4 Relative contribution of various air pollutants to lung cancer. (From Ref.[8].)

The temperature achieved in incineration is the result of heat released by the oxidation process, and has to be maintained high enough to ensure that combustion goes to completion, but not so high as to damage equipment or generate excessive thermal NO_x and metal emissions. Typically, temperatures are controlled by limiting the amount of material charged to the furnace to ensure that the heat-release rate is in the desired range, and then adjusting the resulting conditions by varying the amount of excess air.

Turbulence is needed to provide adequate contact between the waste and oxygen across the combustion chamber (macroscale mixing). Nevertheless, in the final stage, combustion at the molecular level occurs via diffusion or premixed flames, although the former is the dominant mode of waste destruction in practical systems.

Normally, incinerator exhausts are monitored for temperature, CO, NO_x, and O_2. Data covering the entire spectrum of emissions are often collected only for short periods of time. More emission information is needed, especially for dioxins and furans, heavy metals, and PM. Limited research is underway for the development of reliable and rugged technologies that will provide the real time, continuous monitoring of the entire spectrum of emissions from incinerators.[9,10] However, their routine use in incinerators as continuous emissions monitors is not practised yet.

A sketch of a modern waste-incineration facility is shown in Fig. 5. Such a facility includes the following:

1. Waste storage and feed preparation.
2. Incineration furnace producing hot gases and a bottom ash residue for disposal.
3. Exhaust gas cooling, frequently involving heat recovery via steam generation.
4. Further treatment of the cooled gases to remove air pollutants and disposal of residuals from this treatment process.
5. Dispersion of the treated exhaust gases (CO_2 and H_2O) to the atmosphere through an induced-draft fan and stack.

The types of incinerators used are listed in Table 3. Municipal solid-waste furnace designs have evolved over the years, with the newer waste incinerators being waste-to-energy plants that produce steam for electric power generation.

The predominant hazardous-waste incinerator designs are liquid-injection furnaces and rotary kilns. Hazardous wastes are also burned in cement kilns, light-weight aggregate kilns, industrial boilers, halogen–acid recovery furnaces, and sulfuric acid regeneration furnaces. Medical wastes are burned in fixed-hearth incinerators, with staged combustion. The smallest medical-waste incinerators are single-chamber, batch-operated devices, most of them employing afterburners.

Fig. 6 is a sketch of a rotary kiln incinerator, illustrating many of the essential phenomena associated with incineration. Rotary kilns are versatile incinerators because of their ability to treat solid, liquid, and gaseous wastes. Solid and liquid wastes are destroyed primarily through establishment of diffusion flames, i.e., flames that surround solid waste particles or droplets or form a flame sheet adjacent to surfaces.

To achieve highest levels of waste destruction, a secondary combustion chamber is often used in

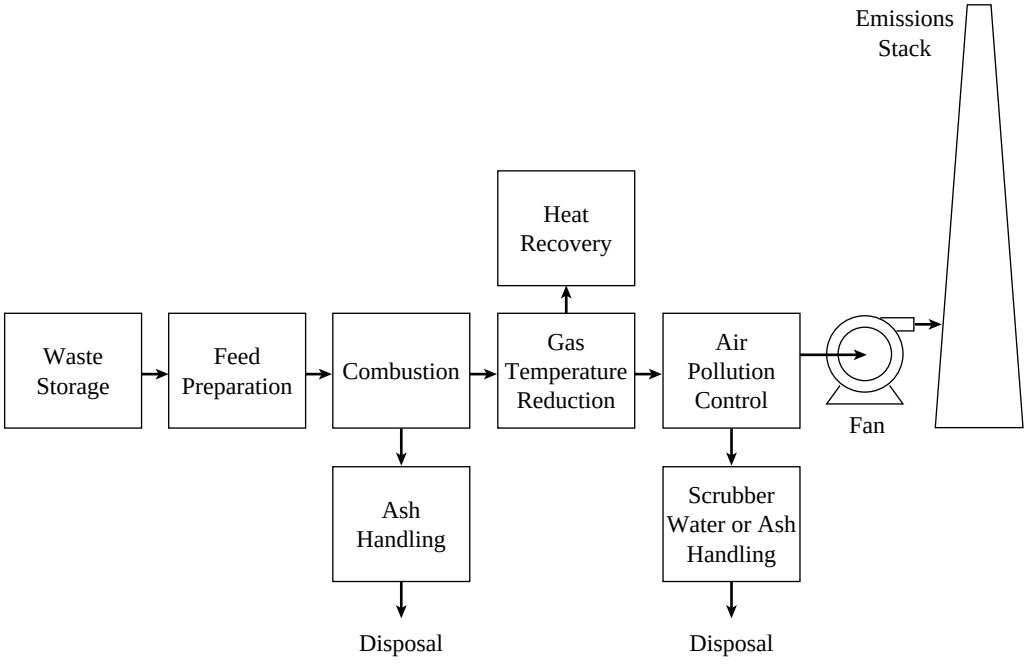

Fig. 5 A schematic of a typical waste incineration facility. Although incinerators have similar components indicated in the figure, combustion chamber designs vary significantly from application to application. (From Ref.[3].)

modern incinerators. The second stage ensures that wastes and by-products that may escape the first stage, for example, because of transient explosions of waste drums or ''puffs,'' are destroyed to achieve the required DRE. Two-stage combustion can also be used to simultaneously achieve waste destruction and NO_x reduction, although the former is the overriding factor in waste incineration. The product gases entraining both organic (i.e., soot) and inorganic (e.g., fly ash) particles are then subjected to a sequence of air pollution control devices (APCD), such as electrostatic precipitators, dust bags, etc. before being discharged

Table 3 Furnace designs used in waste inceneration

Waste type	Furnace design	Type application
Municipal solid waste	Mass burn Waterwall furnace Reciprocating or other continuous moving grate	Most newer municipal-scale facilities
	Mass burn Refractory furnace lining Various grate or stationary hearth designs	Old or small facilities
	Refuse-derived fuel Spreader-stoker/cyclone furnaces	Few facilities in the United States
	Fluidized bed	Foreign applications
Hazardous waste	Liquid injection	Common
	Rotary kiln with secondary combustion chamber	Common
	Fluidized bed	Few in the United States More common for biosludge incinerators
	Fixed hearth with secondary chamber	Mostly with plant trash co-feed
Medical waste	Multiple chamber	Old IIA design for older facilities
	Controlled-air primary chamber with afterburner	Predominant design in the United States since 1970s
	Rotary kiln with afterburner	Few in the United States

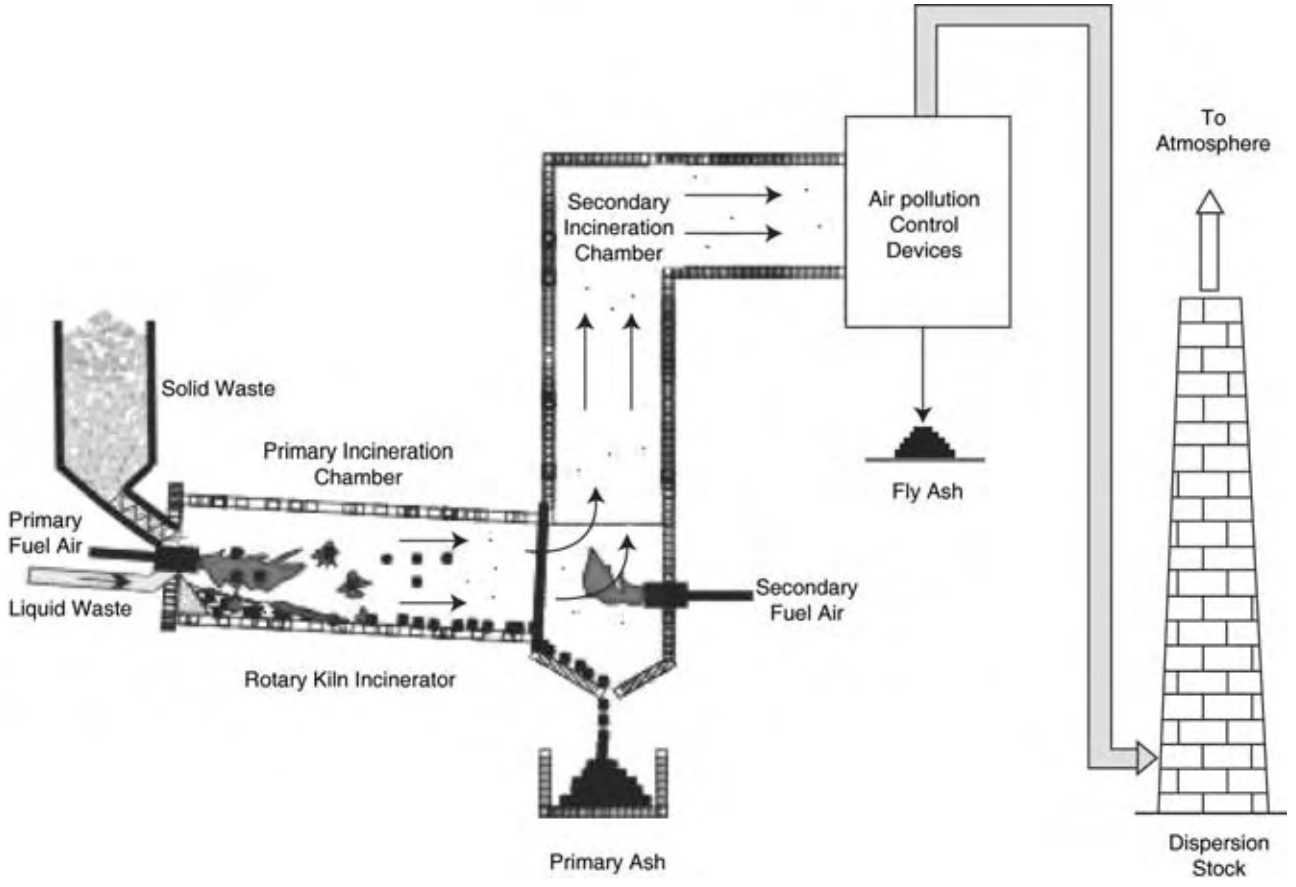

Fig. 6 Schematic of a versatile waste incinerator. Rotary kiln furnaces are preferred because of their applicability to treat different types of wastes, including solid wastes.

into the atmosphere through the stack. The primary ash produced in the main combustion chamber, together with the fly ash collected by the APCD must also be stabilized against leaching and stored in secure landfills.

INCINERATION SCIENCE

Incineration is a rapid, exothermic reaction between a fuel (waste) and oxygen (O_2). Incineration produces the same end products and by-products, whether the material burned is municipal solid waste, hazardous waste, or medical waste. This is because of the fact that complex fuel molecules first undergo thermal decompositions upon being preheated by the preceding flame, forming smaller molecules such as methane, acetylene, ethylene, carbon monoxide, hydrogen, and alike, and it is the combustion of these smaller molecules that primarily influence the nature of combustion products and pollutants formed. This aspect of combustion chemistry has significantly helped in the development of detailed kinetic mechanisms of combustion for all types of hydrocarbon fuels.[5,11,12] Solid decomposition products such as solid carbon (char) and ash also form when the materials being burned lack adequate hydrogen and oxygen or contain metals, respectively.

Premixed and Diffusion Flames

As noted earlier, waste destruction occur as a consequence of premixed and diffusion flames. In premixed flames, the fuel and oxidizer are mixed at the molecular level, and the relative amounts of the reactants are described by the equivalence ratio (ϕ), defined below:

$$\phi = (\text{Fuel amount}/\text{Oxidizer amount})_{\text{actual}}/(\text{Fuel amount}/\text{Oxidizer amount})_{\text{stoichiometric}}$$

Based on this definition, $\phi > 1$ represents fuel-rich and $\phi < 1$ represents fuel-lean conditions. Premixed systems generally are bounded by lower and upper flammability limits, i.e., ϕ, within which self-sustaining flames occur. Flame temperatures (T) first increase and then decrease as a function of increased equivalence

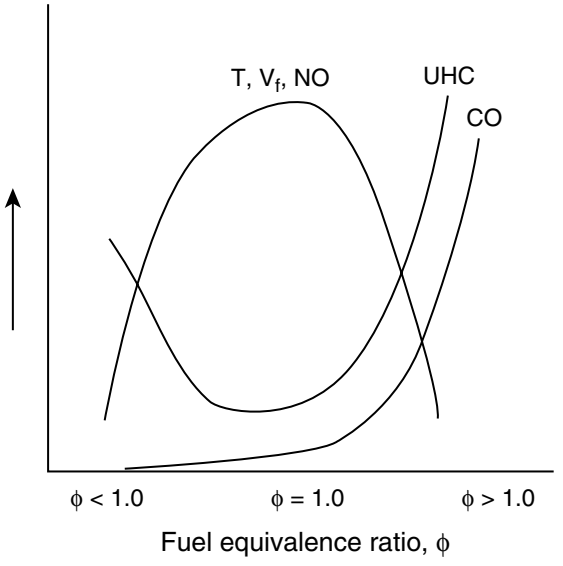

Fig. 7 Effects of equivalence ratio on flame temperature, flame velocity, NO, UHC, and CO.

ratio, exhibiting a maximum around the stoichiometric conditions as shown in Fig. 7. The presence of excess air or excess fuel decreases the maximum attainable flame temperatures. Premixed systems also exhibit a unique combustion wave propagation velocity (V_f), which vary with equivalence ratio similar to temperature. Because increased flame temperature and velocity correspond to increased intensity of combustion, the formation and emission of unburned hydrocarbons (UHC), which include both POHC and PIC, mirror these variables. The NO_x levels produced in flames also follow the temperature pattern because of combined thermodynamic and kinetic reasons as shall be discussed in what follows.

In diffusion flames, combustion reactions occur at an interface to which the fuel and oxygen diffuse from their sources in accordance with the overall combustion stoichiometry. Thus, there is no unique equivalence ratio that describes a diffusion flame. Because a flame is produced at the stoichiometric interface, the maximum flame temperatures reached in diffusion flames are high, e.g., close to adiabatic flame temperatures.

For stable combustion, flame temperatures generally must exceed 1400°C, and typically range approximately between 1500°C and 1900°C or more. The high temperatures preheat the incoming fuel and air through conduction, convection, and radiation. In premixed systems, the extent of air dilution can be used to control the maximum flame temperature. In diffusion flames, however, because stoichiometric concentrations prevail at the flame front, the resulting maximum temperatures are considerably higher, e.g., about 2000°C for natural gas and 2200°C for diesel fuel flames, respectively. Consequently, diffusion flames are easier to stabilize than premixed flames. On the other hand, the higher temperatures associated with diffusion flames promote the formation of certain pollutants, such as NO_x and soot.

In Fig. 8, actual laboratory pictures of premixed and diffusion flames of methane are presented. Flame luminosity increases with increasing equivalence ratio as a consequence of increased production of soot. Increasing luminosity also increases radiative heat transfer, which is desirable to extract as much thermal energy as possible from combustion. Also shown in Fig. 8 are probes to withdraw samples from within the flames, which subsequently can be analyzed by techniques such as gas chromatography, mass spectrometry, or both. Indeed, these types of measurements have been the primary source of information on flame chemistry, contributing significantly to our understanding of the incineration chemistry. For example, we now know that flames can contain hundreds of intermediate species, and detailed chemical kinetic mechanisms must be invoked to describe combustion processes.[13]

Fig. 9 shows concentration profiles of some selected species in a fuel rich, premixed methane flame.[14] Clearly, even the chemistry of combustion of a simple hydrocarbon fuel such as methane is considerably complex. The fuel molecule, before it ultimately produces CO_2 and H_2O, undergoes a series of intermediate

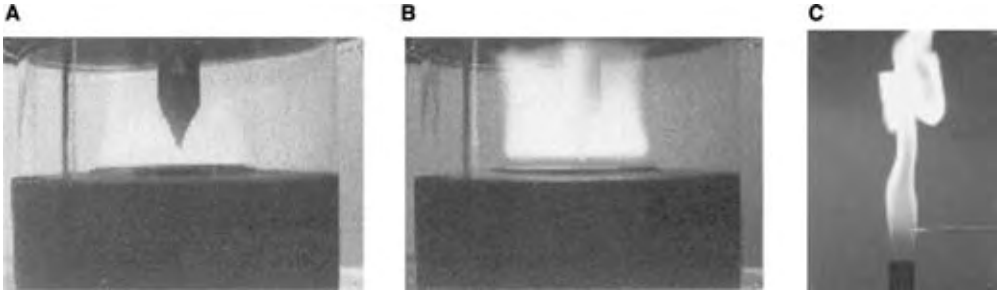

Fig. 8 Laminar premixed flames of methane. (A) Slightly fuel rich; (B) fuel-rich and sooting; and (C) diffusion flame. Note increased luminosity with increasing equivalence ratio.

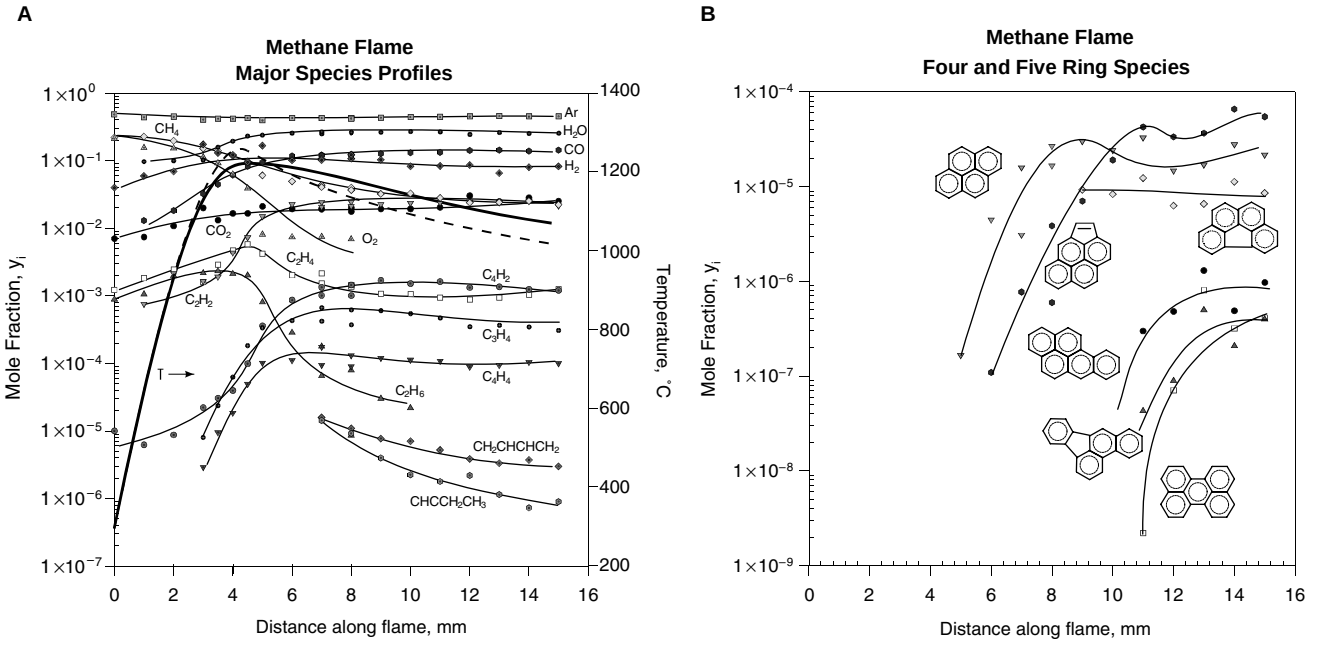

Fig. 9 (A) Major species concentration profiles and (B) Some of the polycyclic aromatic hydrocarbons (PAH) formed in a fuel-rich, premixed laminar methane flame; the formation of a large number of intermediates and by-products are evident. Highly toxic benzo-*a*-pyrene is the 3rd PAH from the bottom. (From Ref.[14].)

reaction steps, which can be described as:

$$CH_4 \rightarrow CH_3^{\bullet} \rightarrow CH_2O \rightarrow CO \rightarrow CO_2$$

(CH3$^{\bullet}$ represents a methyl radical)

where, CO oxidation represents the last sequence in CH_4 combustion, as well as in the combustion of all the hydrocarbons.[11] The main CO oxidation proceeds through its reaction with the OH$^{\bullet}$s:

$$CO + OH^{\bullet} \rightarrow CO_2$$

The OH$^{\bullet}$, together with H$^{\bullet}$ and O$^{\bullet}$, are some of the most important free radicals in flame combustion processes.[15,16] Collectively H$^{\bullet}$, O$^{\bullet}$, and OH$^{\bullet}$ help establish the *radical pool* in flames through the following chain branching reactions:

$$H^{\bullet} + O_2 \rightarrow OH^{\bullet} + O^{\bullet}$$

$$O^{\bullet} + H_2 \rightarrow OH^{\bullet} + H^{\bullet}$$

The interaction of H$^{\bullet}$ radicals with O_2 is particularly significant. At low temperatures, the H$^{\bullet}$ and O_2 combine to form relatively less reactive $HO_2^{\bullet}$. However, at higher temperatures associated with flames, the above chain branching reaction takes over and dominates the combustion process. Because H$^{\bullet}$ plays such a crucial role in flame propagation, its removal from the radical pool has been exploited as a strategy for the development of flame retardants.[17,18]

The above reactions also describe H_2 combustion, an essential submechanism in hydrocarbon combustion. Methane destruction in flames occurs through H$^{\bullet}$, OH$^{\bullet}$, and O$^{\bullet}$ radical attack, which can be shown as:

$$CH_4 + H^{\bullet} \rightarrow CH_3^{\bullet} + H_2$$

$$CH_4 + OH^{\bullet} \rightarrow CH_3 + H_2O$$

$$CH_4 + O^{\bullet} \rightarrow CH_3^{\bullet} + OH^{\bullet}$$

Once formed, $CH_3^{\bullet}$ radicals can then undergo recombination and dehydrogenation reactions forming a variety of C_2 species, the concentrations of which can reach substantial levels in fuel-rich flames (see Fig. 9):

$$CH_3^{\bullet} + CH_3^{\bullet} \rightarrow C_2H_6$$

$$C_2H_6 + H^{\bullet} \rightarrow C_2H_5^{\bullet} + H_2$$

$$C_2H_5^{\bullet} \rightarrow C_2H_4 + H^{\bullet}$$

$$C_2H_4 + H^{\bullet} \rightarrow C_2H_3^{\bullet} + H_2$$

$$C_2H_3^{\bullet} \rightarrow C_2H_2 + H^{\bullet}$$

Based on detailed chemical kinetic modeling studies, the vinyl radicals appear to play an important role

on flame chemistry.[13] In the presence of abundant oxygen, vinyl radicals undergo oxidation reactions producing CO and CO_2:

$$C_2H_3^\bullet + O_2 \rightarrow CHO^\bullet + CH_2O$$

$$CHO^\bullet \rightarrow CO + H$$

$$CO + OH^\bullet \rightarrow CO_2 + H^\bullet$$

However, under fuel-rich conditions, further molecular weight growth becomes likely by the competing polymerization reactions leading to C_3, C_4, C_5, C_6, aromatics, and polyaromatic species.[13,19,20] Examples of these reactions include:

$$C_2H_3^\bullet + CH_3 \rightarrow C_3H_6^\bullet \rightarrow C_3H_4 + H_2$$

$$C_2H_3^\bullet + C_2H_2 \rightarrow C_4H_5^\bullet \rightarrow C_4H_2 + H_2 + H^\bullet$$

$$C_4H_5^\bullet + C_2H_2 \rightarrow C_6H_7^\bullet \rightarrow C_6H_6(\text{benzene}) + H^\bullet$$

$$C_3H_4 + C_3H_3^\bullet \rightarrow C_6H_6(\text{benzene}) + H^\bullet$$

$$C_6H_6 + C_2H_3^\bullet \rightarrow C_6H_6C_2H_3^\bullet(+C_2H_2) \rightarrow C_{10}H_8(\text{naphthalene}) + H_2 + H^\bullet$$

Subsequent molecular weight growth reactions of C_6H_6 (benzene) and $C_{10}H_8$ (naphthalene) then produce even higher molecular weight PAH, some of which are presented in Fig. 8. Further growth in the molecular weights of hydrocarbon by-products results in the formation of species with extremely low vapor pressures. These larger species then condense and further dehydrogenate producing heterogeneous (i.e., liquid) nuclei for soot formation, which is an important universal characteristic of fuel rich flames (Fig. 10).

The nature of intermediates formed in diffusion flames is similar to the premixed ones, albeit differences in the contacting pattern. In Fig. 11, the species concentration profiles in a laminar ethylene diffusion flame front are presented.[21] The fuel and oxygen diffuse toward each other undergoing virtual annihilation within the flame zone concomitant with the establishment of a peak temperature of about 1600°C. Because premixed systems provide a better control of combustor temperature, and many practical combustion devices operate under diffusion limited conditions, considerable effort has been expended to ensure the rapid mixing of fuel and oxygen in combustion chambers and approach premixed conditions.

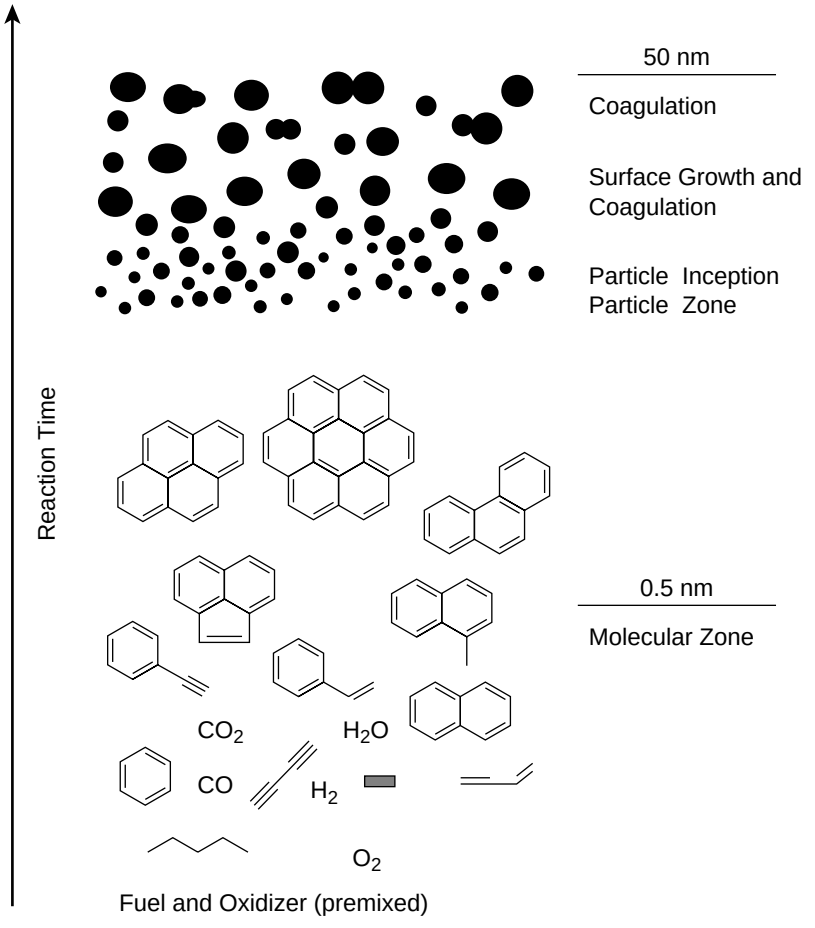

Fig. 10 Schematic of soot growth from fuel molecules through PAH. (From Bockhorn, 1994.)

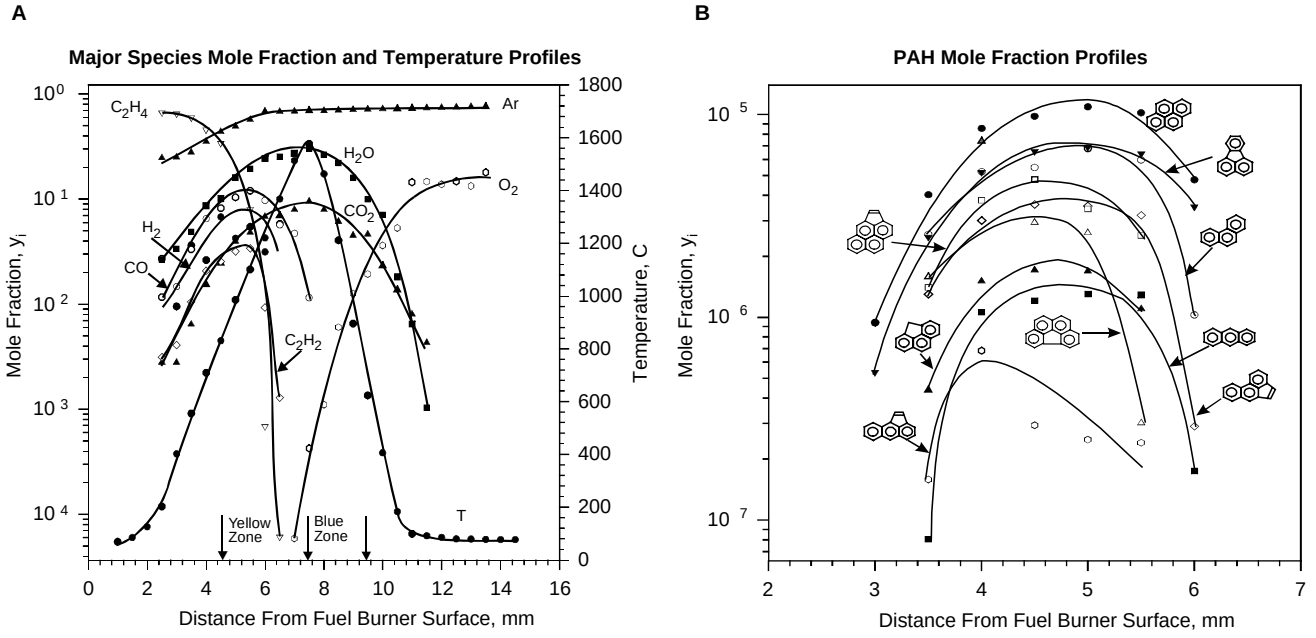

Fig. 11 Species concentration profiles vs. distance from fuel burner surface for (A) major species and (B) PAHs generated in an ethylene opposed flow diffusion flame. (From Ref.[21].)

NO_x, SO_x, and Other Pollutants

Although higher flame temperatures are desirable for improved waste/fuel destruction, there are also drawbacks. Most significantly, the reactions leading to NO_x formation increase with increasing temperature. This is shown in Fig. 12, where equilibrium NO levels are shown to increase with increasing temperature and decreasing fuel equivalence ratio in methane–air mixtures.[22] At high temperatures, molecular nitrogen and oxygen interact with one another in accordance with Zeldovich or ''thermal NO'' mechanism:[22]

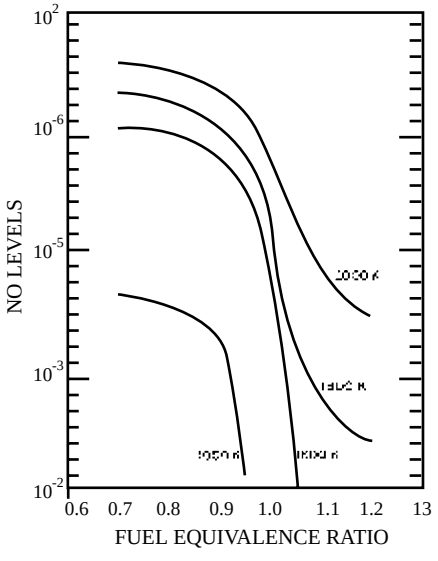

Fig. 12 Equilibrium NO concentration as a function of equivalence ratio for various flame temperatures. (From Ref.[22].)

$$O^{\bullet} + N_2 \rightarrow NO + N^{\bullet}$$

$$N^{\bullet} + O_2 \rightarrow NO + O^{\bullet}$$

The kinetics of these reactions are such that their role becomes significant only above 1500°C. Consequently, diffusion flames are particularly prone to higher levels of thermal NO production because of their higher peak flame temperatures. Besides the Zeldovich mechanism, NO formation can also occur via the ''prompt-NO'' mechanism[23] and from fuel nitrogen sources. In the prompt-NO mechanism, the reactions of CH radicals, produced by the sequential degradation of hydrocarbon fuels, with N_2 are responsible for NO production:

$$CH^{\bullet} + N_2 \rightarrow HCN + N^{\bullet}$$

$$HCN + O^{\bullet} \rightarrow NCO^{\bullet} + H^{\bullet} \quad \text{or} \quad NH^{\bullet} + CO$$

$$NCO + H^{\bullet} \rightarrow NH^{\bullet} + CO$$

$$NH^{\bullet} + O^{\bullet} \rightarrow NO + H^{\bullet}$$

$$NH^{\bullet} + H^{\bullet} \rightarrow N^{\bullet} + H_2$$

$$N^{\bullet} + O_2 \rightarrow NO + O^{\bullet}$$

These and related reactions that are believed to be involved in prompt-NO production are presented in

Fig. 13.[22] This same reaction mechanism also plays an important role in the thermal de-NO_x process to remove NO from combustion products using NH_3 and is discussed later.

When waste materials contain nitrogen bound in organic molecules, they can contribute to the formation of nitrogen oxides. The primary mechanism of NO_x formation in this case is the conversion of fuel-bound nitrogen to HCN and HNCO, followed by the conversion of these species into NH_x and then to NO, as described above. NO_2 and N_2O can also form in combustion processes through reactions such as:

$$NO + HO_2^{\bullet} \rightarrow NO_2 + OH^{\bullet}$$

$$O^{\bullet} + N_2 \rightarrow N_2O$$

There are two primary approaches for NO_x control: 1) combustion process modifications that minimize NO_x production in the first place and 2) postcombustion NO_x reduction methods. The nature of the fuel or combustible waste impacts the selection of the most suitable approach. For low-nitrogen feeds, thermal NO is the major contributor to NO, making temperature control the most important parameter. For incinerator feeds that contain significant levels of bound nitrogen, both the thermal- and fuel-NO formation processes become operative. In this case, the most effective strategy would be to implement staged combustion.[24,25]

Methods to control NO_x emissions in postcombustion gases can be categorized into noncatalytic and catalytic ones. Noncatalytic methods involve the injection of nitrogen-containing additives at concentrations comparable to the NO_x levels, to the combustion exhaust gases over a well-defined temperature window to induce NO_x reduction.[22] A large number of methods have also been developed for the selective catalytic reduction (SCR) of NO_x in combustion products.[26]

Some waste materials, coal, and some petroleum products also contain sulfur thereby creating SO_2 and SO_3 (SO_x) upon combustion. Together, NO_x and SO_x are the contributors to ''acid rain'' by their transformation into HNO_3 and H_2SO_4, respectively, in the atmosphere. These emissions, besides their obvious adverse environmental and health effects, also result in the erosion of structural and ornamental stonework and leads to corrosion of equipment. It is generally agreed that SO_2 formation occurs by the following sequential reactions of sulfur:[27]

$$\text{Fuel-S} \rightarrow RS \rightarrow SO \rightarrow SO_2 \rightarrow SO_3$$

The oxidation of SO_2 to SO_3 is thermodynamically favored at lower temperatures. However, as the homogeneous reaction kinetics are slow at low temperatures, SO_2 emissions dominate SO_x emissions from most combustion systems. On the other hand, significant SO_3 formation can occur through heterogeneously catalyzed reaction pathways, when the waste contains transition metals, especially vanadium. The most effective way to reduce SO_x emissions is to decrease the use of sulfur containing materials in the first place. In the absence of this, sulfur oxides can be readily removed from combustion flue gases by using sorbent adsorption.[28]

$$CaO + SO_2 + \tfrac{1}{2}O_2 \rightarrow CaSO_4$$

The $CaSO_4$ formed is stable, thus can safely be stored. However, the management of massive quantities of $CaSO_4$ that accumulate over a period of time can be a disposal problem. Other regenerative methods of SO_2 removal have also been developed.[28]

Combustion of Halogenated Hydrocarbons

Combustion of halogen containing wastes, in particular chlorine-containing compounds and chlorinated hydrocarbons (CHC) has been the focus of considerable controversy, and therefore, the research over the past several decades (see Refs.[29–32]). Technological and scientific issues faced in the combustion of CHC,

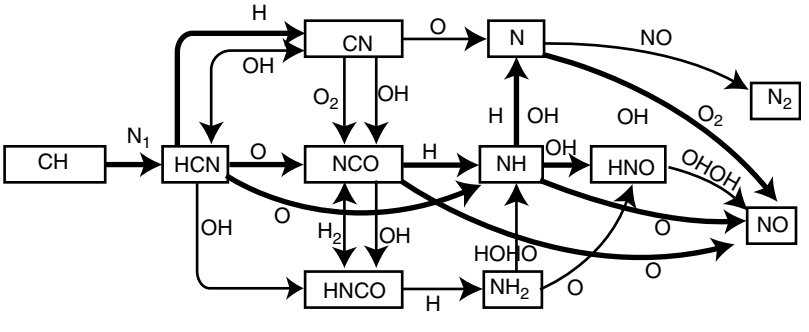

Fig. 13 NO production from fuel reactions. (From Ref.[22].)

in principle, are similar to those associated with the combustion of regular hydrocarbons as discussed in a recent review.[33] However, the differences in the reactivity of chlorine when compared to hydrogen, creates unique issues that must be addressed. For a general CHC designated by the formula $C_xH_yCl_z$, the overall stoichiometry of combustion can be described by the following equation:

$$C_xH_yCl_z + (x + (y - z)/4)O_2 \rightarrow xCO_2 + zHCl + ((y - z)/2)H_2O$$

As indicated above, the thermodynamically preferred CHC combustion product is HCl for $y > z$. However, for CHC compounds in which $y < z$, the formation of molecular chlorine must also be considered:

$$C_xH_yCl_z + xO_2 \rightarrow xCO_2 + yHCl + ((z - y)/2)Cl_2$$

In practical incinerators, the formation of Cl_2 is undesirable as it is difficult to remove from combustion effluents. Consequently, an auxiliary fuel with sufficient hydrogen content is used to increase H/Cl ratio and suppress Cl_2 formation. When methane is used, the overall combustion stoichiometry for the CHC/CH_4 mixture will be:

$$C_xH_yCl_z + (1/R)CH_4 + (2/R + x + (x - y)/4)O_2 \rightarrow (x + 1/R)CO_2 + zHCl + (2/R + (y - z)/2)H_2O$$

where R is the CHC/CH_4 ratio. Another reaction that is of significance in CHC combustion is the Deacon reaction:

$$2HCl + \tfrac{1}{2}O_2 = Cl_2 + H_2O$$

Excess air (fuel lean conditions) and high temperatures favor the conversion of HCl into Cl_2. The formation of Cl_2 can then lead to the production of chlorinated hydrocarbons, as seen in flame experiments.

In Fig. 14, atmospheric pressure premixed, flat flames of C_2H_3Cl are shown under both fuel-rich and fuel-lean conditions. Under fuel-rich conditions, CHC flames exhibit similar luminosity as hydrocarbon flames. However, under excess air conditions, the flames of chlorinated hydrocarbons exhibit white luminosity, likely because of the radiative recombination of chlorine atoms (Fig. 14A). Flames of highly chlorinated hydrocarbons also exhibit soot formation even at stoichiometric conditions (Fig. 14B) owing to the suppression of oxidation reactions.

The kinetics of chlorinated hydrocarbon reactions exhibit several distinguishing features when compared to the reactions of analogous hydrocarbons.[34] First, as a consequence of the weaker C–Cl bond dissociation energies, CHCs decompose at temperatures that are significantly lower than the analogous hydrocarbons. This leads to the early production of Cl radicals, thereby establishing the requisite free radical chain reactions, which destroy the parent CHC and lead to gas phase polymerization, ultimately forming soot.

In Fig. 15, the sooting limits of chlorinated methanes/methane/air mixtures are presented in terms of critical equivalence ratios and as a function of the chlorinated methane/methane molar ratio (R).[35] As the chlorine content of the mixture was increased, sooting occurred at lower equivalence ratios.

Second, chlorine and chlorinated compounds effectively compete with the important combustion chain branching reaction $H^\bullet + O_2 \rightarrow OH^\bullet + O^\bullet$ for the $H^\bullet$ radicals via the following reactions:

$$H^\bullet + CH_3Cl \rightarrow HCl + CH_3^\bullet$$

$$H^\bullet + CHC \rightarrow HCl + R^\bullet$$

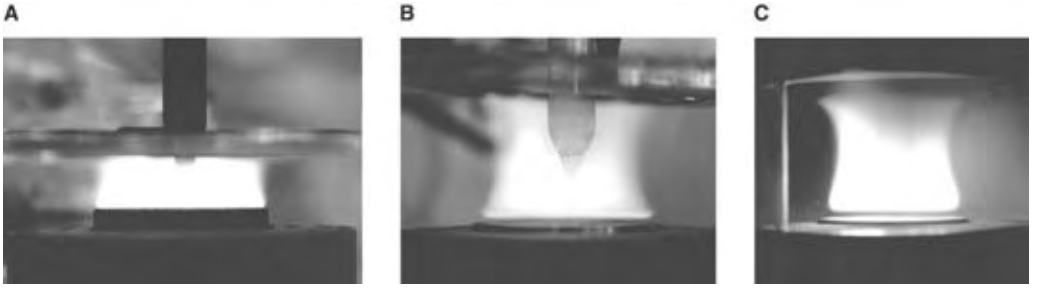

Fig. 14 (A) Premixed flames of trichloroethylene under fuel-rich, (B) stoichiometric, and (C) fuel-rich conditions. In contrast to regular hydrocarbons, soot formation can be seen in CHC flames under stoichiometric, and in some cases even under fuel lean conditions.

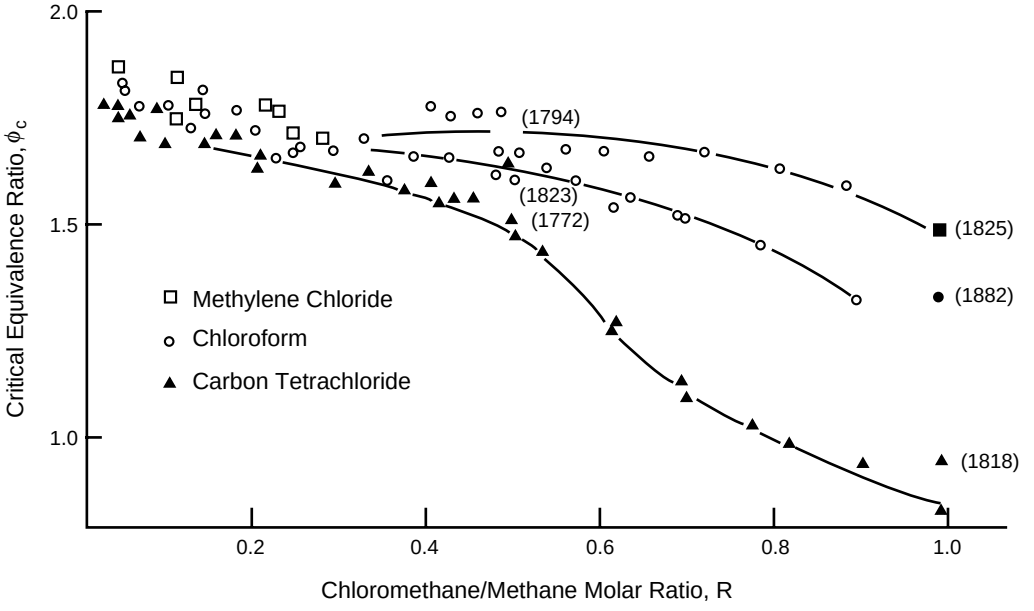

Fig. 15 Critical equivalence ratios (onset of soot formation) of premixed methane and chlorinated methane flames. (From Ref.[35].)

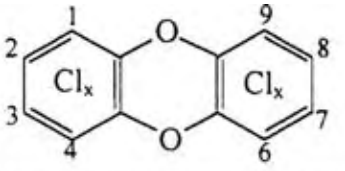
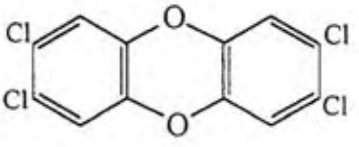
These reactions effectively remove the highly reactive $H^{\bullet}$ from radical pool, thereby inhibiting combustion processes.[18,36] This inhibition also manifests itself by the reduction in laminar burning velocities of hydrocarbon flames and by increased induction periods. In Fig. 16, the laminar burning velocities of chlorinated methanes are compared to methane.[37] Increased chlorination significantly reduces the burning speed of methane, rendering highly chlorinated CHC, such as CCl_4 nonflammable.

To better understand the fate of chlorine in combustion and to help in the design and operation of practical incinerators, the chemistry of flames of chlorinated hydrocarbons has been studied considerably. In Fig. 17, the detailed structures of CH_3Cl/CH_4 flame (more sooting) are compared to the CH_4 flame (less sooting).[38] As seen from this figure, in spite of differences in soot levels, the concentrations of CO, CO_2, and C_2H_2 in both flames were very close to one another, with the expected differences in HCl and H_2O. However, the levels of gas-phase aromatics and PAH in the more sooting CH_3Cl/CH_4 flame were significantly and consistently *lower* than the less sooting CH_4 flame. This is a surprising result with major practical and fundamental implications. Chlorinated compounds appear to assist in the rapid incorporation of PAH into soot, thereby reducing the levels of gas-phase PAH in the more sooting CH_3Cl/CH_4 flame.

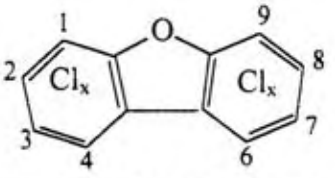
As noted earlier, polychlorinated dibenzo dioxins (PCDD) and polychlorinated dibenzo furans (PCDF) are two important classes of potentially toxic by-products that can form in trace levels (e.g., less than parts per billion, ppb) in waste incineration. The molecular structures of these compounds are:[29,33]



PolyChlorinated Dibenzo Dioxin (PCDD)



2,3,7,8 TetraChloro Dibenzo Dioxin (TCDD)
(most toxic isomer)

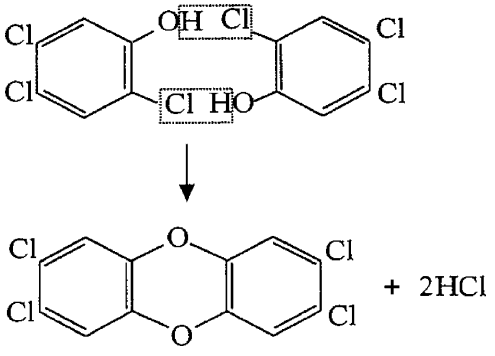


PolyChlorinated Dibenzo Furan (PCDF)

Although there are over 100 isomers of PCDD, the 2,3,7,8-tetrachlorodibenzodioxin has received the most attention because of its high toxicity in animal tests.[7] Three possible mechanisms have been put forward to account for dioxin and furan emissions

from incinerators: 1) unburned dioxins and furans in the original waste stream that survive the combustion chamber; 2) homogeneous gas-phase synthesis from aromatic precursors such as chlorinated benzenes and phenols;[39–41] and 3) heterogeneous and/or de novo synthesis from carbonaceous materials with particulate carbon and carbon species with functional groups believed to be the best starting materials.[29,39,42–44] The latter class also includes the surface assisted formation of PCDD/F from gaseous aromatic precursors.[39]

Conceptually, the simplest PCDD formation mechanism is the recombination of 2-chlorinated phenols via HCl elimination either homogeneously in the gas phase or on surfaces. For the case of 2,3,7,8 TCDD, this involves the combination of 2,4,5 trichlorophenol, as shown:



In homogeneous reaction mechanisms, PCDD and PCDF are considered to be formed from aromatic precursors at temperatures below 600°C with the active participation of OH radicals.[40]

The mechanisms of formation of PCDD and PCDF in heterogeneous systems have been reviewed by Addink and Olie,[29] and the following trends have been noted:

1. Carbon source: Virtually any carbon source seems to produce PCDD/F via the de novo route, including activated carbon, coal, charcoal, and soot.
2. Surface: In addition to fly ash, a large number of materials such as Al_2O_3, $Al_2O_3SiO_2$, carbon, firebrick, glass wool, MgSiO, $MgAlSiO_2$, SiO_2, SiO_2NaOH, and tenax were evaluated for dioxin and furan formation. The production of PCDD/F was possible on most of these surfaces, but the presence of transition metals appeared to be necessary.
3. Chlorine source: Both organic and inorganic, gaseous and solid chlorinated compounds appear to be capable of providing the necessary chlorine atoms for the formation of PCDD and PCDF.
4. Temperature: The lowest temperature reported for the formation of PCDD/F from activated carbon on fly ash has been 200 °C. The temperature range that maximizes PCDD/F formation varies: 300°C for charcoal/fly ash, 300–330°C for residual carbon on fly ash, and 350–375 °C for activated carbon/fly ash. At 470°C, a second maximum was observed with residual carbon on fly ash and detectable amounts of PCDD/F are formed even at 550 °C.
5. Catalysts and promoters: Transition metals such as Cu and Fe are well recognized to promote PCDD/F formation in laboratory experiments.
6. Oxygen source: Free oxygen appears to be essential for PCDD/F formation in most heterogeneous and homogeneous processes.

In spite of the above mentioned investigations that indicated several trends on PCDD/F formation, a study conducted for the American Society of Mechanical Engineers, ASME,[30] concluded that there was no statistically significant cross-incinerator correlation between chlorine content of the waste stream fed to

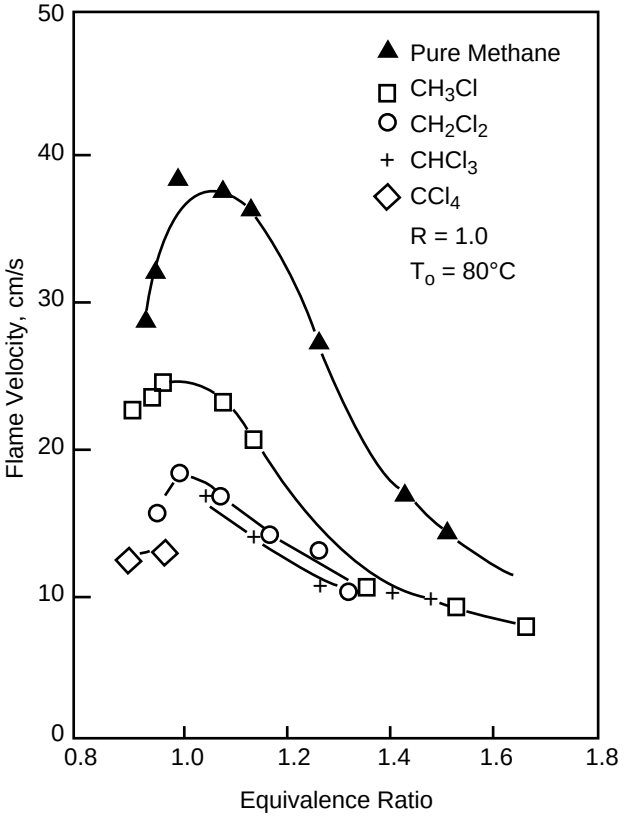


Fig. 16 Laminar burning velocities of chlorinated hydrocarbons as a function of equivalence ratio. Increased flame inhibition with increased chlorine content is evident.

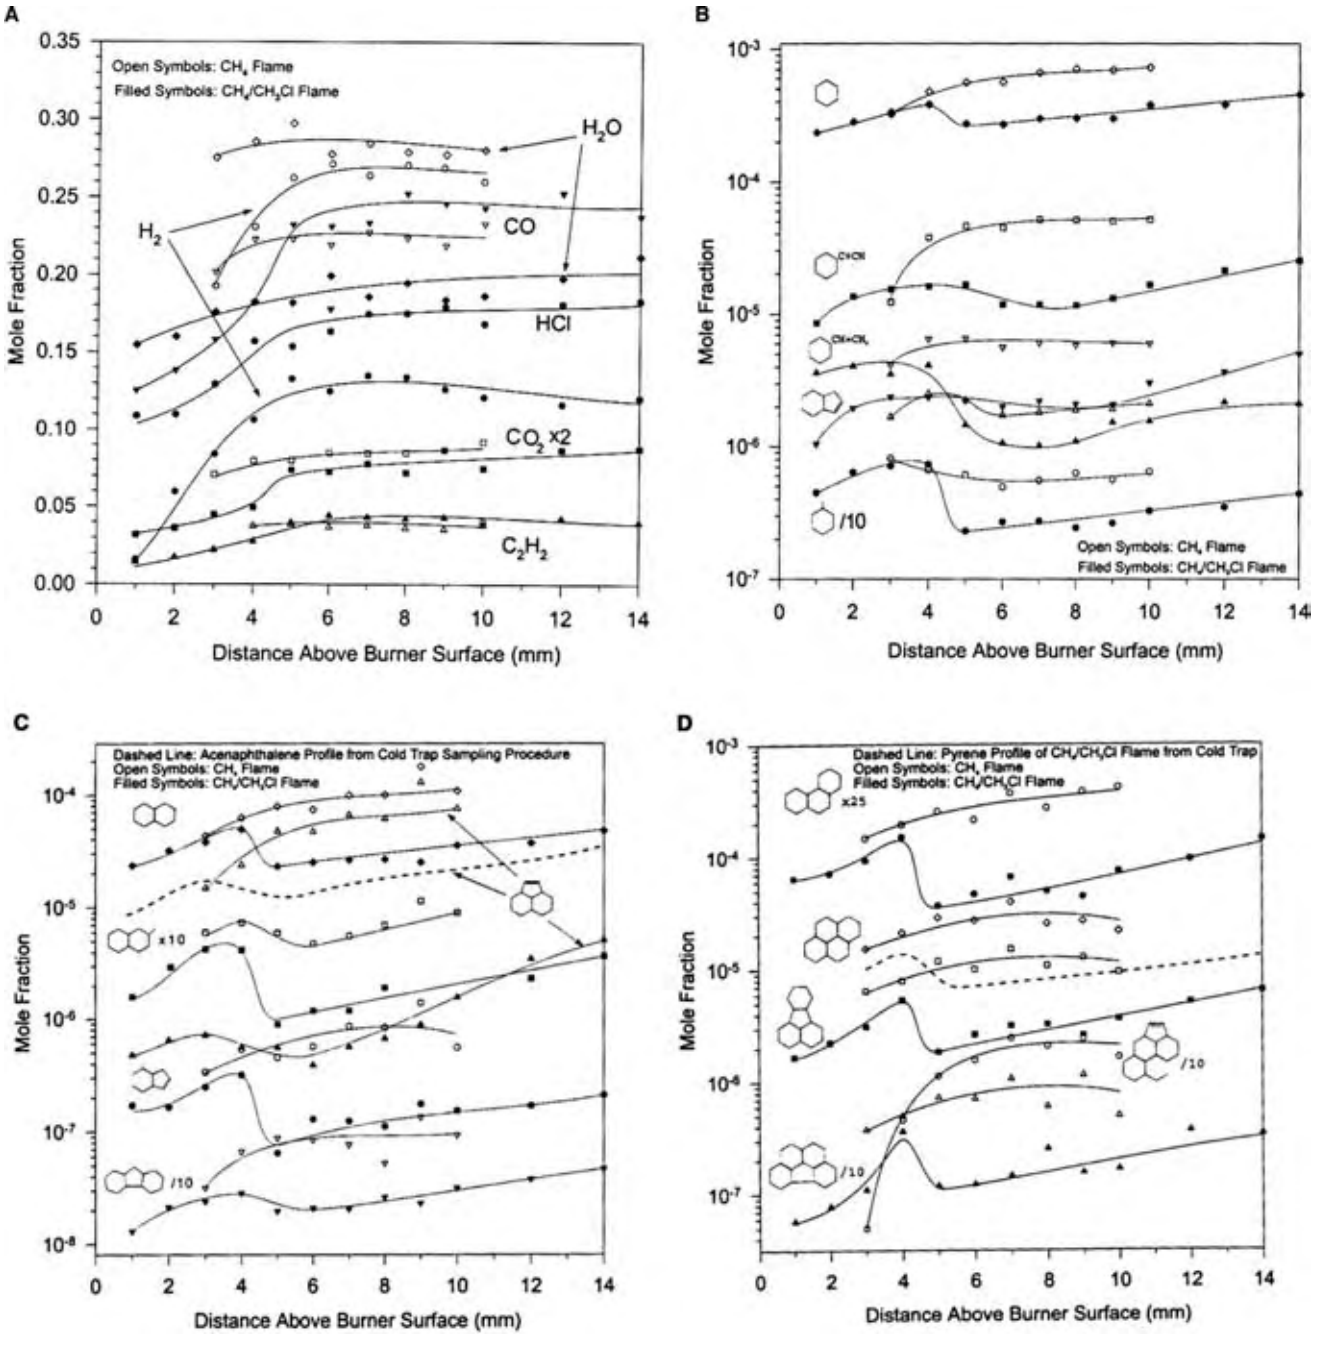

Fig. 17 Comparative species concentration profiles in the flames of CH_3Cl/CH_4 and CH_4 under similar equivalence ratio and carbon density. (A) Major species mole fraction profiles; (B) single ring aromatic species mole fraction profiles; (C) two ring aromatic species mole fraction profiles; (D) three and four ring aromatic species mole fraction profiles. (From Ref.[38].)

incinerators and the PCDD/F concentrations in the emissions from those incinerators. Although numerous factors have been identified above that lead to dioxin and furan formation, the only consensus at this point seems to be that good combustion efficiencies and low postcombustion temperatures reduce the secondary dioxin formation.

Particulate Matter and Heavy Metal Emissions from Incinerators

Particulate matter from waste combustors includes inorganic ash present in the waste and carbonaceous soot formed in the combustion process. The inorganic-ash fraction of the PM consists of mineral matter

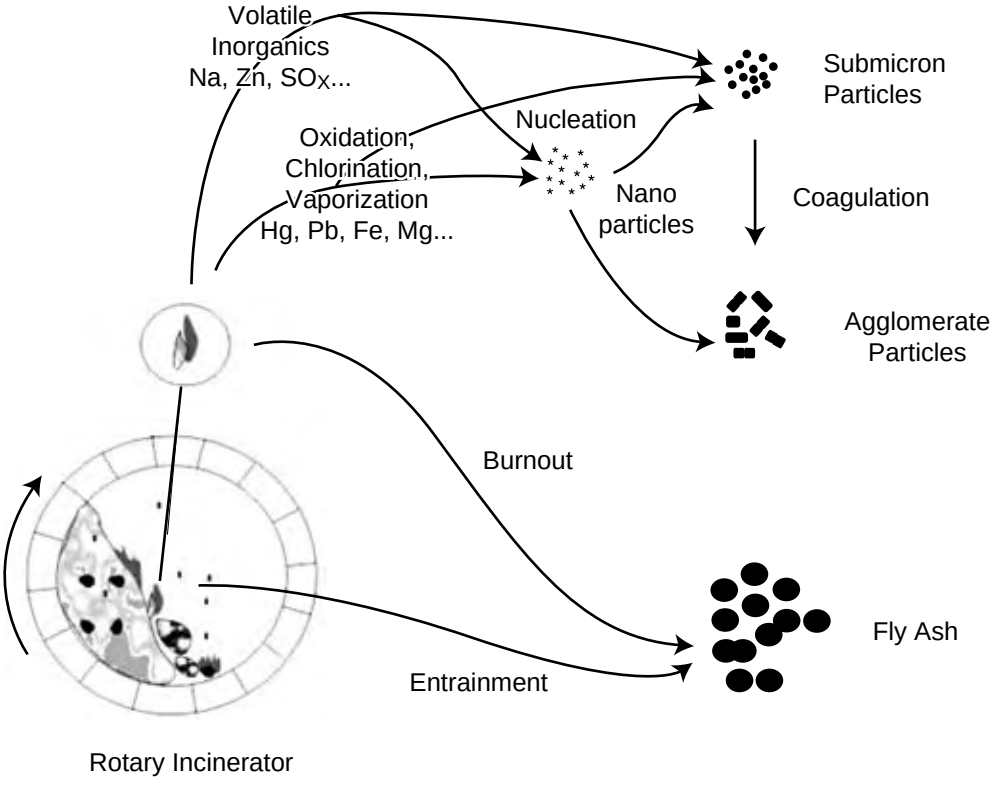

Fig. 18 The fate of metals and inorganics in the incineration of waste materials.

and metallic species. These materials are conserved in the combustion process and leave the combustion chamber as bottom ash or fly ash. Soot is a product of incomplete combustion that consists of unburned carbon in the form of fine particles or as deposits on inorganic particle.[11,45] The fate of metals in incineration is significantly complicated, but similar to those encountered in coal combustion.[46,47] Consequently, readers interested to learn more about metal emissions from incinerators can be well served by the extensive literature on coal combustion.[45–47] Metal emissions from incinerators can either be direct, i.e., through entrainment of small ash particles created during waste combustion or through a variety of physical and chemical processes (Fig. 18). The high temperatures associated with flames in the primary incineration chamber can gasify the more volatile metals such as Na, Hg, and Zn, while some are gasified through reactive processes involving oxidations [e.g., $Ni(CO)_4$], chlorinations (e.g., $PbCl_2$), etc. Subsequent decreases in the gas temperature then result in the nucleation of metal-containing gases, and can create nanoparticles, which can then either grow further by surface reactions, or agglomerate and/or sinter to form submicron size particles.

Particulate matter emissions can be controlled using a variety of APCD that include filtration collectors, including primary fabric filters (baghouses); electrostatic collectors, including dry and wet electrostatic precipitators and ionizing wet scrubbers; and wet inertial-impaction collectors, including venturi scrubbers and advanced designs that use flux-force condensation-enhancement techniques.

In addition to APCD, metal emissions from waste combustors can be minimized by: 1) limiting the metal content of the waste feed via source control; 2) designing and operating the combustion process to minimize metal vaporization; and 3) designing and operating the primary combustion chamber to minimize fly-ash carryover. From a practical standpoint, the second method is likely to be the most difficult to implement because the objective of the incineration process is to burn all the combustible waste completely and avoid PIC formation, both of which require the use of high temperatures. Therefore, the most-reliable methods of limiting metal emissions are source control and efficient use of APCD.

CONCLUSIONS

Today waste incinerators can be designed and operated to achieve better than 99.999% DRE of the waste compounds and to only emit extremely low concentrations of the pollutants of concern under normal

operating conditions. Consequently, incineration can be reliably used to reduce the volume and toxicity of a broad range of waste materials, while allowing the recovery of energy and materials. Like any other combustion process, incinerators can also produce potentially dangerous by-products. Nevertheless, the certain risks posed by specific incinerator emissions, e.g., dioxins, do not appear to be particularly higher than those posed by other combustion generated pollutants. It is unfortunate that the public image of incineration has been tarnished by several unfortunate accidents in the past. However, as we ran out of inexpensive waste management options, e.g., landfills, incineration is likely to become an essential tool in the management of wastes in the future.

Injection Molding

I

David O. Kazmer
Department of Plastics Engineering, University of Massachusetts, Lowell, Massachusetts, U.S.A.

INTRODUCTION

Injection molding is a well-known process that is capable of economically producing very complex components with demanding specifications.[1] Many different kinds of products, from compact discs to audio and video-cassettes, to cutlery and glassware, to automotive parts, are molded using various types of injection molding. In the first half of this entry, a concise review of the process is provided. Then, prevalent guidelines for the design of plastic parts and injection molds are presented.

Continuing global competition is forcing producers of molded parts and suppliers of molding equipment to improve the molding process. Toward this end, an overview of the current state of the art in injection molding is provided in the second half of this entry. Modern machine and process control system designs are presented that provide improved control over the polymer melt. Then, variants of the injection molding process that have been developed to produce molded parts that are hollow, less dense, very thin, or composed of multiple materials are introduced. Finally, a summary of current technological and economic trends in the industry is provided.

PROCESS DESCRIPTION

Injection molding is a net shape manufacturing process in which a polymer melt is forced into an evacuated mold cavity that cools the polymer melt into a desired shape. As shown in Fig. 1, molding machines typically consist of two halves located on opposing sides of a stationary platen: 1) an injection unit that plasticizes the melt and transfers it into the mold, and 2) a clamping unit that closes the mold during the formation of the part and opens the mold for the ejection of the molded product.[2] The design and the operation of molding machines differ substantially, but, in general, adhere to underlying principles that are discussed next.

During the plastication stage, the polymer melt is typically plasticized from solid granules or pellets through the combined effect of heat conduction from the heated barrel and the internal shear heating caused by molecular deformation with the rotation of an internal screw. Screws in injection molding have many similarities with those in single screw extrusion, e.g., most of them have feed, transition, and metering zones. The primary difference, however, is that the screw reciprocates along its axis during the molding cycle. Specifically, the screw moves away from the mold as it rotates and forms a volume of melt at the front of the barrel. The screw then moves forward without turning to force the polymer melt into the injection mold. As such, reciprocating screws in injection molding usually include a nonreturn or check valve to prevent the polymer melt at the front of the barrel from flowing back into the screw during injection. While the dynamics and efficiency of plastication are well known to be a function of the screw design, material properties, and process conditions,[3] many, if not the majority of, molding processes rely on general purpose screw designs that provide reasonable performance for a wide variety of polymer resins.

During the injection stage, the polymer melt is forced from the barrel of the molding machine and enters the mold. Typically, the heated resin travels down a cooled and/or heated feed system, through one or more gates, and into one or more mold cavities where it will form one or more desired shapes. Control of the injection stage is well known to influence the properties of the molded products such as part weight, dimensions, esthetics, orientation, and others.[4–6] As such, modern molding machines allow velocity profiling to control the volumetric flow rate of the polymer melt into the mold during the injection stage. Molding processes are frequently set up so as to best provide a uniform melt front velocity by utilizing a low volumetric flow rate at the start of the injection stage when the polymer melt is just entering the cavity, then a higher volumetric flow rate as the polymer melt diverges and propagates throughout the mold, and then a lower volumetric flow rate as the polymer melt converges toward the end of the mold cavity.

The packing stage typically commences when the mold is filled or nearly filled with the polymer melt and provides additional resin into the mold cavity as the polymer melt cools and contracts. As the packing stage is also crucial to part quality, modern molding machines allow the melt pressure to be profiled as a function of time. The minimum packing pressure is usually set to avoid excessive volumetric shrinkage and

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007819

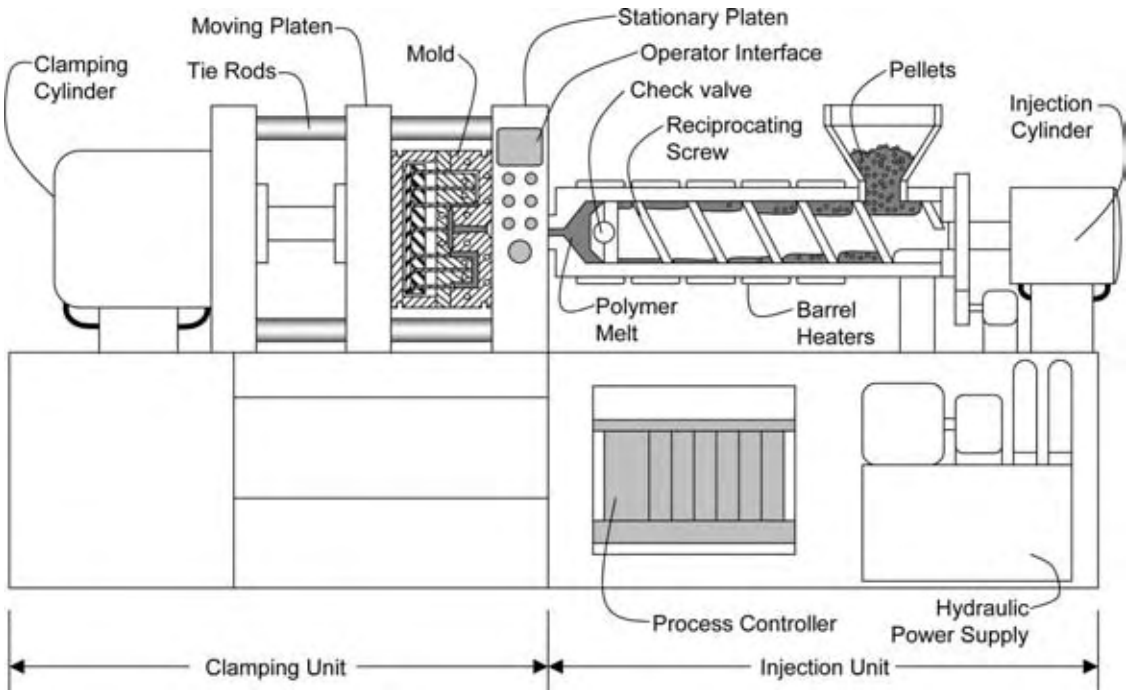

Fig. 1 Schematic of an injection molding machine.

related defects such as sink marks, internal voids, and dimensional instabilities.[7] The maximum packing pressure is usually set to avoid excessive pressure in the mold cavity and related defects such as flashing of the mold, internal stress, and dimensional instabilities.[8] The minimum and maximum packing times are determined by the volumetric shrinkage (required to achieve the desired part dimensions) and the solidification of the gate (which prevents additional polymer melt from entering the cavity at extended pack times), respectively. Accordingly, pack pressure profiling can be used to control the pressure, density, and stress distribution of the polymer melt as it solidifies in the cavity.

After the packing stage, molding processes typically require additional time to plasticate the polymer melt for the next molding cycle while the resin in the cavity solidifies and becomes rigid so that it may be ejected from the mold. Depending on the polymer properties and its inherent recrystallization rate, processing conditions, and the mold design, the cooling stage can range from seconds to minutes.[9] Excessively short cooling times can lead to difficulties in ejecting the part because of either internal compressive stresses that cause the part to remain in the mold cavity or excessive deformation of the part upon actuation of the ejection mechanism(s). Extended cooling times are sometimes used in an attempt to reduce part shrinkage, though this practice can lead to higher internal tensile stresses and difficulties in removing the molded part from the mold core(s) associated with increased ejection forces. Mold release is often utilized to facilitate part removal, though this practice introduces issues related to consistency and contamination. When the polymer melt is appropriately cooled, the molding machine typically actuates the necessary cores, slides, and pins to open the mold and remove the molded part(s).

PRODUCT AND MOLD DESIGN

Injection molding is commonly used because of its ability to form complex parts with features defined in three dimensions, and thereby consolidate the number of components in an assembly, and also reduce the number of fasteners required for the assembly (e.g., Fig. 2). Injection molded parts are usually designed to be thin relative to their length and width dimensions to reduce material and processing costs. As the wall thickness decreases, however, the part becomes very difficult to mold while losing stiffness and strength. As such, part design and mold design are of extreme importance, as a conservative design may result in excessive material and processing costs while an aggressive one may result in inferior performance and require costly design changes.

Computer-aided engineering applications have been developed to optimize the molded part design with respect to manufacturing and end use performance. Many, if not most, commercial molding applications utilize mold filling analyses to analyze the melt flow and pressure distribution in the injection mold before the mold is manufactured. Typically, these analyses

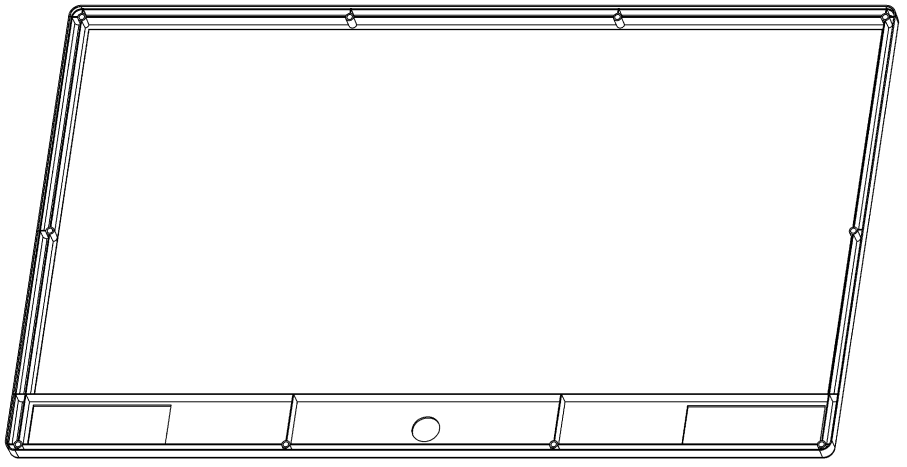

Fig. 2 Front bezel (face plate) for an HDTV with windows, ribs, and bosses.

(e.g., Moldflow, Moldex3D, and Fluent) include non-Newtonian modeling of the polymer viscosity using assumptions for viscous compressible flow. The implemented heat transfer analysis typically includes heat convection with the melt flow, heat conduction from the polymer melt to the metal mold, and internal heat generation from viscous dissipation. In Fig. 3, a typical result for a bezel design in which the flow is introduced at three locations indicated by cones is provided. The contour lines indicate the progressive location of the melt at different times during the mold filling process. For this design, the flow diverges radially from the gates before converging toward the end. This particular design is deficient in that there is a large area of the molded part that has not filled, which would result in localized areas with high melt pressure and nonuniform shrinkage in the molded parts. Most likely, this issue would be rectified by moving the two gates in the window closer together to reduce the flow length.

Computer-aided engineering applications (e.g., Ansys, Cosmos, and Abaqus) are also often utilized to analyze the stiffness and strength of candidate designs. Such concerns often arise in plastic part designs, as: 1) injection molded parts are thin relative to their length and width dimensions, and 2) polymeric materials have low elastic modulus and yield stress compared with metals. Because of this, injection molded parts are frequently designed with vertical ribs to ensure adequate stiffness and strength during end use.[10] As a result, molded plastic parts often have stiffness-to-weight ratios that are preferable to alternatively designed metal components.

Because of the widespread use of injection molded components, many guidelines have been developed with respect to the design of injection molding.[11] In general, it is desirable to use a uniform and optimal wall thickness throughout the part to reduce cooling times, and minimize residual stresses and part distortion upon ejection from the mold. Ribs should be used

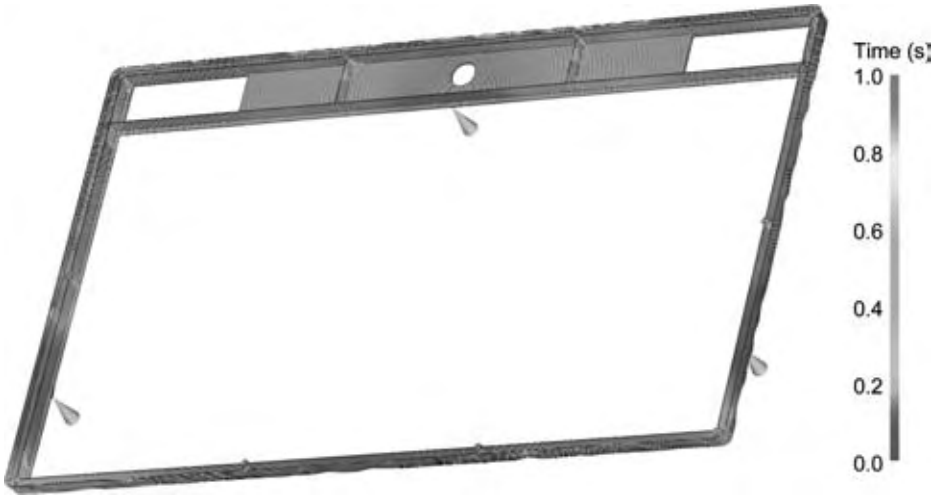

Fig. 3 Progression of polymer melt into mold cavity. *(View this art in color at www.dekker.com.)*

to improve the overall part stiffness, while gussets to secure bosses and other standing features. Generally, the thickness of the ribs and gussets, and other features should be no more than 70% of the part wall thickness to avoid sink and extended cycle times. It is also desirable to use a generous radius at all corners to avoid flow hesitation and mold hot spots during molding as well as stress concentrations in end use; an inside corner radius equal to the wall thickness is often used. Finally, it is important to design the molded parts to facilitate ejection from the mold by minimizing the number of undercuts that requires core pulls and also providing an acceptable amount of draft in the direction of the part ejection.

The design of injection molds[12] has improved with respect to the level of engineering analysis and manufacturing efficiency. Injection molds (e.g., Fig. 4) must be designed to ensure that the molded parts are economically and consistently produced. For a given molding application, the number of molds and mold cavities is first estimated based on the size and thickness of the part, the location of the gates, and the delivery of the polymer melt to the mold cavity(ies). When possible, the melt pressures are computed using mold filling analysis to estimate the forces likely to be exerted by the polymer melt on the mold components. Structural analysis, in the form of plate bending equations or finite element analysis, may be used to determine the number, location, and size of mold plates and support pillars. Cooling analysis is similarly conducted to determine the number, location, and size of cooling lines in the mold. Based on guidance from the material supplier and prior molding experience, the shrinkage of the plastic is estimated, which is used to determine steel-safe cavity and core designs that will form the molded part(s).

Because of the number of subsystems in an injection mold, mold design often requires multiple design iterations. For example, it is not uncommon for the design of the cooling lines to interfere with the placement of ejector pins. As such, the design must be continually refined until the designer is satisfied that the mold will function as desired. As mold making generally requires extensive machining and finishing time, it is quite common for mold makers to order the components and begin rough machining before the detailed mold design is completed. Owing to such concurrent engineering techniques and modern computer controlled machining centers, the cost and time required to produce a high quality mold have decreased significantly over time. After the mold is completed, the mold maker and molder typically perform molding trials to identify and correct any issues prior to the initiation of high volume production.

PROCESS CONTROL

Injection molding machines can control machine elements only with feedback from sensed process data. A fundamental difficulty in polymer processing is that very few of the final part properties can be ascertained within the molding cycle. Instrumentation does not yet exist, and may never exist, to yield information about

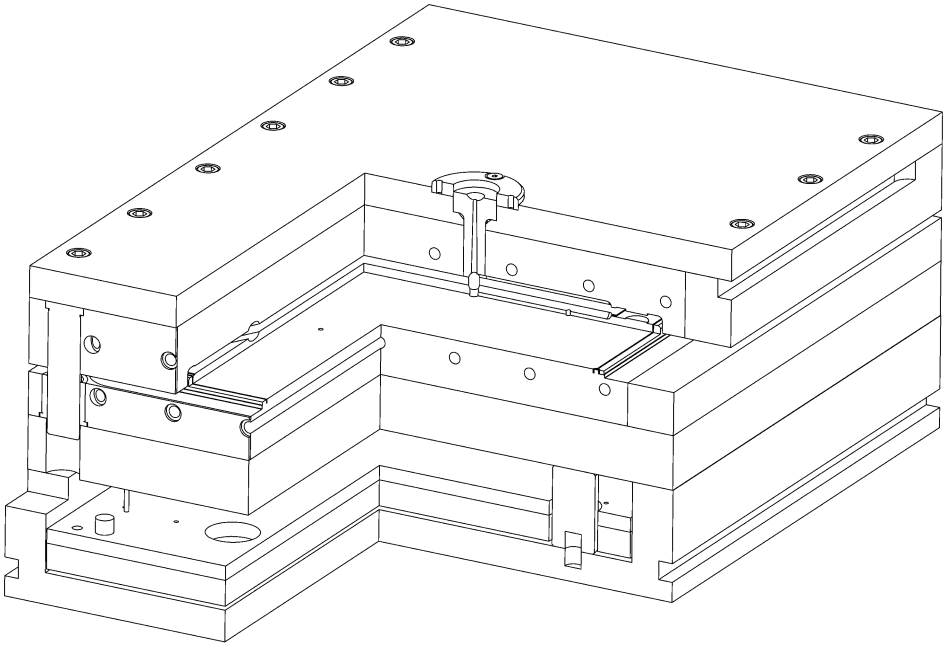

Fig. 4 Partial cutaway section of an injection mold.

esthetics, shrinkage, or structural integrity prior to removal of a plastic part from the mold. As the quality of the molded part is not available, in situ, molding machines operate in an open loop mode with respect to the quality of the molded products. Given the limited number of molding machine control settings, the process capability of injection molding will generally decline with an increasing number of molded parts and related specifications that are simultaneously demanded.[13]

Most machine manufacturers have adopted the use of standard programmable logic controllers in which multiple analog and digital input and output modules are used to acquire or transmit necessary feedback and control signals. The control signals may be generated through the CPU module in the programmable logic controller or alternatively through the use of dedicated axis controllers for faster response. Increasingly, industrial PCs are being used as an interface between the process controller and the operator, such that the PC provides enhanced ease of use, process diagnostics and maintenance, network connectivity, upgradability, and access to third party software.

The dynamics of the molding process are determined through control of different but related machine elements such as motors, heaters, servovalves, etc. These machine elements are typically controlled via a hierarchical closed loop control architecture as shown in Fig. 5.[14] At the innermost level, only the machine elements are regulated by real time comparison of the desired machine set points with the machine feedback, such that the difference (or error) is used to correct the process. At the second level, state variables such as melt temperature and melt pressure are controlled to track prespecified profiles and provide more precise control of the state of the melt. At the outermost level, the machine inputs are adjusted by the machine operator to improve the quality of the part through specification of better set points given feedback of part quality.

The performance of a closed loop controlled molding machine is dependent upon a number of system properties, such as the inertia and dynamic behavior of the process, availability and amount of control energy applied to the machine, the time response and resolution of the sensors providing feedback, and the validity of the control laws that convert perceived errors into corrective actions. Sustained advances in machine design and software algorithms have led to substantial gains in process control performance, such that the molding process control is not usually limited by the sweep time or algorithmic complexity of the controller. While there remains a significant variation in sweep time between molding machines, a control system sweep time (from input of feedback signal to output of control signal) of 2 msec is quite common, with much faster response times widely available. However, the process dynamics are not so dependent upon the response time of the controller, but rather on that of the integrated system. Consider the task of increasing the temperature of a 100 kg steel barrel (heat capacity of 473 J/kg °C) by 10°C, which theoretically requires 473,000 J. If four 1000 W heaters are utilized, then the minimum theoretical response time is about 120 sec or 2 min. Realistically, however, the response time will be much longer than the theoretical minimum, depending upon whether the system is over- or underdamped, and how much error is tolerable. As such, a reduction in the control system response time is likely to be less important than an improvement in the control law, controller tuning, heater design, or barrel design.

While machine control is important, it is the polymer state (pressure, temperature, and morphology) that directly determines the molded part quality. As such, recent technology developments have focused on closing the loop between the machine parameters and the polymer state. Conformal cooling and pulsed cooling are two molding technologies that have been

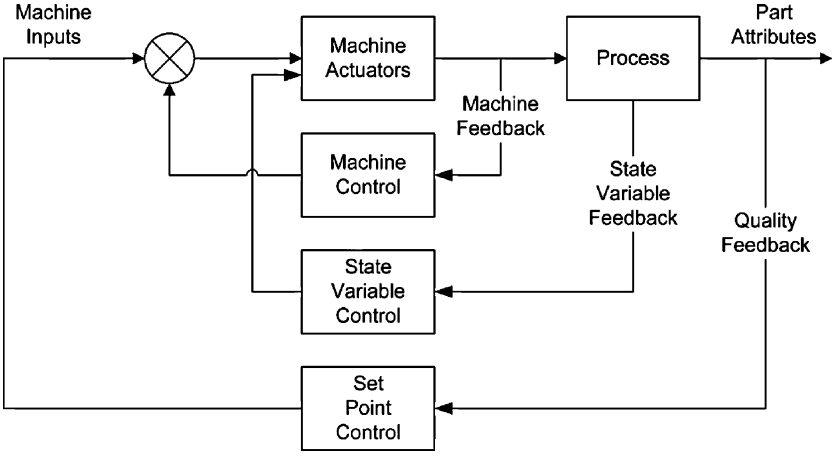

Fig. 5 A three-level hierarchical control architecture.

developed to control the state of the melt temperature in the mold cavity. In conformal cooling,[15] the injection mold is manufactured from powdered materials that are deposited in layers and selectively joined with binder from an ink-jet style printhead. Because of this manufacturing process, the mold tooling can be developed with cooling channels designed to be conformal with the molding cavity. Accordingly, such conformal cooling provides the ability to provide a uniform temperature across the molding cavity throughout the process cycle. Pulsed cooling[16] utilizes heaters to affect the surface temperature of the mold. By adding heat prior to and possibly during the molding process, it is possible in the pulsed cooling process to control boundary temperature condition at the polymer–mold interface during the subsequent injection molding cycle. However, cycle time and energy consumption may be increased because of the added heat.

Another fundamental state variable that can be regulated during the cycle is cavity pressure. Closed loop control of cavity pressure could automatically compensate for variations in melt viscosity and injection pressure to achieve a consistent process and consistency of molded products. Adaptive control methods have been developed to track the cavity pressure profile at one location in the mold.[17,18] In these earlier works, cavity pressure control was handicapped by the absence of actuators for distributed pressure control, as conventional molding machines are equipped with only one actuator (the screw), which prevents the simultaneous cavity pressure control at multiple points in the mold. This problem has been solved with the development of dynamic melt flow regulators that allow control of the flow and pressure of the polymer melt at multiple points in the mold.[19,20]

The traditional approach to machine setup in the plastics industry has been trial and error. For this, shots are taken during start-up, and part quality attributes are measured after each shot to evaluate the acceptability of produced parts. The process engineers then use their knowledge of the process to adjust the machine inputs in such a way as to improve the quality of the part from shot to shot. This tuning exercise is repeated until the specifications for part quality are satisfied. The main drawback of the traditional tuning approach is its inefficiency because of its ''ad hoc'' nature. An alternative to the traditional trial and error approach is the use of expert systems where corrective guidelines are presented in the form of if-then rules.[21] The main shortcoming of expert systems is that a generalized set of rules may not be applicable across a broad range of part geometries, material properties, and machine dynamics.

An analytical alternative for set point specification in more advanced molding operations is to develop an empirical model based on data obtained from a design of experiments (DOE).[22] Based on the developed empirical models, an objective function of an optimization problem is defined as a function of the part quality attributes. The set of inputs that produces the best set of quality attributes is obtained as the optimal point of this optimization problem. Alternatively, the Extensive Simplex Method has been developed to derive the global feasible process window using a constraint-based approach.[23] Such DOE-based methods offer a systematic approach for process setup,[24] but require significant investment in training and technology. The use of such methods, however, has increased with the increasing interest in Six Sigma and improved process capabilities.

ADVANCED MOLDING PROCESSES

While conventional injection molding is a very capable net shape manufacturing process, process variants are being continuously developed to efficiently produce molded parts with improved properties. In Fig. 6, a classification of several common variants of the injection molding process is provided. As suggested, these variants allow for the molding process to produce parts that are hollow, less dense, very thin, or composed of multiple materials. Other molding technologies have also been developed that are suitable for very high production quantities.

Several molding processes are available for the production of hollow parts. In gas assist[25,26] and water assist[27] molding, the injection mold is designed with thick flow channels. During the molding process, the polymer melt is injected and partially fills the mold. Gas or water is then injected at one or more points and forces the polymer melt to continue flowing down and out of the flow channel and into thinner adjacent sections while the gas or water cores out the molten center of the flow channel. Both processes thereby provide parts with defined external geometry and thicker sections that are coarsely hollowed out (e.g., door handles). Compared with gas assist, water assist provides faster heat transfer and improved internal surface finish, but requires handling of water from the molded part and around the molding machinery.

Injection blow molding and lost core molding are more advanced processes for producing parts with controlled external and internal geometry. In injection blow molding,[28] an injection mold is used to produce a preform with specific thickness and shape. The warm preform is then transferred to a subsequent blowing station where internal pressure is applied and forces the preform to the extremities of a differently shaped mold cavity to provide a hollow part with controlled wall thickness (e.g., soda bottles). In lost core molding,[29] a metal core with low melting temperature is cast with

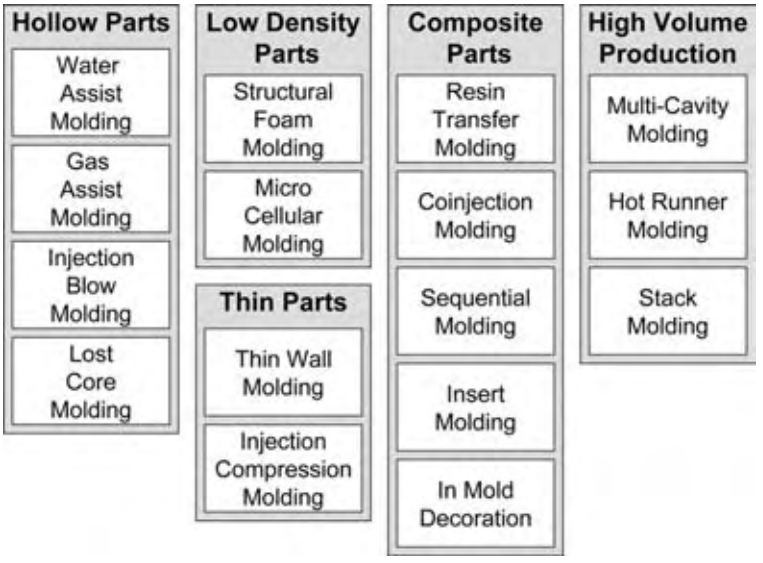

Fig. 6 Classification of various injection molding processes.

complex geometry and placed into an injection mold and then overmolded with the polymer melt per conventional injection molding. After the part is formed and cooled, the core is then melted out, thereby enabling complex internal and external part geometry with repeatable dimensional accuracy (e.g., automotive air intake manifolds) that could not otherwise be made.

Structural foam molding and microcellular molding are processes for creating molded parts with lower density. In structural foam molding[30] (also known as low pressure molding[31]), the polymer melt is used with a reactive blowing agent to create a foamed melt that is injected into the mold cavity. The process is frequently utilized with part designs that are thicker than those produced with conventional injection molding. The resulting molded parts usually exhibit a solid outer skin with an internal foamed core, thus achieving a very high stiffness-to-weight ratio. However, surface finish, foam consistency, and cycle economics are sometimes issues in application. More recently, microcellular molding[32] (also known as MuCell™) has been developed for application to thinner wall parts. In this process, a supercritical inert fluid is introduced into the polymer melt at a high pressure prior to the injection stage. During injection, the supercritical fluid reduces the melt viscosity, thereby reducing the injection pressure and clamp tonnage. With the subsequent pressure and temperature decay, the supercritical fluid rapidly changes to a gas with very small cell size and low cellular interconnectivity. With adequate process control, the resulting parts can thereby have a significant density reduction without a significant reduction in mechanical properties.

Thin wall molding and injection compression molding are processes utilized to obtain very thin molded parts. In thin wall molding, broadly defined as a mold design in which the length of flow is greater than one or more hundred times its wall thickness, resins with reduced melt viscosity are directly injected at a high pressure into a conventional injection mold.[33] Injection pressures in excess of 200 MPa and sometimes 400 MPa may be utilized to rapidly force the polymer melt throughout the mold cavity, thereby forming thin and complex parts (e.g., laptop housings). Because of the high pressures, thin wall molds are typically designed to be very stiff to avoid deflection during the molding process. In injection compression molding,[34] one side of the mold is displaced during the molding process so as to provide a larger wall thickness during injection of the polymer melt to allow for lower injection pressures. During or after the injection stage, the mold is closed to provide a reduced wall thickness while compensating for volumetric shrinkage. Accordingly, injection compression molding can be utilized to mold thin parts at lower pressures with uniform properties and reduced residual stress (e.g., compact discs[35]).

Given that assembly operations are expensive and can lead to failures, many molding processes have been developed to incorporate multiple materials and/or components into a single composite molding with improved properties and functionality. In resin transfer molding,[36] a composite mat or fabric is placed into a mold. The mold is then closed and the polymer injected into and around the composite fibers. The resulting parts (e.g., automotive body panels) usually have very good structural properties, though surface finish can be an issue. Coinjection molding[37] is another process that utilizes the serial injection of different materials into the mold cavity. Typically, a first

material with the desired esthetic and structural properties is injected to form the skin of the molding after which a second material is injected to form the core of the molding. One common application is the molding of fenders and door panels in the automotive industry with a high gloss exterior and internal recycled content.[38] To gain complete control of the distribution of multiple materials in a composite molding, sequential molding[39] (also known as two-shot or multishot molding) is commonly used. In this process, a molded part is produced in a first mold cavity with a first polymeric material. The part is then transferred to a second mold cavity into which a second polymeric material is injected, which fuses with the first molded part. The resulting parts may consist of multiple colors (e.g., automotive tail lights) or structural properties (e.g., soft grip razors).

Insert molding[40] can be considered a more generic version of sequential molding, as most components can be placed into an injection mold and overmolded with a polymeric material. Common applications of insert molding include the integration of electrical connectors in the housings of electrical devices as well as the incorporation of metal stiffeners and fasteners in structural components. Recently, in-mold decoration has become common.[41] In this process, a thin decorative film is inserted into the mold cavity and overmolded with the polymer melt. The resulting parts (e.g., cell phone faceplates) typically have complex printed patterns between the highly glossy surface and the polymer substrate.

While a single injection mold cavity may provide hundreds of thousands of moldings, applications requiring higher production volumes typically require multiple cavities to increase production rates and reduce production costs. In a multiple cavity mold, two or more cavities are connected via a runner system to the nozzle of the molding machine.[42] In a naturally balanced runner system, the mold geometry is symmetric such that the same melt flow and pressure are provided to each mold cavity. In this manner, a number of molded parts can be produced in the time normally taken to produce one molded part. Unfortunately, the runner system can utilize a significant amount of polymeric material and require extended cooling times to adequately solidify for ejection. To avoid excessive waste across many molding cycles and also to enable the operation of a higher number of mold cavities, the mold may be fitted with a hot runner system. In a hot runner system, the polymer melt is transmitted through a series of heated channels directly to the mold cavity. As a result, the polymer melt remains molten in the hot runner system and there is no wasted material or time. Typically, hot runner molding also improves molded part quality because of the improved melt transmission between the nozzle and the mold cavities.[43]

A difficulty with multicavity molding is that the force exerted by the melt onto the molding machine is proportional to the number of mold cavities. To reduce these clamping forces while operating with a higher number of cavities, stack molding was developed.[44] In stack molding, a second set of cavities is placed directly behind a first set of cavities in an injection mold. Both sets of cavities are molded at the same time, with the mold opening on two parting planes for ejection of the parts. As the molding pressures within the sets of mold cavities are opposing, two sets of mold cavities can be operated with the clamping forces required to mold only one set of cavities. As such, stack molds provide for very rapid and economical production of a large quantity of molded parts, given the additional upfront investment in molding technology.

CONCLUSIONS

While injection molding is a widely used and mature process, technological advances in computer-aided engineering and process control have brought new capabilities with respect to product design, mold making, and molding machine design. Product designs have become more complex and lightweight, with an ever-increasing number of designs incorporating composite material systems. Mold making has become extremely efficient in which the mold design utilizes current solid modeling techniques with libraries of mold components, and the mold manufacturing utilizes numerical controlled programming derived from the mold design on numerically controlled machining centers. Molding machines have become more capable and energy efficient with advances in machine components as well as easier to use with the incorporation of computer technology into user interfaces.

The selection adoption of advanced molding technologies is necessary to remain competitive. There has been a long term trend of consolidation by mergers and acquisition in the plastics industry. The resulting larger producers generally have a broader technology portfolio compared with the smaller producers. The smaller producers are responding by focusing on niche applications with a specialized technology strategy. These industry conditions are dynamic, but provide for very competitive services to customers.

INTRODUCTION

Ion exchange is a reversible chemical reaction where—in the most commonly used form—an ion from solution is exchanged with an equivalent amount of another ion of the same charge that is attached to an immobilized solid phase. However, presently the application of this technology has diversified to deal with gaseous streams as well as solids. The immobilized solid-phase particles are either naturally occurring inorganic zeolites or synthetic, organic ion-exchange resins. The primary morphology of ion exchangers is spheres of diameter 75–1000 μm, but membranes, composite sheets, and nanoparticles are increasingly being used for specialty applications. In most applications, the ion being removed from solution is a contaminant and is replaced by a benign ion from the solid phase, but this technology can easily be adapted to concentrate valuable ions also. The vast potential of this technology is derived from its ability to generate specific ion exchangers that have a high affinity for target ions. Thus selectivity of the ion exchanger plays a critical role and it allows engineers to design ion-exchange processes where the target ion is almost completely removed from the influent and the effluent contains ''nondetect'' amounts of it. Moreover, ion-exchange technology is almost always employed as a cyclical process. Therefore, the ability of a regenerating solution to desorb the target ion from the surface of the ion exchanger and reuse the ion exchanger for another exhaustion cycle is the critical factor in its success.

EVOLUTION OF ION EXCHANGE

The phenomenon of ion exchange was observed and scientifically documented for the first time by Way[1] and Thompson[2] in 1850. They confirmed the ion-exchange properties of soils and simulated the following naturally occurring cation-exchange reactions for calcium–potassium and calcium–ammonia systems:

$$2K^+(aq) + \overline{Ca^{2+}\text{–soil}} \Leftrightarrow \overline{(K^+)_2\text{–soil}} + Ca^{2+}(aq) \quad (1)$$

$$2NH_4^+(aq) + \overline{Ca^{2+}\text{–soil}} \Leftrightarrow \overline{(NH_4^+)_2\text{–soil}} + Ca^{2+}(aq) \quad (2)$$

Besides validating the occurrence of ion exchange, the experimental results of Waley and Thompson also established the preference of soil toward ammonium and potassium over calcium—a phenomenon that helped explain how ion exchange plays a key role in plants' uptake of nutrients from soils. In principle, the ion exchangers present in soil with varying selectivities toward different ions opened a new avenue to separate dissolved species by a simple filtration process.

The evolution of the ion-exchange process, however, happened rather slowly during the 19th and 20th centuries because of the difficulty associated with modifying or manipulating naturally occurring, inorganic clayey materials with low ion-exchange capacity. Also, the scientific understanding of ion-exchange fundamentals lagged well behind its application potential. It was gradually recognized that the primary factors that influence the relative selectivities of ions for such inorganic exchangers are:

1. Electrostatic (or coulombic) interaction between the ion-exchange sites and dissolved ions.
2. Hydrated ionic radii, which in turn are dependent on the solvation energy of the relevant ions.

Inorganic zeolites (synthetic or naturally occurring aluminosilicates) later found widespread application in softening hard water, i.e., removal of dissolved polyvalent cations, principally calcium and magnesium, through exchange with sodium.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120030553

However, anion-exchange processes still remained unexplored and practically unobserved.

The immense potential of ion-exchange technology hit a new high when the first organic-base (polymeric) cation exchanger was synthesized by Adams and Holmes in 1953.[3] In less than 10 years, D'Alelio prepared the first polymeric anion exchanger.[4] Since then, synthesis of new ion exchangers has continued at an unceasing rate, and applications of ion exchangers in industries as diverse as power utilities, biotechnology, agriculture, pharmaceutics, chemicals, microelectronics, environmental treatment, etc. are growing. Ironically, the World War II and, more specifically, the race for nuclear technology helped catalyze the growth and maturity of the field of ion exchange at an accelerated pace. Ion exchange was found to be a viable process for separating some of the critical transuranium elements and, for understandable reasons, its application aroused lot of interest. In fact, some of the most fundamental studies on ion-exchange equilibria and kinetics were carried out during World War II and reported afterward in technical literature.[5,6] Since then, the understanding of ion-exchange fundamentals has kept good pace with new application frontiers. In this regard, the publication of the landmark *Ion Exchange* by Friedrich Helfferich in 1962 provided a strong theoretical framework, especially for scientists/engineers working in this field.[7]

ION-EXCHANGE THEORY

In an ion-exchange reaction between the aqueous phase and the polymeric ion exchanger, the latter can be viewed as a strongly ionized electrolyte with a relatively low dielectric constant. Consequently, attempts have been made to mimic specific aqueous-phase interactions in the solid phase. The following interactions are often operative in selective ion-exchange processes:

1. Electrostatic (or coulombic type).
2. Hydrophobic (or Van der Waals type).
3. Lewis acid–base (metal ligand type).
4. Ion–dipole.
5. Dipole–dipole.
6. Ion sieving.
7. Ion exclusion.
8. Steric effect.

Many of these interactions can be characterized and enhanced by modifying or tailoring the following composition variables of the ion exchangers:

- Polymer matrix.
- Covalently attached functional groups.
- Crosslinking.
- Porosity.

Also, for the ion-exchange processes to be viable, the ion exchangers should be amenable to regeneration or desorption so that they may be used for hundreds of cycles. In fact, the overall economy of an ion-exchange process is often dictated by the operating costs of the regenerant chemicals as opposed to the fixed cost of the ion exchangers. Thus, ideally, an ion-exchanger process should be reversible so that the target solutes can be desorbed efficiently, thus leading to energy-efficient separation. In reality, however, efficiency of desorption (or regeneration) tends to diminish for highly selective sorbents because of the strong bonding (or high free energy change) between the target ion and the sorbent.

To strike a balance between selectivity and regenerability, the intensity of solute–sorbent interaction has to lie within an envelope where ion exchange is selective but at the same time reversible. Fig. 1[8] helps quantify such a working regime for various types of interactions. The importance of reversibility is also well recognized for homogeneous separation processes using specialty complexing agents.[9] It is worthwhile to note that more than one interaction may be operative for the sorption (ion exchange) of a single solute. In such cases, individual free energy changes are additive and may enhance the overall sorption affinity. For example, perchlorate and chloride are identical electrostatically, i.e., both are monovalent anions. But perchlorate exhibits much higher affinity toward an anion exchanger with polystyrene matrix and tributyl functional group because of accompanying hydrophobic bonding between perchlorate and the resin matrix.

ION-EXCHANGE EQUILIBRIUM

The preference of the ion exchanger for the target ion is often expressed as a separation factor, α_{ij}, or a selectivity coefficient, K_{ij}, for binary exchange.[10] Consider, for example, the cation-exchange reaction of Na^+ for H^+ in a cation exchanger:

$$\overline{R^-H^+} + Na^+ \leftrightarrow \overline{R^-Na^+} + H^+ \tag{3}$$

$$K = \frac{\{\overline{R^-Na^+}\}\{H^+\}}{\{\overline{R^-H^+}\}\{Na^+\}} \tag{4}$$

In Eqs. (3) and (4), overbars denote the ion-exchanger phase. For a cation-exchange reaction as shown here, the exchangeable ions (Na^+ and H^+) are termed "counterions" and the negatively charged ions in solution are called "coions." K is the thermodynamic equilibrium constant, and {} denotes ionic activity. For convenience of measurement, concentrations are used in practice in place of activities. In this case, in Eq. (4), based on concentration, the selectivity

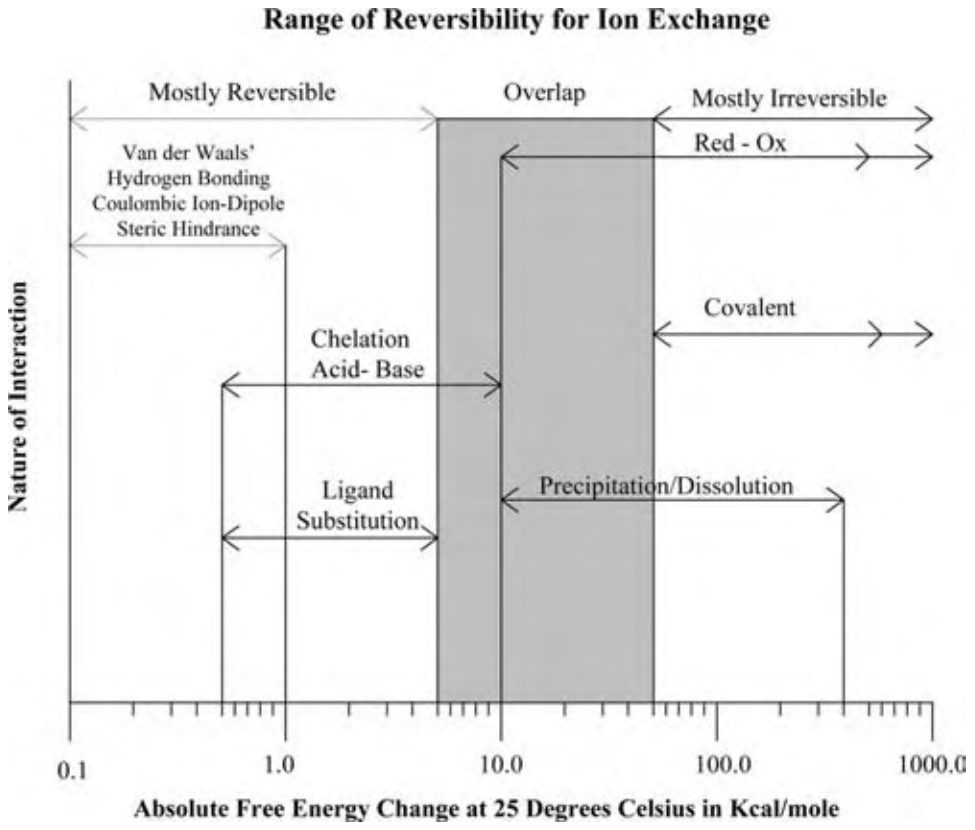

Fig. 1 A quantitative measure of various interactions in ion-exchange type sorption processes.

coefficient $K_{Na/H}$ describes the exchange. Note that $K_{Na/H}$ includes activity coefficient terms that are functions of ionic strength and thus is not a true constant, varying with different ionic strengths.

$$K_{Na/H} = \frac{[\overline{R^-Na^+}][H^+]}{[\overline{R^-H^+}][Na^+]} = \frac{q_{Na}C_H}{q_H C_{Na}} \quad (5)$$

where [ ] is the concentration (mole/L), q_{Na} the resin-phase concentration of sodium (equiv./L), and C_{Na} the aqueous-phase concentration of sodium (equiv./L).

The binary separation factor $\alpha_{Na/H}$ is a useful parameter that describes the ion-exchange equilibria because it is dimensionless:

$$\alpha_{ij} = \frac{\text{distribution of ion } i \text{ between phases}}{\text{distribution of ion } j \text{ between phases}} = \frac{y_i/x_i}{y_j/x_j} \quad (6)$$

Thus for the example above

$$\alpha_{Na/H} = \frac{y_{Na}/x_{Na}}{y_H/x_H} = \frac{y_{Na}x_H}{x_{Na}y_H} = \frac{(q_{Na}/q)(C_H/C_T)}{(C_{Na}/C_T)(q_H/q)} = \frac{q_{Na}C_H}{q_H C_{Na}} \quad (7)$$

where y_{Na} is the equivalent fraction of Na in resin (q_{Na}/q), y_H the equivalent fraction of H in resin (q_H/q), q_{Na} the concentration of Na on resin (equiv./L), q_H the concentration of H on resin (equiv./L), q the total exchange capacity of resin (equiv./L), x_{Na} the equivalent fraction of Na in water (C_{Na}/C_T), x_H the equivalent fraction of H in water (C_H/C_T), and C_T the total ionic concentration of water (equiv./L).

Eqs. (5) and (7) show that for homovalent exchange, the separation factor α_{ij} and the selectivity coefficient K_{ij} are equal. For our example, this translates as

$$K_{Na/H} = \frac{q_{Na}C_H}{q_H C_{Na}} = \alpha_{Na/H} \quad (8)$$

However, for heterovalent ion exchange, the separation factor is not equivalent to the selectivity coefficient. If we consider the case of calcium–sodium exchange,

$$\overline{2(R^-Na^+)} + Ca^{2+} \leftrightarrow \overline{(R^-)_2Ca^{2+}} + 2Na^+ \quad (9)$$

$$K_{Ca/Na} = \frac{q_{Ca}C_{Na}{}^2}{q_{Na}{}^2 C_{Ca}} \quad (10)$$

while

$$\alpha_{Ca/Na} = \frac{y_{Ca}/x_{Ca}}{y_{Na}/x_{Na}} \quad (11)$$

Combining Eqs. (10) and (11) we obtain,

$$\alpha_{Ca/Na} = K_{Ca/Na}\frac{q/C_T}{x_{Na}/y_{Na}} \quad (12)$$

Eq. (12) clearly shows that for heterovalent ion exchange, the separation factor can be manipulated through the total ionic concentration of the solution, C_T. The capacity of the resin, q, is a constant. The higher the C_T, the lower the $\alpha_{Ca/Na}$; i.e., selectivity tends to reverse in favor of the monovalent ion as the ionic strength increases. There is a general selectivity sequence for a typical cation or anion exchanger as shown in Table 1. Based on Table 1, it can be understood that a sodium-loaded cation exchanger can be used to remove a divalent cation such as Ca^{2+} from a dilute concentration of water—as is the case with hard water—as selectivity for $Ca^{2+} > Na^{+}$. When the resin is exhausted, a very high concentration Na^{+} solution (as NaCl) is passed through the resin bed.

Table 1 Relative selectivity of various counterions for a strong-acid cation exchanger

Counterion	Relative selectivity for AG 50W-X8 resin
H^{+}	1.0
Na^{+}	1.5
NH_4^{+}	1.95
K^{+}	2.5
Cu^{+}	5.3
Ag^{+}	7.6
Mn^{2+}	2.35
Mg^{2+}	2.5
Fe^{2+}	2.55
Zn^{2+}	2.7
Co^{2+}	2.8
Cu^{2+}	2.9
Cd^{2+}	2.95
Ni^{2+}	3.0
Ca^{2+}	3.9
Sr^{2+}	4.95
Hg^{2+}	7.2
Pb^{2+}	7.5
Ba^{2+}	8.7

AG 50W-X8 is a strong-acid cation exchanger with sulfonic acid functional group attached to a styrene-divinylbenzene copolymer matrix with 8% divinylbenzene and is available from Bio-rad Inc., California.

Based on Eq. (12), we see that as the C_T is increased, $\alpha_{Ca/Na}$ is decreased and for a certain C_T value, $\alpha_{Ca/Na} = 1.0$. If C_T is increased further, $\alpha_{Ca/Na} < 1.0$, i.e., selectivity reversal takes place and now the resin prefers Na^{+} to Ca^{2+}, which means that Ca^{2+} is easily eluted from the ion exchanger and it is back in Na^{+} form, where it can be used for another exhaustion cycle. This is best explained by the ion-exchange isotherm shown in Fig. 2. An ion-exchange isotherm is a constant temperature equilibrium plot of ion-exchanger-phase concentration vs. aqueous-phase concentration. A "favorable'' isotherm (convex to the x-axis) means that species i (which is plotted on each axis) is preferred to species j, the hidden or exchanging species. Thus if the isotherm is a 45° line, it means that the ion exchanger has no preference of i over j. And if the curve is concave to the x-axis, it indicates that j is preferred to i.

ION-EXCHANGE PROCESSES

Softening

The softening of hard waters (containing polyvalent cations) by ion exchange entails the substitution of polyvalent cations (principally Ca^{2+} and Mg^{2+}) by Na^{+}. This eliminates the undesirable characteristics of hard water, such as not lathering well, causing a scum in plumbing fixtures, and leaving hard, crusty scales on hot water heaters, coffee pots, etc. If the water has bicarbonate alkalinity, the ion-exchange reaction may be written as:

$$\overline{2R^{-}Na^{+}} + Ca(HCO_3)_2 \leftrightarrow \overline{(R^{-})_2Ca^{2+}} + 2NaHCO_3 \quad (13)$$

In a typical softening scenario, the combination of the facts that the influent is dilute (ionic strength of a few mequiv./L) and that divalent ions are more favored by the ion exchanger vis-à-vis monovalent ions results in almost complete migration of the target ion (Ca^{2+} in this case) from the solution to the ion-exchanger phase. When the ion-exchange capacity of the exchanger is reached, the ion-exchanger bed is backwashed with clean water at 6–8 gpm/ft^2 of bed area to expand the bed by about 50%. Then regeneration of the ion exchanger back to the sodium form is achieved by passing through the ion exchanger a strong brine solution (≈10%) to effect selectivity reversal. About 150–200% of theoretical amount of brine is needed to regenerate the exchanger. The regeneration cycle must be followed by a rinse cycle to remove the remaining brine from the bed. The total amount of rinse water needed is 20–35 gallons per cubic foot of

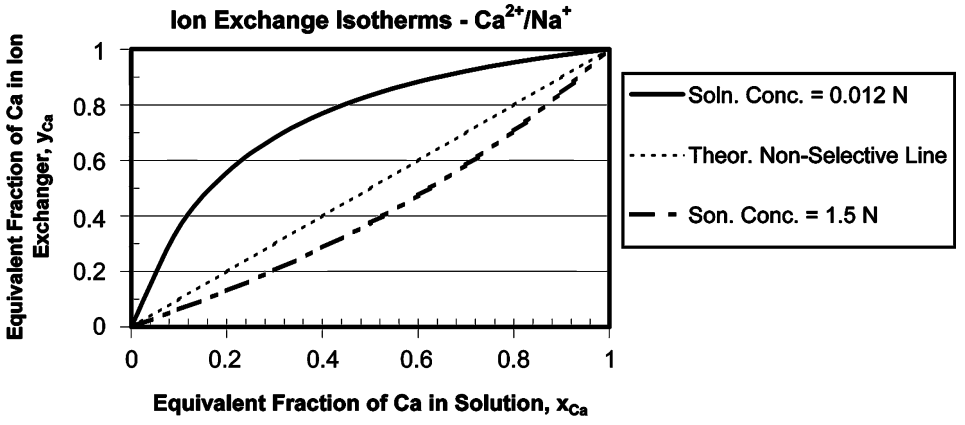

Fig. 2 Ion-exchange isotherm for Ca^{2+}/Na^{+} exchange showing selectivity reversal at high solution concentration.

resin. The total volume of the brine that is used during a regeneration cycle, together with the rinse water that follows, varies from 1.5% to 7% of the amount of water softened by the unit. The chloride concentration in this wastewater could be as high as 35,000–45,000 mg/L; therefore disposal of the spent brine becomes an important criterion. The steps in a conventional ion-exchange operation are shown in Fig. 3.

Demineralization

In many application scenarios such as high-pressure boilers, production of electronic components, synthesis of pharmaceuticals, etc. it is desirable to remove all the dissolved ions from the water. This process is termed demineralization. The primary use of ion exchangers is in demineralization because it can achieve the goal at low cost, and the quality is comparable to that by distillation. The process depends on two reaction stages. In the first, all cations are removed and replaced by H^{+}, using a hydrogen-loaded cation exchanger. In the second stage, acids produced are removed by a hydroxide-loaded anion exchanger. The cation exchanger is regenerated with an acid and the anion exchanger with an alkali. The reactions are

Cation-exchange step:

$$\overline{R^{-}H^{+}} + NaCl \leftrightarrow \overline{R^{-}Na^{+}} + HCl \quad \text{(service)} \tag{14}$$

$$\overline{2R^{-}Na^{+}} + H_2SO_4 \leftrightarrow \overline{2R^{-}H^{+}} + Na_2SO_4 \quad \text{(regeneration)} \tag{15}$$

Anion-exchange step:

$$\overline{R\text{–}CH_2N^{+}(CH_3)_3OH^{-}} + HCl \leftrightarrow \overline{R\text{–}CH_2N^{-}(CH_3)_3Cl^{-}} + H_2O \quad \text{(service)} \tag{16}$$

$$\overline{R\text{–}CH_2N^{+}(CH_3)_3Cl^{-}} + NaOH \leftrightarrow \overline{R\text{–}CH_2N^{-}(CH_3)_3OH^{-}} + NaCl \quad \text{(regeneration)} \tag{17}$$

Another major contaminant of pure water is silica. It is removed in the demineralization process by a strong-base anion exchanger in hydroxide mode.

Silica removal:

$$\overline{R\text{–}CH_2N^{+}(CH_3)_3OH^{-}} + H_4SiO_4 \leftrightarrow \overline{R\text{–}CH_2N^{+}(CH_3)_3H_3SiO_4^{-}} + H_2O \quad \text{(service)} \tag{18}$$

With a silica-loaded exchanger, a unique reaction of polymerization of silica inside and its migration into the interior of the exchanger also takes place that can

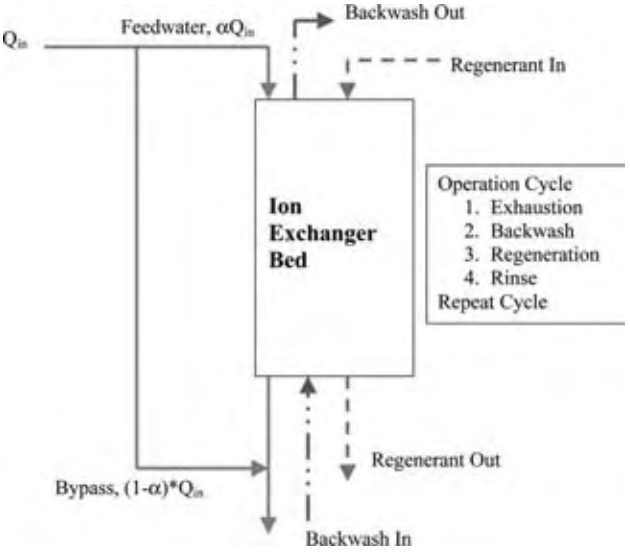

Fig. 3 Schematic of a conventional ion-exchange cycle. *(View this art in color at www.dekker.com.)*

be represented by the following reaction:

$$\overline{R\text{–}CH_2N^+(CH_3)_3H_3SiO_4^-} + xH_4SiO_4 \leftrightarrow \overline{R\text{–}CH_2N^+(CH_3)_3H_3SiO_4^- \cdot xH_4SiO_4} \quad \text{(polymerization)} \tag{19}$$

The exchanger is regenerated by a strong alkali:

$$\overline{R\text{–}CH_2N^+(CH_3)_3H_3SiO_4^- \cdot xH_4SiO_4} + NaOH \leftrightarrow \overline{R\text{–}CH_2N^+(CH_3)_3OH^-} + NaH_3SiO_4 + xH_4SiO_4 \tag{20}$$

ION-EXCHANGE MEMBRANE

Ion-exchanger membranes have been in use since the 1950s. A ''membrane,'' according to the usual definition, ''is a solid or liquid film or layer with a thickness that is small compared to its surface.''[7] In the case of ion-exchanger membranes, a broader definition has come into use. It includes any ion-exchange material, irrespective of its geometrical form, which can be used as a separation wall between two solutions. Two types of ion-exchanger membrane are in use: ''homogeneous'' and ''heterogeneous.'' ''Homogeneous'' membranes are coherent ion-exchanger gels in the shape of disks, ribbons, etc. Their structure is that of the usual ion-exchange resins. They are homogeneous only in dimensions that are large compared with the mesh width of the matrix. ''Heterogeneous'' membranes consist of colloidal ion-exchanger particles embedded in an inert binder (polystyrene, polyethylene, wax, etc.; see Fig. 4. Their mechanical stability is superior, but their electrochemical properties such as conductivity and barrier action are not as good as those of the homogeneous membranes.[11] However, at present, the combination of a strong fabric and a chemically stable binder has made heterogeneous membranes the material of choice in many industrial processes. Table 2 provides details of an anion-exchanger and a cation-exchanger membranes that are commercially available from Sybron Chemicals, Inc., a Bayer Company (no commercial endorsement implied).

The ability of ion-exchanger membranes to act as a separation wall, along with the chemical and electrochemical properties of the ion exchangers, provides manifold opportunities toward selective separation and movement of ions. The principal phenomenon in any ion-exchanger membrane is Donnan coion exclusion. Consider an ion-exchanger membrane that separates two solutions containing ions (both cation and anion) of different concentration. If the ions were without any charge, these concentration differences would be leveled out by diffusion. However, in the case of ions, such a process would disturb electroneutrality. For example, if a cation-exchanger membrane separates two solutions, any migration of anion from the solution to the membrane would result in the accumulation of negative charge in the membrane. The first few anions that diffuse into the membrane thus build up an electric potential between the two phases. This so-called ''Donnan potential'' pulls anions back into the solution. Thus, when in contact with electrolyte solutions of low or moderate concentrations, the membrane contains a large number of counterions but relatively few coions. Counterions are admitted to the membrane and have little difficulty in passing through from one solution to the other. Coions, on the other hand, are rather efficiently excluded from the membrane and thus find it difficult to pass through. In other words, the membrane is perm selective for counterions.

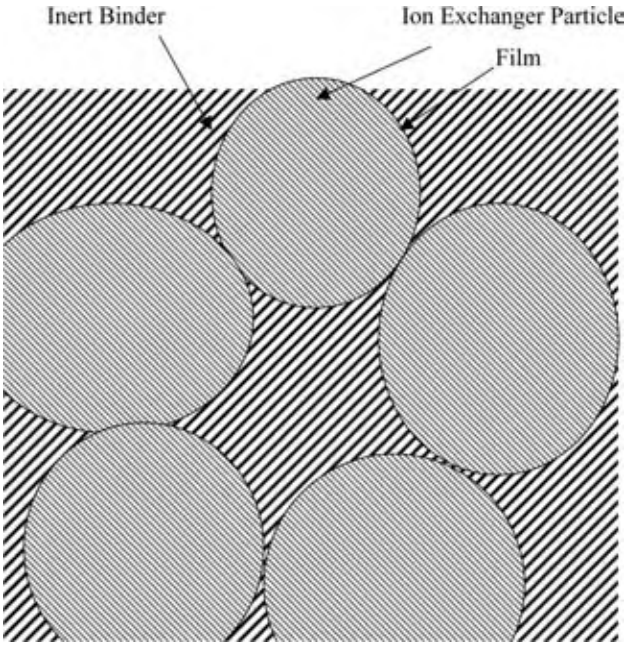

Fig. 4 Structure of a heterogeneous membrane (schematic). Colloidal ion-exchanger particles (1–10 μm in diameter) are embedded in an inert binder. (From Ref.[7].)

ELECTRODIALYSIS

Electrodialysis is an ion-exchanger membrane process used to treat brackish water. In this process, electric energy is used to transfer ionized salts from feedwater through membranes, leaving behind a purified product water.[12] In this process, cation- and anion-selective membranes are placed alternately between two electrodes (cathode and anode), as shown in

Table 2 Properties of two ion-exchanger membranes

Type	Cation	Anion
Brand name	MC-3470	MA-3475
Width (m)	1.09	1.22
Length (m)	3.1	3.1
Thickness (mm)	15	16
Exchange capacity (mequiv./g)	1.4	0.9
Mullen Burst test (bar)	10.3	10.3
Area resistance (Ω/cm)		
0.1 N NaCl	25	50
1.0 N NaCl	10	25
Permselectivity (0.5 N NaCl)	96	99
Water permeability (ml/hr/ft^2 at 5 psi)	25	25
Temperature stability (max.; °C)	80	80
Chemical stability (pH)	1–10	1–10
Current density (max.; A/ft^2)	50	50
Ionic form (as shipped)	Sodium	Chloride

Fig. 5. These cation- and anion-selective membranes are separated by cut-out plastic spacers to form what is known as a membrane stack. A typical membrane stack has several hundred cell pairs, with each pair consisting of one ''dilute'' and one ''concentrated'' cells as shown in Fig. 6. The electrodes are charged by a direct current source. The anions and cations move through the respective selective membranes to form concentrated and dilute/pure solutions in the cell between alternating membranes. The concentrated and pure solutions are collected via separate piping manifolds for ultimate disposal or use. A patented process by Ionics of Watertown, Massachusetts, termed electro dialysis reversal (EDR) provides a

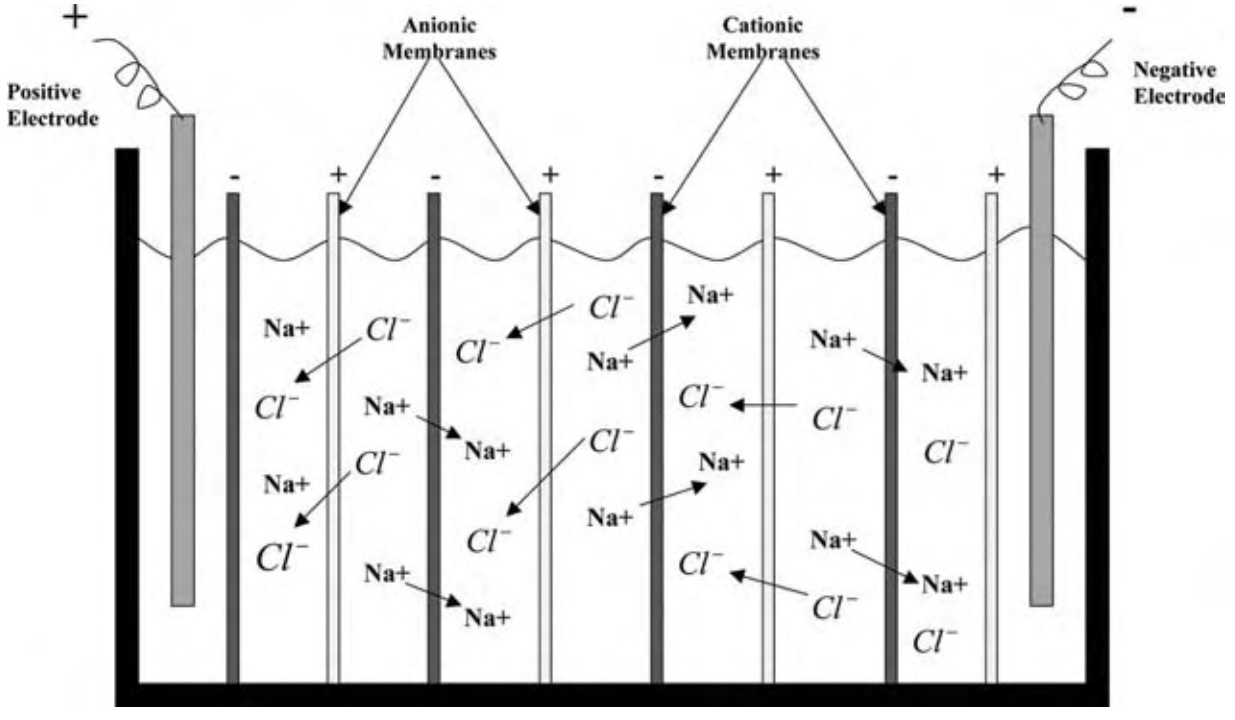

Fig. 5 Schematic of electrodialysis showing the electrodes and membrane stack. *(View this art in color at www.dekker.com.)*

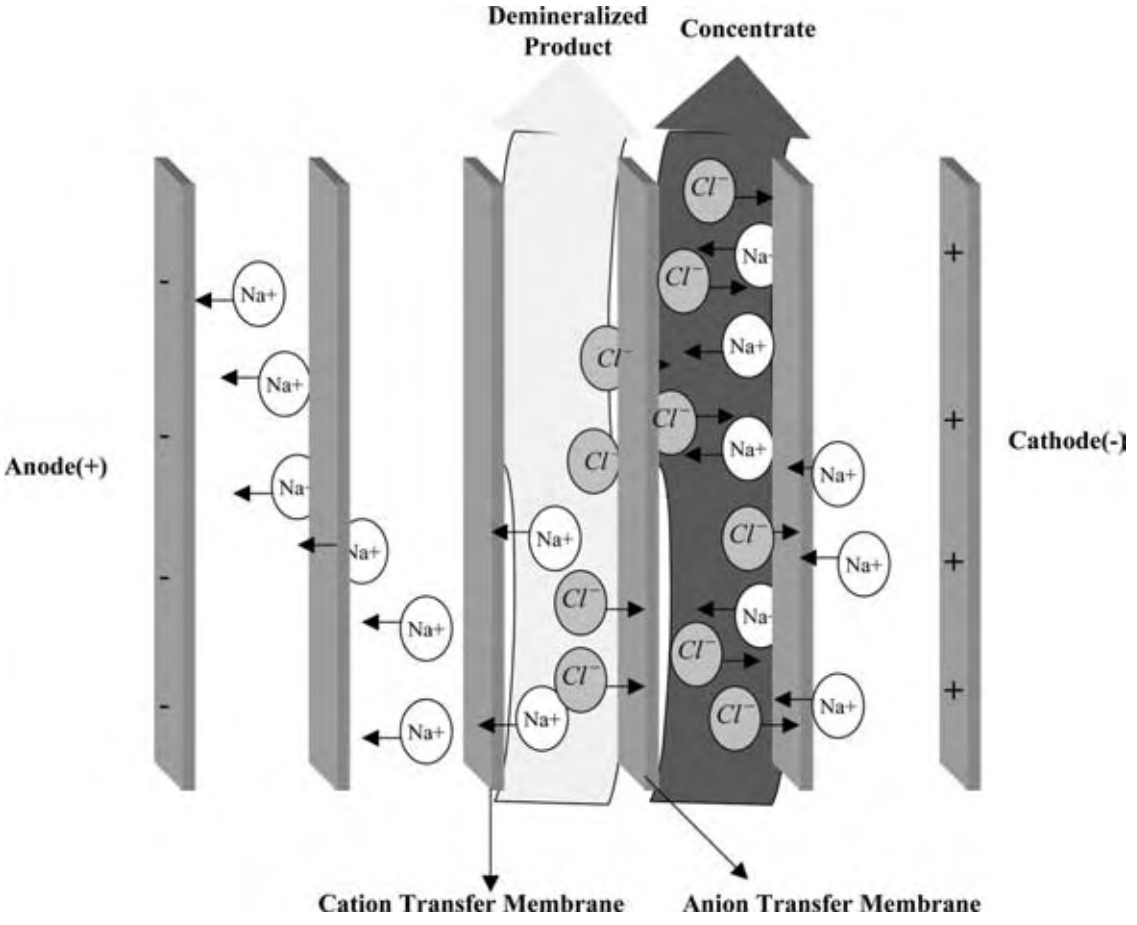

Fig. 6 Schematic of electrodialysis showing concentrate and product water. *(View this art in color at www.dekker.com.)*

self-cleaning capability that enables desalting of scaling or fouling waters and recovery of up to 94% of the feed as product water.

FLUXES IN MEMBRANE SYSTEMS

The overall flux J_i of an arbitrary species i is composed of three additive terms: the diffusion flux $(J_i)_{\text{diff}}$ caused by the chemical potential gradient of the species (Fig. 7), the electric transference $(J_i)_{\text{el}}$ caused by the electric potential gradient, and the transfer $(J_i)_{\text{con}}$ caused by convection. The diffusion flux is

$$\begin{aligned}(J_i)_{\text{diff}} &= (-)D_i C_i \operatorname{grad} \mu_i \\ &= (-)D_i(\operatorname{grad} C_i + C_i \operatorname{grad} \ln f_i)\end{aligned} \tag{21}$$

The electric transference is

$$\begin{aligned}(J_i)_{\text{el}} &= (-)u_i z_i C_i \operatorname{grad} \phi \\ &= (-)D_i z_i C_i \frac{\Gamma}{RT} \operatorname{grad} \phi\end{aligned} \tag{22}$$

and the transfer by convection is

$$(J_i)_{\text{con}} = C_i \beta \tag{23}$$

where β is the rate of motion of the center of gravity, T the absolute temperature, R the universal gas constant, Γ Faraday's constant, φ the electric potential, C_i the concentration of the ion, z_i the electrochemical valence of the ion, D_i the diffusion coefficient of the ion, u_i the electrochemical mobility of the ion, μ_i the chemical potential of the ion, and f_i the molar activity coefficient of the ion.

Thus the overall flux is given by

$$\begin{aligned}J_i &= (J_i)_{\text{diff}} + (J_i)_{\text{el}} + (J_i)_{\text{con}} \\ &= (-)D_{\text{i}}\left(\operatorname{grad} C_i + z_i C_i \frac{\Gamma}{RT} \operatorname{grad} \phi \right. \\ &\qquad \left. + C_i \operatorname{grad} \ln f_i\right) + C_i \beta\end{aligned} \tag{24}$$

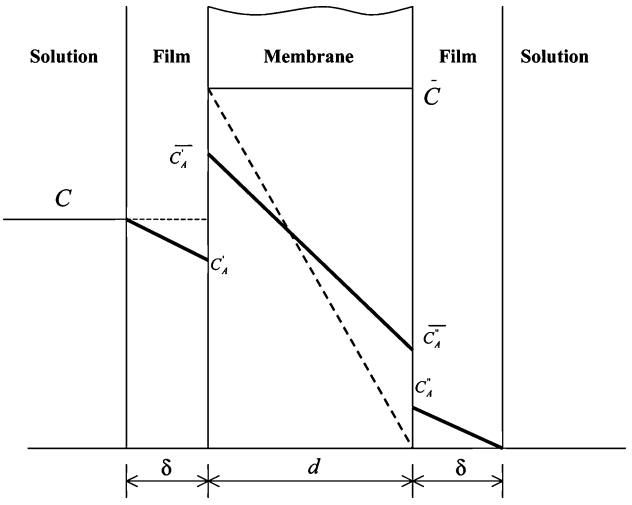

Fig. 7 Schematic of counterion diffusion across ion-exchange membrane.

DONNAN DIALYSIS

Donnan dialysis is based on the same principles as electrodialysis except that there is no external potential gradient applied; the only physical force causing movement of ions is diffusion. It has been used in wastewater and drinking water treatment, and in hydrometallurgical operations.[13–18] Its main advantage is that there is no need for an external electric field or a pressure gradient. Thus it is a cheap and a passive process, making it extremely easy to operate. It has been used mainly to concentrate (and recover) ions from a lower to a higher concentration, primarily by forcing the movement of a benign counterion in the opposite direction. For example, in Fig. 8, Donnan dialysis is used to concentrate NH_4^+ and PO_4^{3-} ions from sewage sludge. The sludge is placed in the central chamber. On one side of the sludge chamber is an acid chamber and on the opposite side is the alkali chamber. Both the side chambers are of much smaller volume than the sludge chamber. The acid chamber is separated from the sludge chamber by a selective cation-exchange membrane. This membrane only allows cations to pass through and is impermeable to anions. Similarly, the alkali chamber is separated from the sludge chamber by a selective anion-exchange membrane that only allows anions to pass through and is impervious to cations. A strong mineral acid is placed in the acid chamber. Because the acid chamber has a very high H^+ concentration and the sludge chamber is almost neutral, there is a high gradient of H^+ established and H^+ will tend to move from the acid chamber to the sludge chamber. At the same time, the sludge chamber has a very high concentration of NH_4^+, but the acid chamber has no NH_4^+ ion in the beginning. Therefore, to even out this high difference of concentration, NH_4^+ will move from the sludge chamber to the acid chamber. To maintain electroneutrality, each equivalent of H^+ that moves across the membrane in one direction has to be equal to an equivalent of NH_4^+ that moves in the opposite direction. Please note that NH_4^+ being a cation, it cannot move across the anion membrane. Similarly, the alkali chamber will contain a strong alkali in the beginning. This will set up a similar situation for the PO_4^{3-} to move from the sludge chamber to the alkali chamber and this will be equal to the equivalents of OH^- that will move from the alkali chamber to the sludge chamber. This process will go on until the concentrations of H^+ and NH_4^+ are partitioned to equilibrium in the sludge and the acid chambers, and the concentrations of OH^- and PO_4^{3-} are partitioned to equilibrium in the sludge and the alkali chambers. The net result is that NH_4^+ and PO_4^{3-} are concentrated in the acid and the alkali chambers, respectively. As the acid and alkali chambers have much smaller volume than the sludge chamber, the equilibrium concentrations of NH_4^+ and PO_4^{3-} in the acid and the alkali chambers are much higher than the final concentration in the sludge chamber. Please note that because of the low concentration of the heavy metals in the sludge and the selective nature of the cation-exchange

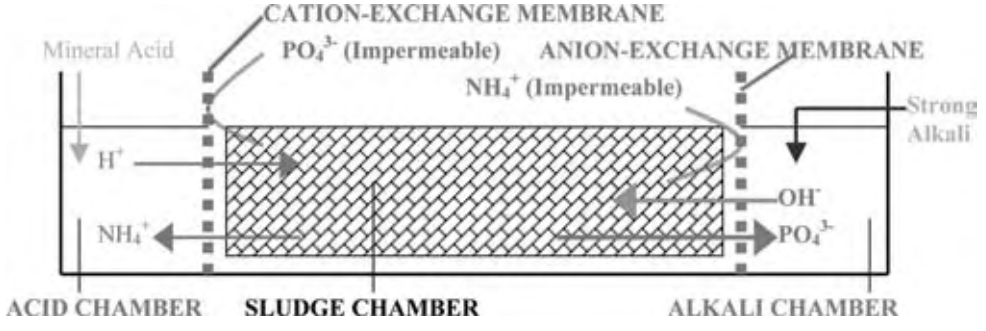

Fig. 8 Schematic diagram of Donnan dialysis process. *(View this art in color at www.dekker.com.)*

membrane, heavy metals remain in the sludge. The details of chemical equations are as follows:

When equilibrium is achieved, the redistributed NH_4^+ and H^+ will satisfy the following equation:

$$\left(\frac{C_{NH_4,AC}}{C_{NH_4,SC}}\right)^{z_H} = \left(\frac{C_{H,AC}}{C_{H,SC}}\right)^{z_{NH_4}} \quad (25)$$

The diffusion flux and the electric transference flux are provided in Eqs. (21) and (22). The convective flux is zero. The principle of electroneutrality mandates that the concentration of all counterions is equal to those of fixed ions, viz., the exchange capacity of the membrane (Q):

$$z_H q_H + z_{NH_4} q_{NH_4} = Q \quad (26)$$

Because of the condition of zero current, the sum of flux of feed ions J_H and that of driving ions J_{NH_4} is zero.

$$z_H J_H + z_{NH_4} J_{NH_4} = 0 \quad (27)$$

On solving the above equations simultaneously, the flux for ammonium transference can be determined. A similar set of equations can be generated for phosphate–hydroxide exchange. Table 3 shows data of preliminary, unpublished study conducted by the lead author in this area.

The advantages of this process are as follows:

1. It selectively extracts N and P from the sludge in a concentrated form that can be used as a mineral fertilizer.
2. The heavy metals and organic contaminants remain in the sludge.
3. It is a simple and passive process that does not require strict supervision.
4. The ion-exchange membranes (cation and anion) do not need any regeneration. Just a slight rinse after each cycle is adequate for its sustained performance.

COMPOSITE ION-EXCHANGE MATERIAL

Until now, our discussion was confined to using ion exchangers for removal of selective ions from a pure aqueous phase, i.e., there were no suspended solids in the wastestream, or using ion-exchanger membranes in Donnan dialysis. The ion-exchange resins involved were granular or spherical. With ion-exchanger membranes, they could be used with sludges and high-suspended solids only in Donnan dialysis, where the mixture is undisturbed. Lately, however, we have been encountering challenging environmental separation problems where the medium is essentially a slurry or sludge with high-suspended solid content. A vast new area of application would open up if the morphology of ion-exchanging polymers can be modified to remove selective ions from a solid-phase background. For example, a widespread environmental problem is the disposal of sludges or treatment of soil contaminated with minor fraction (often less than 5%) of heavy metals in the solid phase in an otherwise innocuous background of materials that are not important from a regulatory viewpoint. This problem stems from the fact that the heavy metals present can cause the sludge/soil to be designated as a ''hazardous'' waste, thus greatly increasing the cost of disposal. Selective and targeted removal of the heavy metals from the background solid phase would constitute an efficient treatment process as it would render the sludge non-hazardous, and may make it possible for the heavy metals to be concentrated and recycled/reused. The physical configuration of conventional ion exchangers (spherical or granular) makes their use inappropriate for such a case. A material identified in Refs.[19–26] shows potential of being appropriate under such conditions. It is a new class of sorptive/desorptive composite ion-exchange material (CIM) available commercially as thin sheets (approximately 0.5 mm thick) and is suitable for heavy-metal decontamination from sludges/slurries. The morphology of the material—along with its physical texture and tensile strength—makes it compatible for use with sludges/slurries. This property

Table 3 Results of preliminary, unfunded research

Time (days)	Nitrogen concentration in sludge chamber (mg/L)	Nitrogen concentration in acid chamber (mg/L)	Phosphorus concentration in sludge chamber (mg/L)	Phosphorus concentration in alkali chamber (mg/L)
0	2800	0	1000	0
1	2700	1200	900	800
2	2600	1800	850	1200
3	2550	2400	800	1900
5	2500	2800	760	2200
7	2450	3400	710	2800

of the material, when combined with the adapting of the chemistry of the reactor and/or creating an electric gradient induced ion-transport process, makes it possible to selectively remove heavy metals from a solid-phase background composed primarily of nonregulated elements. The CIM is a thin sheet prepared by comminuting a crosslinked polymeric ion exchanger to a fine powder and fabricating it mechanically into a microporous composite sheet consisting of ion-exchange particular matter enmeshed in polytetrafluoroethylene (PTFE). During this mechanical process, the PTFE microspheres are converted into microfibers that separate and enmesh the particles.[19] When dry, these composite sheets consist of >80 wt.% particles (polymeric ion exchanger) and <20 wt.% PTFE. They are porous (usually >40% voids, with pore size distribution that are uniformly below 0.5 μm). The ion-exchange microspheres are usually <100 μm in diameter and with a total thickness of ≈0.5 mm. As such, they are effective filters that remove suspended solids that are >0.5 μm from permeating fluids. Because of such sheetlike configuration, this material can be easily introduced into or withdrawn from a reactor with high concentration of suspended solids, with the target solutes being adsorbed onto or desorbed from the microadsorbents. Fig. 9 shows the electron microphotograph of the composite iminodiacetate (IDA) membrane (top) and a schematic depicting how the microbeads are trapped within the fibrous network of PTFE (bottom). Table 4 provides the salient properties of the composite IDA membrane used in the study. Note that the chelating microbeads constitute 90% of the composite membrane by mass. This feature allows the membrane to achieve the same level of performance as the parent chelating beads used in a fixed-bed operation. More details about characterization of the membrane are available in Ref.[24]. It may be noted that this material differs fundamentally from traditional ion-exchange membranes used in industrial process like Donnan dialysis (DD) and electrodialysis (ED) because of its high porosity. The membranes used in DD and ED have very low porosity and are strongly influenced by the "Donnan coion exclusion principle,"[27] which does not allow anions to pass through cation-exchange membrane and vice versa. However, in the case of a composite membrane, large gaps between ion exchangers allow anions to pass through freely even though it is a cation-exchange membrane. The suspended solids that

Chemical stability	Methanol; 1 N NaOH, 1 N H_2SO_4
Commercial availability	3M Corp., Minnesota, and Bio-Rad, California

are >0.5 μm are not able to penetrate across the skin of the membrane because of the pore size of the material, as explained above. However, water molecules and ions can easily move in and out of the thickness of the sheet, thus allowing for unimpeded ion-exchange reactions between target ions in solutions (heavy metals in this case) and the counterions of the membrane, as shown schematically in Fig. 10 and explained in detail by Sengupta.[19–26] After a design time interval, the membrane can be taken out and chemically regenerated with strong (3–5%) mineral acid solution.

PROCESS CONFIGURATION

Fig. 11 shows a conceptualized process schematic where a composite membrane strip is continuously run through the contaminated sludge (sorption step) and an acid bath (desorption step). Such a cyclic process configuration is relatively simple and can be implemented by using the composite membrane as a slow-moving belt. For a sludge containing heavy-metal hydroxide, say $Me(OH)_2$, the process works in two steps:

1. *Sorption:* The CIM, when in contact with the sludge, selectively removes dissolved heavy metals from the aqueous phase in preference to other nontoxic alkali and alkaline earth metal cations. Consequently, fresh heavy-metal hydroxide dissolves to maintain equilibrium, and the following reactions occur in series:

$$\text{Dissolution:}\quad Me(OH)_2\,(s) \Leftrightarrow Me^{2+} + 2\,OH^- \tag{28}$$

$$\text{CIM uptake:}\quad \overline{RN(CH_2\,COOH)_2} + Me^{2+} \Leftrightarrow \overline{RN(CH_2\,COO^-)_2\,Me^{2+}} + 2\,H^+ \tag{29}$$

3. *Desorption:* When the CIM is immersed in the acid chamber, the exchanger microbeads are efficiently regenerated according to the following reaction:

$$\overline{RN(CH_2COO^-)_2Me^{2+}} + 2H^+ \Leftrightarrow \overline{RN(CH_2COOH)_2} + Me^{2+} \tag{30}$$

The regenerated CIM is then ready for sorption again and the cycle is repeated. For such an arrangement to be practically feasible, the CIM sheet needs to be physically tough enough to withstand conveyor belt tension and resilient to the chemical forces that are created during sorption and regeneration. Previous studies conducted[21] in this area have confirmed that the CIM sheet is durable enough to withstand cyclical forces (physical and chemical) for more than 200 cycles.

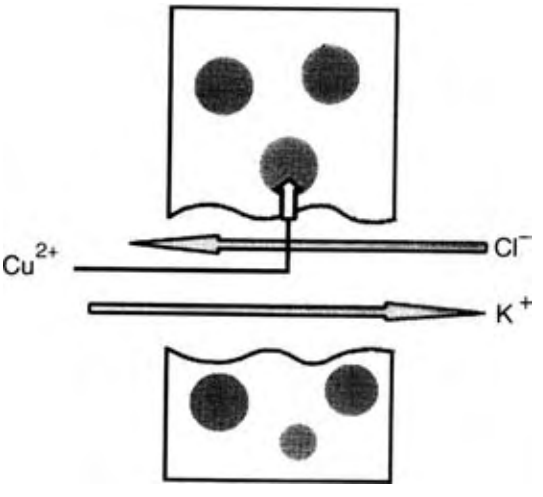

Fig. 10 Schematic diagram showing the porosity of the CIM to cations and anions and selective entrapment of heavy-metal cations.

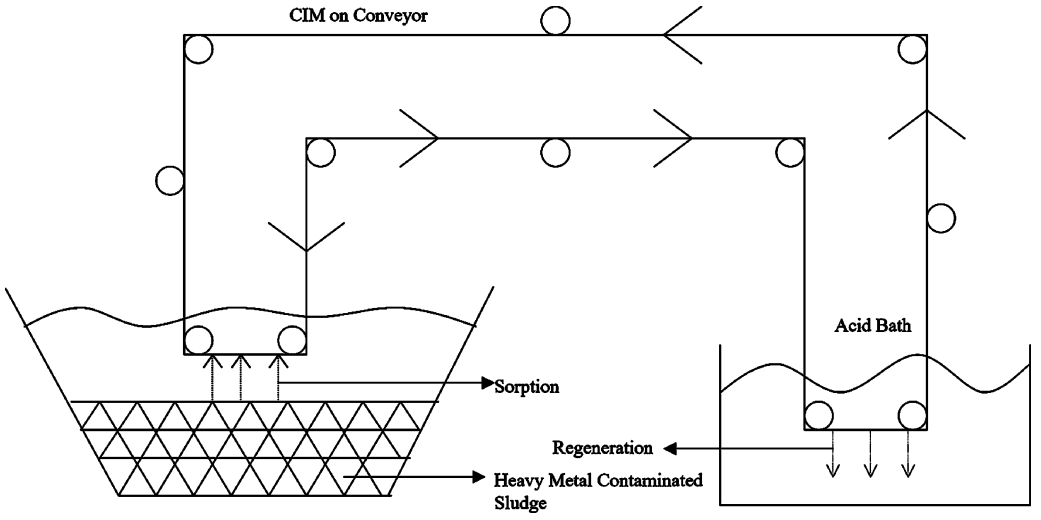

Fig. 11 A conceptualized continuous decontamination process for heavy-metal removal from a sludge reactor using CIM.

SORPTION KINETICS OF THE CIM

With chelating ion-exchanger beads that are used for heavy-metal removal, intraparticle diffusion is the most probable rate-limiting step. But for CIM composed of chelating resin, a significantly different physical configuration of the CIM may introduce additional diffusional resistance within it. As may be observed from the schematic diagram in Fig. 12, fairly stagnant pore liquid is present in the channels of the CIM between individual microbeads, and the solutes need to be transported through this pore liquid for sorption or desorption. This additional resistance to sorption/desorption is likely to retard kinetic rate.

Fig. 13 shows the results of a batch kinetic study (fractional metal uptake vs. time) comparing the parent chelating exchanger with the CIM under otherwise identical conditions. Fractional metal uptake, $F(t)$, is dimensionless and is defined as the ratio of the metal uptake $q(t)$ after time t and the metal uptake at equilibrium, q^0, i.e., $F(t) = q(t)/q^0$. Although the parent chelating microbeads were bigger in average diameter (50–100 mesh) than the microbeads within the CIM, the copper uptake rate, as speculated, was

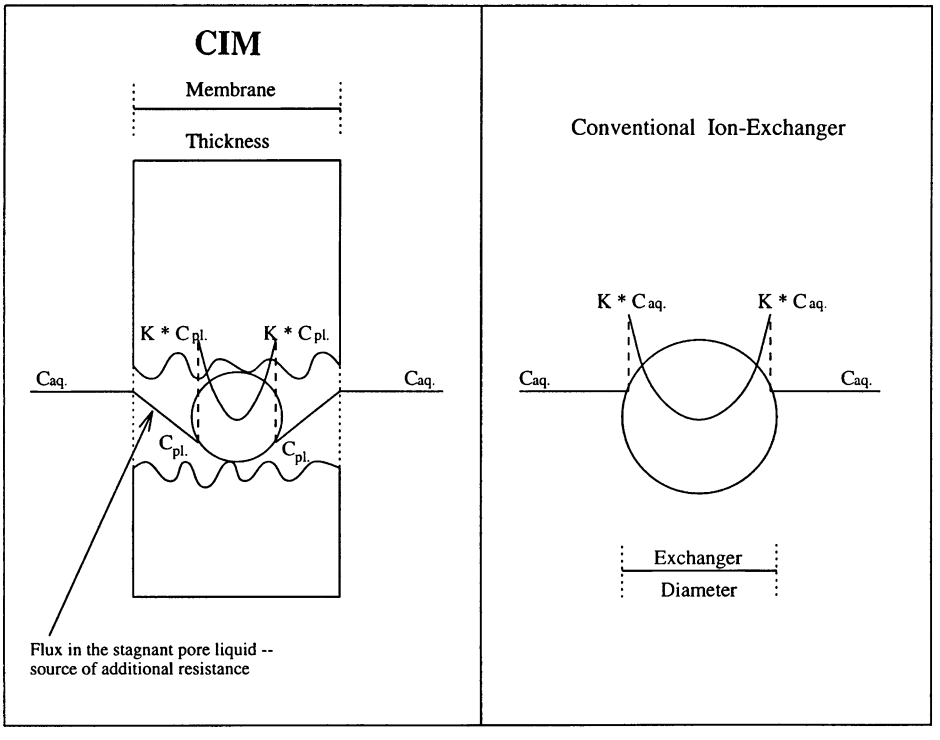

Fig. 12 Schematic showing the difference in flux curves between a conventional (spherical bead) ion exchanger and the CIM.

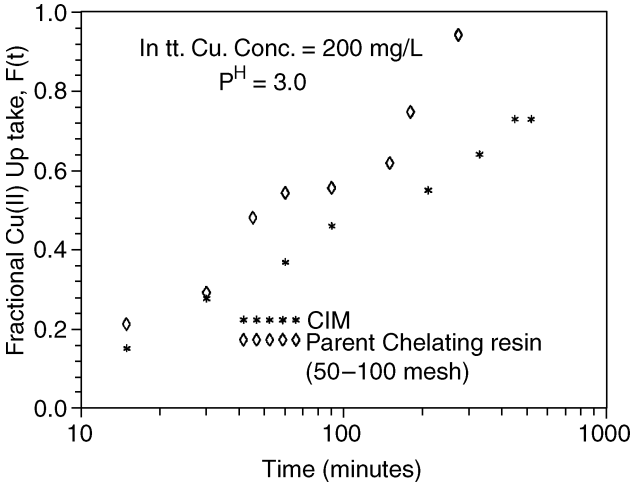

Fig. 13 Cooper uptake rates for the CIM vs. the parent chelating exchanger under identical solution condition.

slower with the CIM. To overcome the complexity arising because of the heterogeneity of the CIM (chelating microbeads randomly distributed in non-adsorbing Teflon fibers), a model was proposed,[20,21] in which the thin-sheetlike CIM may be viewed as a flat plate containing a pseudohomogeneous sorbent phase as shown in Fig. 14. Under the experimental conditions, it may be assumed that

1. Surface of the CIM is in equilibrium with the bulk of the liquid phase.
2. Total amount of solute in the solution and in the CIM sheet remains constant as the sorption process is carried out.
3. Solute (heavy metal) has high affinity toward the thin-sheet sorbent material.

This is a case of diffusion from a stirred solution with limited volume. The CIM is considered as a sheet of uniform material of thickness $2w$ placed in the solution containing the solute, which is allowed to diffuse into the sheet. The sheet occupies the space $-w \leq x \leq +w$, while the solution is of limited extent and occupies the space $-w - a \leq x \leq -w$, $w \leq x \leq +w + a$. The concentration of the solute in the solution is always uniform and is initially C_0 while initially the sheet is free from solute. Considering an apparent metal-ion diffusivity within the CIM phase, the PDE that must be solved in this case of metal uptake through a plane sheet (the thickness of the CIM) from a solution of limited volume is given as:

$$\frac{\partial C}{\partial t} = \overline{D}\frac{\partial^2 C}{\partial x^2} \tag{31}$$

where x is the axial space coordinate in the direction of CIM thickness and C the concentration of solute in the solution.

The IC of the above PDE is

$$C = 0, \quad -w < x < +w, \; t = 0 \tag{32}$$

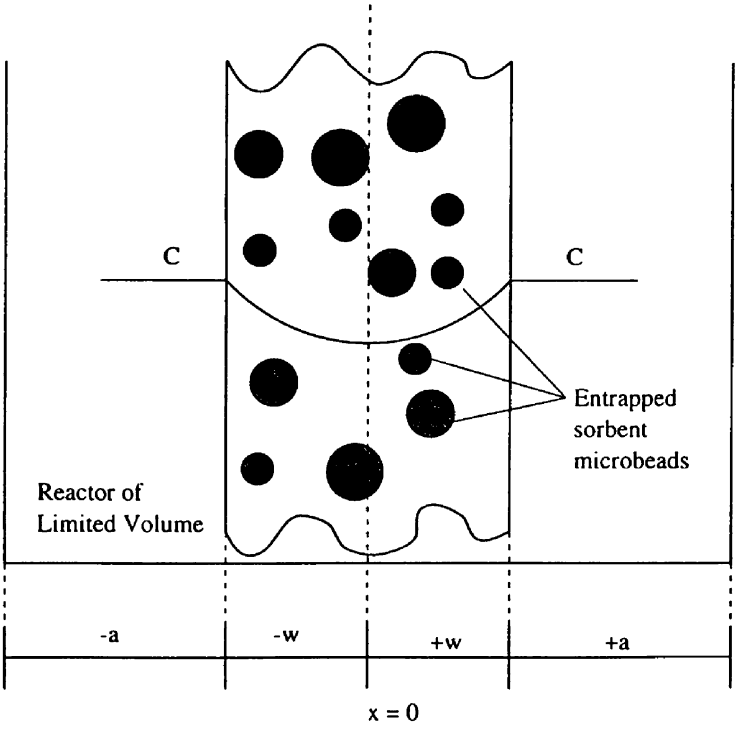

Fig. 14 Schematic showing sorption through an assumed flat flate with constant diffusivity from a reactor of limited volume.

and the BC expresses the fact that the rate at which the solute leaves the solution is always equal to that at which it enters the sheet over the surfaces, $x = \pm w$. This condition is mathematically expressed as

$$\frac{a}{K}\frac{\partial C}{\partial t} = \pm\overline{D}\frac{\partial C}{\partial x}, \quad x = \pm w,\ t > 0 \tag{33}$$

where K is the partition factor between the CIM and the solution, i.e., the concentration just within the sheet is K times that in the solution.

An analytical solution of this problem is given as,[28]

$$F(t) = \frac{q_t}{q^0} = 1 - \sum_{n=1}^{\infty}\frac{2\alpha(1+\alpha)}{1+\alpha+\alpha^2 q_n^2}\exp\left(\frac{-\overline{D}q_n^2 t}{w^2}\right) \tag{34}$$

where the q_n values are the nonzero positive roots of

$$\tan q_n = -\alpha q_n \tag{35}$$

and $\alpha = a/(Kw)$.

CONCLUSIONS

Ion-exchange technology has now matured enough to be the primary choice for a variety of applications spanning many industrial and municipal applications. Its primary advantage is that it can remove ions to almost nondetect levels from the matrix. Also, ion-exchange technology has the ability to selectively remove some ions from the background of other, nontarget ions. The primary area of research in this field is the synthesis of new ion exchangers (primarily organic) that can carry out selective removal of target ions that are determined to be toxic at very trace concentrations (at the level of μg/L or less), such as perchlorate, radium, uranium, cesium, heavy metals, oxyanions, etc. Other important areas of development in this field are the morphology of the ion exchanger and the nature of contact between the exchanger and the contaminated matrix, be it solid, liquid, or gas. Ion-exchanger membranes, composite ion-exchange material, nanofibers, microspheres, etc., have shown potential in many scenarios where the traditional ion-exchanger beads cannot be used. Lastly, the efficient disposal of wastestreams from regeneration of ion exchangers and the ability to recover/recycle valuable ions from this wastestream have received widespread attention of many researchers. It is expected that future developments in this area will result in ion-exchange technology making inroads into new application scenarios, either as a stand-alone operation, or in a treatment scheme in combination with other physical/chemical, biological, or thermal processes.

INTRODUCTION

An ion exchange resin consists of a cross-linked framework—termed matrix—that consists of an irregular, macromolecular, three-dimensional network of hydrocarbon chains. Charged functional groups are attached to the matrix by covalent bonding. The predominant form of ion exchange resins is as spherical beads in the size range of 75–1500 μm. If the resin is capable of exchanging cations, it is termed as a cation exchange resin and the functional groups are negatively charged. Similarly, if the resin exchanges anions, it is termed as an anion exchange resin and the functional groups are positively charged. The fixed functional groups are balanced by counterions of opposite charge to maintain electroneutrality. The counterions are exchanged with other ions of the same charge in solution.

The matrix of a majority of ion exchange resins is made by the coplymerization of styrene and divinylbenzene (DVB). Styrene provides the general backbone, while DVB acts as the cross-linker, i.e., it interconnects the various styrene chains. This cross-linking agent makes the ion exchange resin insoluble, an extremely important characteristic of the material. However, the resin is elastic and can swell by taking up solvent. The chemical, thermal, and mechanical stability and the ion exchange behavior of the resins depend primarily on the structure and the degree of cross-linking and on the nature and number of the fixed ionic groups.[1] In general, the ability of a resin to absorb moisture and swell depends mainly on two factors: the functional group substitution and the degree of cross-linking. The influence of the functional group on swollen volume is described in the next section. The effect of cross-linking is inversely proportional to swollen volume. This can be easily understood by assuming the cross-linker to provide a higher spring constant. Because the moisture content of a resin varies widely, its density also varies; typically, the specific gravity of cationic resins is in the range of 1.10–1.35, while that of anionic resins varies from 1.05 to 1.15.[2] The bulk or apparent density of a resin will vary from 600 to 800 mg/L when wet.

The most important property of an ion exchange resin is its exchange capacity, i.e., the number of equivalents of counterion that can be exchanged. Please note that the unit of ion exchange is always equivalents (rather than moles) because ion exchange is an equivalent exchange process. As the volume of an ion exchange resin depends on the amount of moisture absorbed by the resin, the best way to report capacity is dry weight and it is usually reported in milliequivalents of counterion per dry gram of the resin. It is simply a measure of the extent of functional group substitution in the exchanger and is constant for a specific resin. It is generally in the 2–5 meq/g range. Please note that this number is the total or the theoretical exchange capacity: actual or operating capacity is always less than total and is dependent on operating conditions, such as superficial liquid velocity, regeneration scheme, column bed porosity, etc. Ion exchange resins are typically synthesized as gel type, with a pore size of 20–50 Å. This results in increased chemical and mechanical stability and lower water content. Therefore, more ionized groups are available per unit volume, resulting in higher capacity. Macroporous resins, on the other hand, have much wider pores (50–1,000,000 Å), with internal surface area ranging from 7 to 1500 m^2/g, much greater than the standard gel-type resins. The transport of reactants inside these resins is through internal pores or channels: this guarantees access to the interior of the beads even when nonpolar solvents are used.

GENERAL TYPES OF ION EXCHANGE RESIN

The ionizable group attached to the resin structure determines the functional capability of the ion exchange resin.[2] The four general types of ion exchange resin are as follows:

Strong-Acid Cation Exchange Resin: They contain the strongly acidic sulfonate (SO_3^-) functional group

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120008053

and thus can operate over a very wide pH range. Two typical reactions of this type of resin are:

$$2\overline{RSO_3^-Na^+} + CaCl_2 \Leftrightarrow \overline{(RSO_3^-)_2Ca^{2+}} + 2NaCl \quad (1)$$

$$2\overline{RSO_3^-H^+} + CaCl_2 \Leftrightarrow \overline{(RSO_3^-)_2Ca^{2+}} + 2HCl \quad (2)$$

As may be noted from Eq. (2), strong-acid resins can convert neutral salts into their corresponding acids if operated in the hydrogen cycle. This ability is known as salt splitting, and distinguishes them from weak-acid resins. Also, note that Eq. (1) is a water-softening reaction. Details of softening are available in the entry ''Ion Exchange.'' Strong-acid resins have their largest swollen volume in the hydrogen form.

Weak-Acid Cation Exchange Resin: Weak-acid resins differ from strong-acid resins in that weak-acid resins function only in the neutral to alkaline pH range because the functional groups have a high affinity for H^+ and thus are not ionized at low pH.[3] The most common functional group is carboxylate (COO^-). Thus, weak-acid cation exchange resins require the presence of some alkali species to react with the more tightly held H^+ of the resin, for example:

$$\overline{2R^-H^+} + Ca(HCO_3)_2 \Leftrightarrow \overline{(R^-)_2Ca^{2+}} + 2H_2CO_3 \quad (3)$$

The exchange is, in effect, a neutralization with the alkalinity (HCO_3^-) neutralizing the H^+ of the resin. Because of the high affinity of weak-acid cation exchange resins for H^+, they show excellent regeneration efficiency with mineral acid. Weak-acid resins do not require the same sort of concentration driving force required to convert strong-acid resins to the hydrogen form. Weak-acid resins have their smallest swollen volume in the hydrogen form and the volume increases as the resin is converted to the salt form.

Strong-Base Anion Exchange Resin: They operate well throughout the entire pH range and will split neutral salts into their corresponding bases if operated on the hydroxide cycle. For example:

$$\overline{R^+OH^-} + NaCl \Leftrightarrow \overline{R^+Cl^-} + Na^+ + OH^- \quad (4)$$

The functional sites are derived from quaternary ammonium groups. Two types of strong-base anion exchange resins are available: 1) Type I has three methyl groups on the nitrogen atom, as shown in Figs. 1 and 2) Type II resins have an ethanol group that replaces one of the methyl groups, as shown in Fig. 2. Type I resins are more strongly basic, and therefore

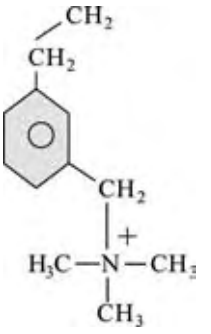

Fig. 1 Schematic presentation of a Type I strong-base anion exchange resin. *(View this art in color at www.dekker.com.)*

can provide better silica and carbonate removal vis-à-vis type II resins. Type II resins have greater regeneration efficiency and capacity. Strong-base resins have their largest swollen volume in the hydroxide form.

Weak-Base Anion Exchange Resin: They can be operated only in the acidic pH region where the primary, secondary, or tertiary amine functional groups are protonated, and thus can act as positively charged exchange sites for anions. The weak-base resins remove free mineral acidity, such as HCl or H_2SO_4, but cannot split salts. Consider the following reaction:

$$\overline{R_3N:} + HCl \Leftrightarrow \overline{R_3NH^+Cl^-} \quad (5)$$

$$\overline{R_3NH^+Cl^-} + HNO_3 \Leftrightarrow \overline{R_3NH^+NO_3^-} + HCl \quad (6)$$

In Eq. (5) the free form of the weak-base anion exchange resin becomes protonated on contact with a mineral acid (and low pH). To maintain electroneutrality in the resin, an equivalent of Cl^- enters the resin with every equivalent of H^+. Now this Cl^- loaded resin is ready for anion exchange as shown in Eq. (6), but this anion exchange will take place only at low pH. As with weak-acid resins, weak-base resins display excellent regenerability. They can be regenerated with

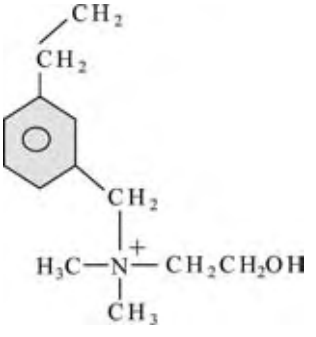

Fig. 2 Schematic presentation of a Type II strong-base anion exchange resin. *(View this art in color at www.dekker.com.)*

NaOH, NH_4OH, Na_2CO_3, or $Ca(OH)_2$. For complete regeneration, only slightly higher than the stoichiometric amount (<20%) is required. The swollen volume of a weak-base resin is the minimum when it is in the free form and increases as it is converted to salt forms.

ION EXCHANGE RESIN SELECTIVITY

Ion exchange resins display preference for certain ions over others and this characteristic is extremely critical during the choice of a resin for a particular application scenario. The fundamentals of ion exchange equilibria and selectivity are explained in the entry on ''Ion Exchange.'' This subject has been studied extensively by many researchers.[1,4] The following empirical rules can be used to approximate selectivities of resins.

The ion exchange resin tends to prefer:

1. The counterion of higher valence at low concentration and ordinary temperature. Thus,

   $$Th^{4+} > Al^{3+} > Ca^{2+} > Na^{+}$$

   and

   $$PO_4^{3-} > SO_4^{2-} > CI^{-}$$

2. For the case of constant valence, the counterion of higher atomic number (lower hydrated radius or smaller solvated volume) at low concentration and ordinary temperature. Thus,

   $$Cs^{+} > Rb^{+} > K^{+} > Na^{+} > Li^{+}$$

   $$Ba^{2+} > Sr^{2+} > Ca^{2+} > Mg^{2+} > Be^{2+}$$

3. For the case of constant valence, the counterion with greater polarizability at ordinary temperature and low concentration. A measure of polarizability is the Debye–Hückel parameter $\mathring{a}$, which gives the distance of closest approach between ions of opposite sign. Thus, highly polarized counterions, such as Ag^{+} and Tl^{+}, have abnormally low $\mathring{a}$ values and are preferred to alkali ions by the cation exchange resins with sulfonic acid groups.
4. The counterion that interacts more strongly with the fixed ionic groups or with the matrix. The former is the basis for chelating ion exchange resins and many other specialty resins and is explained in detail in the subsequent section. The interaction of the counterion with the matrix is the primary reason for a selectivity sequence for ClO_4^{-} shown below:

   Tributyl amine functional group
   > triethyl amine > trimethyl amine

5. The counterion that participates least in the complex formation with the coion. The explanation is straightforward: if the counterion forms a complex with the coion in solution, it will not be available for exchange with the loaded ions of the resin. Please see Refs.[5–9] for details on ion exchanger selectivity.

SPECIALTY ION EXCHANGE RESINS

In very few applications is ion exchange technology used to remove all cations/anions from a solvent. Perhaps, the only case of such an approach is in water demineralization, which is explained in detail in the entry ''Ion Exchange.'' The more common application scenario is that the solvent contains many counterions, most of which are benign but some counterions exist that are present in much lower concentration (than the benign counterions) and need to be removed from the solvent. Specialty ion exchange resins play an important role in such situations and offer a distinct advantage over other technologies. For example, in many waste streams, which are contaminated with heavy metals, the concentration of heavy metals is much smaller than benign cations, such as Ca^{2+}, Mg^{2+}, Na^{+}, etc. For example, let us consider a typical cation exchange reaction between Ni^{2+} and Ca^{2+}:

$$\overline{R_2Ca} + Ni^{2+} \leftrightarrow \overline{R_2Ni} + Ca^{2+} \tag{7}$$

Assuming ideality, the equilibrium constant or selectivity coefficient of Eq. (7) is:

$$K_1 = \frac{[\overline{R_2Ni}][Ca^{2+}]}{[Ni^{2+}][\overline{R_2Ca}]} \tag{8}$$

The ratio of Ni^{2+} to Ca^{2+} in the aqueous phase is, in general, much less than unity. Thus, for the Ni^{2+} removal process to be selective (i.e., high R_2Ni), the equilibrium constant, K_1, needs to be extremely high. Conventional cation exchangers with coulombic (electrostatic) type interaction are unable to attain such high selectivity (charge of calcium and nickel ion is the same).

Metal-Selective Chelating Resins

Most of the heavy-metal cations of interest, such as Cu^{2+}, Hg^{2+}, Pb^{2+}, Ni^{2+}, Cd^{2+}, Zn^{2+}, etc., are transition-metal cations and exhibit Lewis acid characteristics (electron acceptors). With organic and inorganic ligands (Lewis bases), all these heavy-metal cations form fairly strong complexes. Most of the complexes of these metal cations, depending on their coordination number, have regular or slightly distorted tetrahedral, octahedral, or square pyramid structures.[10] As Ca^{2+}, Mg^{2+}, and Na^{+}—the most commonly encountered competing nontoxic cations in water and wastewater—do not undergo such strong complexation, incorporating organic ligands as functional groups into the polymer matrix of the ion exchanger through covalent bonding was a natural progression of ideas to improve the exchanger's selectivity toward the toxic metal ions. These functionalized polymers are often referred to as chelating polymers, coordinating polymers, or metal selective ion exchange resins. Fig. 3 shows the chelating exchanger with imino-diacetate functionality, the workhorse of metal-selective exchangers and available from every major resin manufacturer around the world. Fig. 4 shows two commonly used routes for synthesizing this chelating polymer from styrene monomers (cross-linking not shown).[11] A typical ion exchange reaction between a metal ion, Me^{2+}, and Na^{+} for this resin may be presented in the following way:

$$\overline{RN(CH_2COONa)_2} + Me^{2+} \Leftrightarrow \overline{RN(CH_2COO)_2Me} + 2Na^{+} \quad (9)$$

Eq. (9), however, fails to reveal the Lewis acid–base (LAB) type interaction between the metal ion and the imino-diacetate functionality. Assuming that the water molecule has four coordinated water molecules in the aqueous phase, $[Me(H_2O)_4]^{2+}$, the overall exchange is shown in the below equation.

Note that three water molecules (ligands) from the coordination sphere of the metal ion are replaced by one nitrogen and two oxygen donor atoms in the imino-diacetate functionality. The arrows indicate the metal–ligand or LAB interaction and the high metal ion selectivity for this type of functional group is often attributed to the accompanying coordination

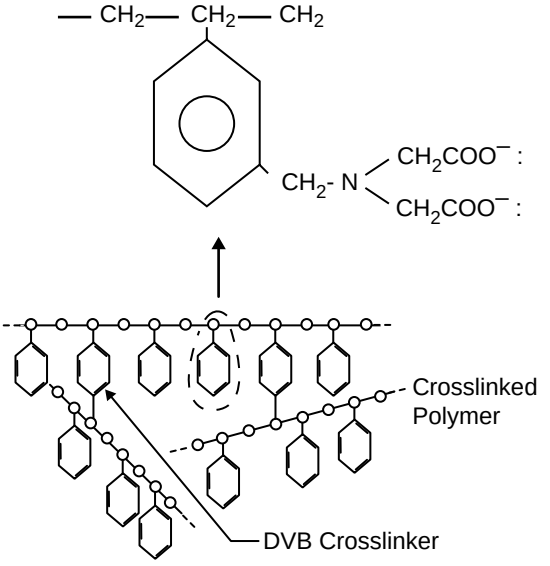

Fig. 3 Schematic presentation of three-dimensional cross-linked polystyrene with imino-diacetate functional group.

reaction in conjunction with exchange of ions. Fig. 5 provides experimentally determined Me^{2+}/Ca^{2+} separation factors for three commercial ion exchange resins (imino-diacetate functionality—IRC 718, thiol functionality—GT73, and picolylamine functionality—XFS4195) for various heavy metals at varying pH values, and the high selectivity of the metal ions can be readily noted.[12] Please see the entry "Ion Exchange" for details about separation factor. Like Ca^{2+}, these metal ions have a charge 2+ and, therefore, only coulombic/electrostatic interaction cannot be the reason for such a high Me^{2+}/Ca^{2+} separation factor. On the contrary, such a high selectivity is always attributed to a relatively strong Lewis acid characteristic of the toxic-metal cations favoring their selective uptake through coordination reactions.

To characterize high metal ion selectivity for chelating ion exchangers from a thermodynamic perspective, the metal ion uptake can be divided into two consecutive steps—ion exchange (IX) followed by LAB interaction, i.e.,

$$Me^{2+}(aq) \xrightarrow{IX(Step\ I)} \overline{RMe} \xrightarrow{LAB(Step\ II)} \overline{RMe}$$

$$\text{R}-\text{CH}_2\text{N}(\text{CH}_2\text{COO}^-\text{Na}^+)_2 + \text{Me}(\text{H}_2\text{O})_4^{2+} \longleftrightarrow \text{R}-\text{CH}_2\text{N}(\text{CH}_2\text{COO}^-)_2 \rightarrow \text{Me}(\text{H}_2\text{O})^2 + 2\text{Na}^+ + 3\text{H}_2\text{O} \quad (10)$$

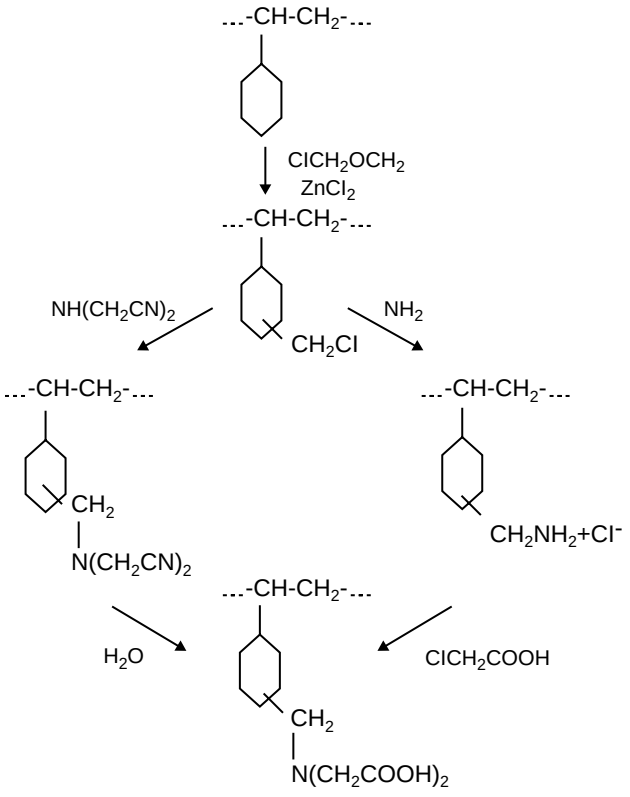

Fig. 4 Two parallel routes for synthesis of imino-diacetate resins from polystyrene (cross-linking not shown).

At the standard state, the overall free energy at equilibrium between Me^{2+}(aq) and RMe is given by:

$$\Delta G^0_{\text{overall}} = \Delta G^0_{\text{IX}} + \Delta G^0_{\text{LAB}} \tag{11}$$

or

$$-\text{RT ln } K_{\text{overall}} = -\text{RT ln } K_{\text{IX}} - \text{RT ln } K_{\text{LAB}}$$

or

$$K_{\text{overall}} = K_{\text{IX}}\, K_{\text{LAB}} \tag{12}$$

In general, for ion exchangers with chelating functionality, K_{LAB} is very high for most of the heavy-metal ions of interest because of their Lewis acid characteristics. Therefore, the overall equilibrium constants, according to Eq. (12), are also very high. For sodium, Na^+, LAB interaction (step II) is practically absent and hence,

$$K_{\text{overall}} = K_{\text{IX}} \tag{13}$$

For Ca^{2+}, however, LAB interaction is present but much weaker compared to most of the heavy-metal cations, and thus as a general rule, selectivity sequence for chelating exchangers may be written as follows:

$$K_{\text{overall}}\ (\text{heavy metal}) \gg K_{\text{overall}}\ (\text{calcium}) \gg K_{\text{overall}}\ (\text{sodium})$$

Such a high metal ion selectivity and more stringent environmental regulations have aroused high interest in the application of these chelating polymers for removal, separation, and purification of metal ions from heavy-metal contaminated water and wastewater streams.[13–21] Many chelating exchangers have been synthesized during the last 30 yr.[22–24] Table 1 provides composition of several commercially available chelating exchangers and other relevant information. These exchangers contain chelating functionalities with one or more donor atoms that can form coordinate bonds with metal ions. Depending on the number of donor atoms present in a repeating functionality, these exchangers are often referred to as mono-, bi-, or polydentate. Nitrogen, oxygen, and sulfur are the donor atoms in almost every chelating exchanger synthesized to date. Identifying the active donor atoms for a given application may provide useful clues to assess metal ion selectivity and other related properties for a given chelating polymer. These donor atoms form only a part of the complete chelating functionality, which is essentially either weak acid (say carboxylate, diacetate, thiol, etc.) or weak base (tertiary amine, pyridine, etc.). Because of the weak-acid or weak-base characteristic, these chelating functionalities exhibit high affinity toward the hydrogen ion. As a result, selective uptake of heavy-metal cations by chelating exchangers under highly acidic conditions (pH $<$ 2.0) is adversely affected because of strong competition from H^+. On the other hand, at neutral to alkaline pH, heavy-metal cations are quite insoluble because of low solubility product values for their hydroxides, carbonates, sulfides, etc. For effective heavy-metals removal, the optimum pH range for most of the chelating polymers is, thus, often limited to 2.0–7.0. Fig. 6 shows total copper uptake for different chelating exchangers as a function of pH.[25] Notice how metal removal capacity is essentially lost for IRC-718 (imino-diacetate functionality) and ES-467 (amino-phosphonate functionality) at pH $<$ 1.5. Note also the unusual behavior of XFS 4195; there is practically no reduction in copper uptake capacity even at a pH as low as 1.5. This is due to its unique metal ion binding mechanism and will be discussed later.

Chelating ion exchange resins can be titrated in a manner very similar to other aqueous-phase weak acids and weak bases. For example, strong-acid cation exchangers show an abrupt change in pH whereas weak-acid cation exchangers show gradual increase in pH—indicative of the latter's high affinity for H^+—as may be seen from Fig. 7. Titration curves are,

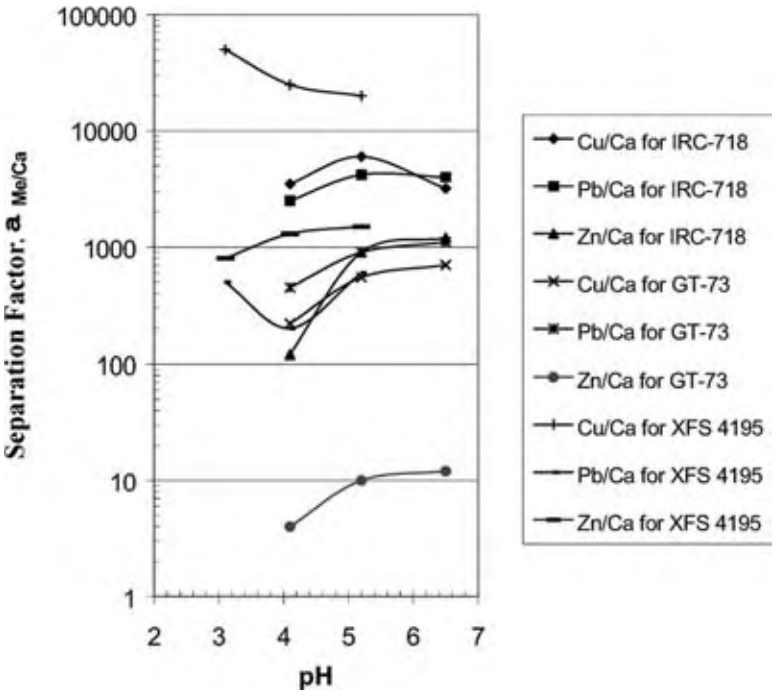

Fig. 5 Metal(II)/Ca separation factor for different commercial resins. *(View this art in color at www.dekker.com.)*

however, dependent on the aqueous-phase electrolyte concentration also; see excellent discussions of this subject by Marinsky and Helfferich.[1,26] A relationship to compute the apparent dissociation constant, K_a, of a weak-acid exchanger as a function of pH and aqueous-phase electrolyte concentration has been proposed by Helfferich and may be stated as follows:[1]

$$pK_a = pH - \log[A^-] + \log\left[\frac{\overline{X}}{2}\right] \quad (14)$$

where $[A^-]$ is the aqueous-phase anion concentration and $[\overline{X}] = [RH] + [R]$ is the total concentration of (dissociated and undissociated) ionogenic groups in the exchanger. Note that the apparent pK_a decreases at a constant pH with an increase in electrolyte concentration (i.e., A^-), implying enhanced ionization of the exchanger.

Chelating exchangers' high preference for H^+ is often viewed as a shortcoming for heavy-metal removal under highly acidic conditions, but it offers an excellent regeneration of metal-loaded chelating polymers with moderately concentrated (2–10%) mineral acid. From a practical viewpoint, high regeneration efficiency of a chelating exchanger is just as desirable as the high metal ion affinity. Fig. 8 shows the regeneration of copper-loaded IRC-718 with 2% HCl.[27] As expected, copper desorption/elution was very sharp with copper concentration in the spent regenerant as high as 15,000 mg/L, indicating efficient regeneration in accordance with the principles of displacement chromatography.[1] Incidentally, several toxic metals, viz., Cu, Pb, Hg, Cd, Zn, and Ni, are included in EPA's list of priority pollutants and one of the major challenges is to minimize the volume of these metal-contaminated wastes.[27] High metal ion selectivity of the chelating exchangers accompanied by excellent acid-regeneration efficiency offers opportunities to concentrate and reduce the volume of metal-laden dilute wastewater streams, often by over 1000 times.[28]

KINETICS AND RATE PROCESSES

In spite of their high affinity toward most of the heavy-metal cations and favorable thermodynamics over a wide pH range, the metal-selective chelating cation exchange resins are often criticized because of their slow kinetics, which are primarily diffusion-controlled rate-limiting processes.[29–31] Several factors influence kinetics; they include degree of cross-linking and accompanying rigidity, steric property of the functional group, charge density, nature of polymer matrix, e.g., gel, macroporous, or pellicular, mechanism of metal ion binding, particle size, and other hydrodynamic conditions. Although no two cases are likely to be identical, ion exchange kinetics for chelating ion exchange resins is improved by decreasing the amount of cross-linking, by decreasing the hydrophobic nature of the polymer matrix, and, above all, by reducing the size of the polymer beads. Metal ion diffusivity in the exchanger is strongly dependent on the cross-linking because it influences the

Table 1 Salient information on some chelating ion exchange resins

Functionality	Electron donor atoms	Matrix, cross-linker	Nature of chelating group

	1 Nitrogen,2 Oxygen	Polystyrene, divinylbenzene	Aminophosphonate
	3 Nitrogen	Polystyrene, divinylbenzene	Picolyl-amine based
	2 Nitrogen	Polystyrene, divinylbenzene	Pyridine based
	1 Sulfur	Polystyrene, divinylbenzene	Thiol

swelling characteristic and water content of the polymer phase. Boyd and Soldanho determined the diffusivity of zinc ion for strong-acid cation exchange resins with varying degrees of DVB cross-linking, as reproduced in Table 2.[32] Note that effective zinc ion diffusivity drops by almost two orders of magnitude as the DVB increases from 5% to 23.8%.

In general, metal ion exchange by a chelating resin is intraparticle diffusion controlled (IPDC) accompanied by chemical reaction (chelation).[29–36] Both Fick's law and Nernst–Planck Eq.[30] have been used to describe ion exchange kinetics by intraparticle diffusion. For ion exchange resin beads with spherical geometry and constant exchanger-phase diffusion coefficient, the mathematical representation may be given as follows:

$$\frac{\partial \overline{C_i}}{\partial t} = \overline{D}\left(\frac{\partial^2 \overline{C_i}}{\partial r^2} + \frac{2}{r}\frac{\partial \overline{C_i}}{\partial r}\right) \tag{15}$$

where r = radial space coordinate, i.e., distance from bead center.

This equation is to be solved under the appropriate initial and boundary conditions. For the simple case of infinite solution volume, where the aqueous-phase concentration does not change because of sorption or desorption, fractional attainment of equilibrium, F, is given by:

$$F \approx \left[1 - \exp\left(-\frac{\overline{D}\, t\, \pi^2}{r_0^2}\right)\right]^{1/2} \tag{16}$$

where D is intraparticle self-diffusion coefficient of the exchanging ion, t is the time since the beginning of the run, and r_0 is the radius of the spherical ion exchange bead. The half-time, $t_{1/2}$, for attainment of 50% equilibrium capacity (i.e., $F = 0.5$) can be computed from Eq. (16) to give the following relationship:

$$t_{1/2} = \text{constant}\frac{r_0^2}{D} \tag{17}$$

The relative rate (inverse of $t_{1/2}$) is thus proportional to the diffusion coefficient in the exchanger

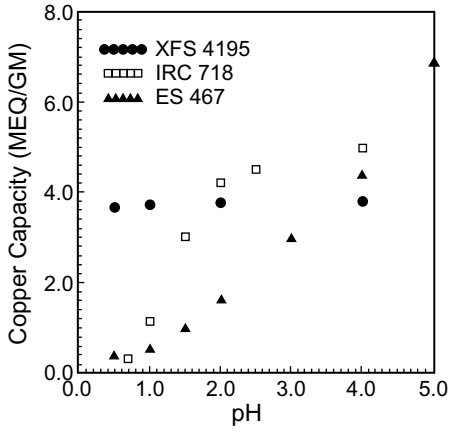

Fig. 6 Comparison of copper(II) uptake as a function of pH for three chelating exchangers in equilibrium with 300 mg/L Cu^{2+}. (From Ref.[25].)

and inversely proportional to the square of the bead radius. Note that $t_{1/2}$, according to IPDC is independent of any concentration term.

The above rate expression assumes homogenous exchanger phase where transport of ions takes place only in the solid phase. Such an assumption is valid for a gel-type resin but is truly debatable for macroporous exchangers. For a macroporous resin, solid phase and macropores (in the order of 500 Å) coexist in the interior of the resin and, therefore, parallel diffusion of counterions in the solid phase and also in the macropore is a strong possibility. Effective diffusivity in such cases tends to be concentration dependent.[35–38] Price, Helditch, and Streat studied this aspect quite rigorously with respect to Ni^{2+}–Na^{+} exchange for a macroporous chelating exchanger (ES 467, Duolite) with aminophosphonate functionality. Some of the salient findings of the study are:[37]

- Experiments carried out at different temperature (5–55°C) and different stirring speeds (200–3000 rpm) clearly indicated that the kinetics is

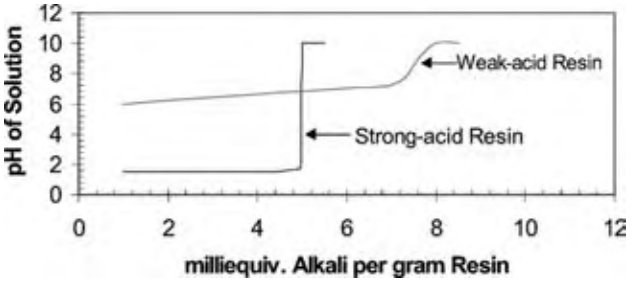

Fig. 7 pH titration curve of a strong-acid and a weak-acid cation exchange resin. *(View this art in color at www.dekker.com.)*

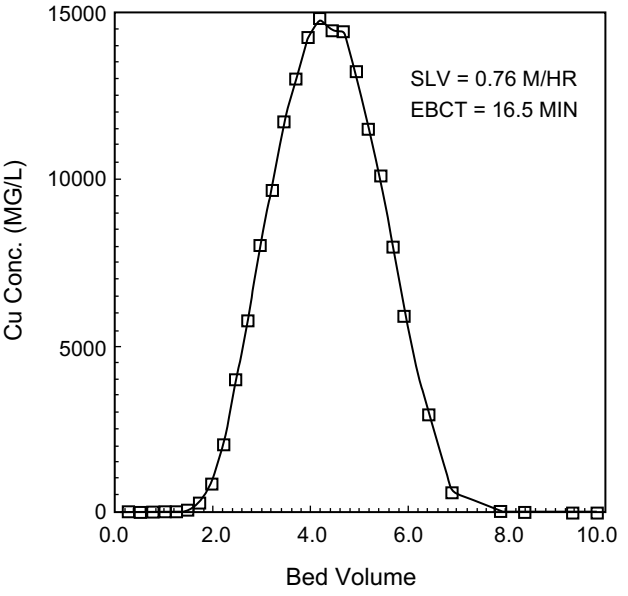

Fig. 8 Demonstration of high regeneration efficiency of copper(II)-loaded IRC-718 (imino-diacetate functionality) with 2% HCl.

IPDC. This was further confirmed by plotting $t_{1/2}$ vs. ion exchanger bead radius, r_0; $t_{1/2}$ varied with r_0^2 in agreement with Eq. (17).

- Aqueous-phase Ni concentration, however, was found to have a pronounced effect on ion exchange kinetics, which is not consistent with prediction from the IPDC model based on the Nernst–Planck equation. Experimental results could, however, be accounted for with the aid of a macroporous model, originally developed by Yoshida and Kataoka based on the assumption of parallel diffusion of counterions in the solid-gel phase and in the macropores.[38] This model predicts the concentration dependence of the effective self-diffusion coefficient, D_e, of counterion "i'' according to the following equation:

$$D_e = \frac{D_p\varepsilon_p + D_g(1-\varepsilon_p)Q/Z\,C_0}{\varepsilon_p + (1-\varepsilon_p)Q/ZC_0} \tag{18}$$

where D_p = diffusivity in the pore space, D_g = diffusivity in the gel phase, ε_p = void

Table 2 Effective diffusion coefficients for zinc ion in sulfonic acid cation resins of different cross-linking

Cross-linking (% DVB)	D_{Zn} (cm^2/sec)
5	3.7×10^{-7}
10	3.8×10^{-8}
16.2	8.1×10^{-9}
23.8	3.2×10^{-9}

fraction of pores, Q = total exchange capacity per unit volume, Z = charge of counterion i, and C_0 = concentration of i in the aqueous phase.

An increased counterion concentration in the aqueous phase has a favorable effect on kinetics for macroporous resins, i.e., $t_{1/2}$ decreases with an increase in aqueous-phase nickel concentration. This feature helps macroporous resins during regeneration also as the concentration of the regenerant (acid or alkali or salt) is usually very high (2–10%).

For gel-type resins, macropores are absent and intraparticle diffusion through the gel phase is the only mechanism for transport of the counterions. Hoell provided an optical verification to this effect for a gel resin with carboxylate functionality (IRC-84, Rohm & Haas Co.) using Ca^{2+}–H^+ exchange.[39] The exchanger was originally loaded with calcium ions and then placed in an acid solution; Ca^{2+} ions from the gel phase were slowly eluted out by hydrogen ions, progressing from the circumference toward the center. With time, the calcium-loaded core gradually shrank and eventually disappeared. Fig. 9 provides an excellent photographic testimony of this hypothesis.[31,39]

Helfferich discussed four scenarios of ion exchange kinetics and highlighted how the premises of some mathematical models are incompatible with facets of physical reality.[40] The specific cases considered were:

1. Nonlinear concentration gradients in Nernst–Planck film model.
2. Shell-core model in the absence of a mechanism that can produce shell-core behavior.
3. Reaction-controlled shell-core model.
4. Model for macroporous beads where diffusion in both the gel-phase and the macropores is comparable.

The guidelines proposed in this communication may serve as a basis to verify the applicability of any mathematical model under a given operating condition.[40]

MULTICOMPONENT ION EXCHANGE

In a typical ion exchange process the resin is loaded on a column and the influent containing the pollutant ions is passed through this bed during the exhaustion phase. It is common to find benign ions along with the pollutant ions in the influent. In fact, the concentration of benign ions is almost always greater than the pollutant ions. It is also expected that the ion exchange resin selected has maximum selectivity toward the most pollutant ion, i.e., the ion that needs to be removed to the maximum degree. Thus, we have a situation of an ion exchange resin in contact with n ions, each of different concentration and each having different selectivity toward the resin. In most applications, the ion that is preloaded on the resin (and the one that is exchanged for ions from the influent) has the least selectivity. When such a system is run, the effluent profile of each ion is different, and some ions undergo chromatographic elution, i.e., their effluent concentration may be higher than the influent concentration.

Table 3 Feedwater composition and binary separation factor ($\alpha_{Cu/ion}$) for the resin

		Feed water composition			
	Component	meq/L	Fraction	Presaturant composition (%)	α-value
1	Cu^{2+}	0.300	0.13043	0.00	1.00
2	Ni^{2+}	0.400	0.17391	0.00	3.00
3	Ca^{2+}	0.600	0.26087	0.00	5.00
4	Na^{2+}	1.000	0.43478	100.00	10.00
Total feed concentration		2.300			

Table 4 Equivalent fraction of mobile-phase composition in the four zones

	Component	1	2	3	4
1	Cu^{2+}	0.13043	0.00000	0.00000	0.00000
2	Ni^{2+}	0.17391	0.23698	0.00000	0.00000
3	Ca^{2+}	0.26087	0.30091	0.48226	0.00000
4	Na^{+}	0.43478	0.46211	0.51774	1.00000

Zone 1 = Na^{+}—presaturant, Zone 2 = Ca^{2+}—rich, Zone 3 = Ni^{2+}—rich, and Zone 4 = Cu^{2+}—rich according to Fig. 10.

As this can create a highly unfavorable situation, it is important to understand the following rules as they apply to multicomponent ion exchange:[41–43]

- The most preferred species will be the last to exceed the column and its effluent concentration will never exceed the influent concentration, i.e., it will never undergo chromatographic elution.
- The species exit the column in reverse preference order, with the least preferred species exiting first. Thus it is good practice to preload the ion exchange resin with the ion that is least preferred.
- The less preferred species will be concentrated in the ion exchange column and at some time will exit the column in concentrations exceeding their influent concentration. They will undergo chromatographic elution.
- When all the breakthrough fronts have exited the column, the entire bed is in equilibrium with the influent. At this time the effluent and the influent concentrations are equal.
- The effluent concentration of the presaturant ion decreases in steps as each new ion breaks through because the total equivalent concentration must be the same throughout the column run.

Let us visualize this through an example.

Let us assume a hypothetical influent with the following concentrations of cations:

Copper, Cu^{2+}	9.53 mg/L
Nickel, Ni^{2+}	11.74 mg/L
Calcium, Ca^{2+}	12.02 mg/L
Sodium, Na^{+}	23.0 mg/L

The equivalent concentration of each ion and the binary separation factors for each pair are provided in Tables 3–5. Please note that:

1. The ion exchange resin prefers copper the most.
2. The ion exchange resin prefers sodium the least and it is preloaded on the resin.

The ideal resin concentration profile inside the column is shown in Fig. 10. Based on the rules enumerated above, sodium exits at the beginning of the column run and for the first bed volumes, only sodium is present in the effluent at a concentration of 52.9 mg/L. The effluent breakthrough profile is shown in Fig. 11. Thus, sodium undergoes chromatographic elution. At bed volume 3520, calcium, the ion with the second-last preference for the resin, starts to exit from the resin bed. The emergence of calcium is simultaneous with a drop in sodium concentration, because the total equivalent concentration of the effluent has to be equal to its influent concentration, 2.3 meq/L. From 3520 to 4691 bed volumes, both sodium and calcium experience chromatographic elution. At bed volume, nickel appears in the effluent concomitant with a drop in sodium and calcium effluent concentration. From 4691 to 9184 bed volumes, sodium, calcium, and nickel experience chromatographic elution. At 9184 bed volume, copper appears in the effluent concomitant to a drop in the effluent concentration of sodium, calcium, and nickel. At this time the resin bed is exhausted and should be regenerated. Details of column cycle stages are explained in the entry ''Ion Exchange.'' From Fig. 11 it is clear that if both nickel and copper are to be removed from the influent, the column has to be stopped before nickel appears in the effluent (i.e., before 4691 bed volumes of operation)

Table 5 Equivalent fraction of solid-phase composition in the four zones

	Component	1	2	3	4
1	Cu^{2+}	0.45918	0.00000	0.00000	0.00000
2	Ni^{2+}	0.20408	0.42610	0.00000	0.00000
3	Ca^{2+}	0.18367	0.32463	0.65071	0.00000
4	Na^{+}	0.15306	0.24927	0.34929	1.00000

Zone 1 = Na^{+}—presaturant, Zone 2 = Ca^{2+}—rich, Zone 3 = Ni^{2+}—rich, Zone 4 = Cu^{2+}—rich according to Fig. 10.

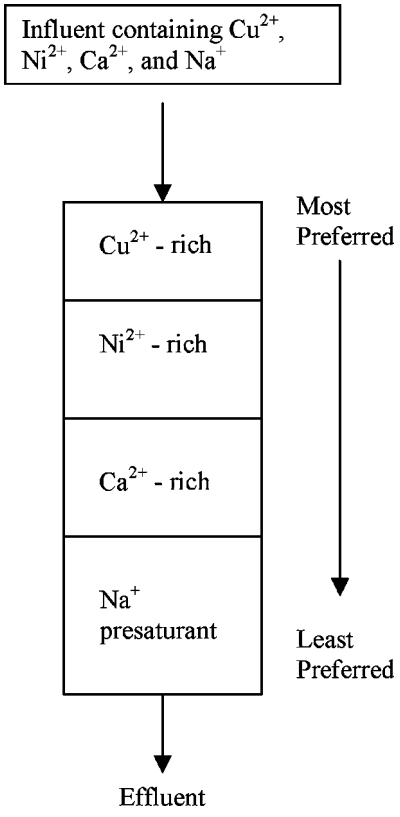

Fig. 10 Concentration profile of various ions inside the resin column.

because otherwise nickel would appear in the effluent at a concentration higher than the influent.

DEVELOPMENTS IN OVERCOMING SHORTCOMINGS OF CONVENTIONAL ION EXCHANGE PROCESSES

Particle Size Effects and Recoflo® Short-Bed Process

Like other heterogenous processes using small (<1 mm) particles, various reactor configurations have evolved for ion exchange, viz., packed bed, continuous countercurrent, fluidized bed, contact followed by sedimentation, etc. However, the packed-bed or fixed-bed process where the mobile liquid passes through stationary ion exchange beads in a column is by far the most popular unit operation because of its simplicity of construction and operation. This method is routinely used for metal ion removal, water softening, and water demineralization. The following steps are followed in a fixed-bed process:

- Exhaustion or removal of the contaminant
- Backdating
- In situ regeneration
- Rinsing
- Return to exhaustion

Timewise, exhaustion is much longer than all the other steps combined, and is practically equal to cycle time, t_{cycle}. Particle diameter in a packed bed influences both pressure drop and kinetics of ion exchange. For rigid, spherical particles like ion exchange beads, the pressure drop under laminar conditions can be estimated from the following equation:[44]

$$\Delta P = \frac{\mu v L}{K_p d_p^2} \tag{19}$$

where K_p is the permeability, μ is the viscosity of the liquid stream, L is the length of the packed bed, and v is the superficial liquid-phase velocity. Note that the pressure drop is inversely proportional to d_p^2. This is the reason why smaller diameter particles cannot be used in a packed bed. Assuming μ, v, and K_p to remain constant, the pressure drop remains the same if L/d_p^2 is kept constant. If, in addition, the L/t_{cycle} is kept constant, the capacity of the two columns of different heights will be the same even though the shorter column will exhaust faster.[45]

Poor kinetics is one of the major limitations of metal-selective ion exchange resins and as pointed out earlier, intraparticle diffusion is often the rate-limiting step. During the exhaustion cycle, there are three specific zones for a solute in a fixed bed, viz., saturated, unused, and mass-transfer zone (MTZ), as shown in Fig. 12. As the cycle advances, MTZ moves from the inlet toward the exit of the column. For a favorable isotherm, L_{MTZ} does not change during its passage inside the column but is dependent on the size of the adsorbent particle.[41,46] For intraparticle diffusion, L_{MTZ} is proportional to d_p^2. Improving kinetics in a fixed-bed process essentially means reducing L_{MTZ}. Thus, both hydrodynamic (high-pressure drop) and mass transfer (intraparticle diffusion) limitations in a fixed-bed process can be overcome by reducing the size of the polymer beads in accordance with the following guidelines:

1. If d_p is reduced in a way that L/d_p^2 remains constant, pressure drop across the bed does not change. In addition, if L/t_{cycle} is kept constant the column will have the same capacity as any larger column.
2. With a reduction in particle size, d_p, mass transfer rate by intraparticle diffusion will be enhanced and the length of the MTZ, L_{MTZ}, will be reduced in a way so that L_{MTZ}/L remains

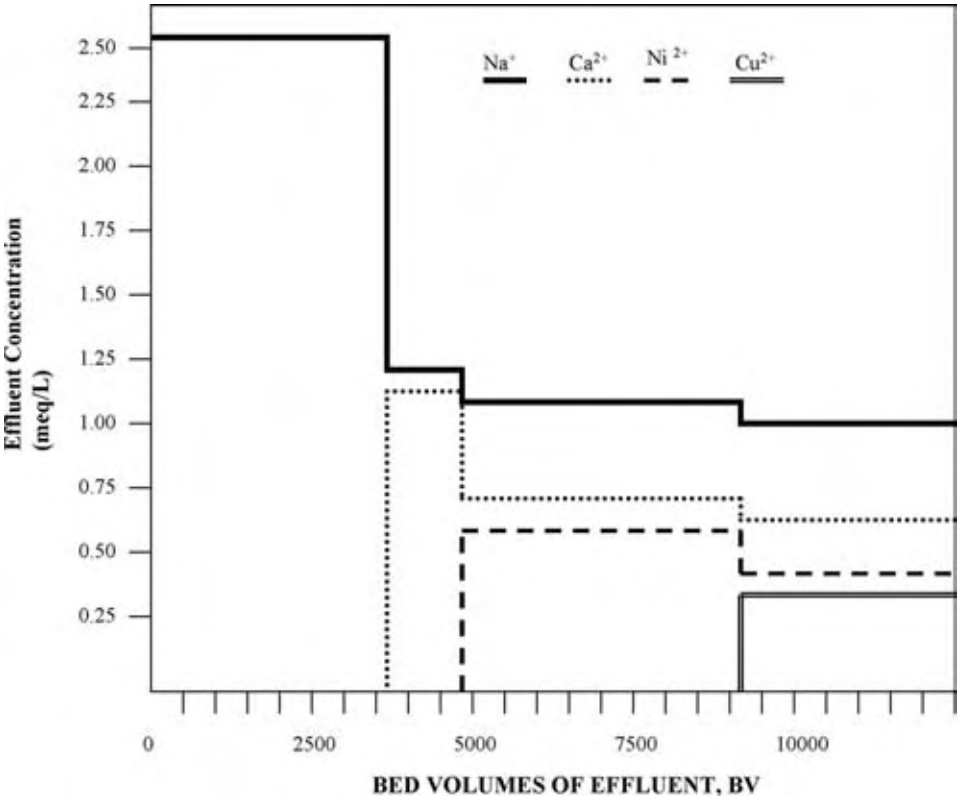

Fig. 11 Effluent history of the hypothetical influent solution based on the selectivity values provided in Table 3.

constant for a favorable isotherm, i.e., the fractional utilization of the column per cycle is unchanged.

The above theoretical principles form the basis of the ''Recoflo Short-Bed IX Process'' of ECO-TEC Limited, Ontario, Canada.[47,48] Recoflo uses much finer particle size (100–200 mesh) than is normally used in industrial ion exchange processes (20–40 mesh). Depending on the application, the total cycle time can vary from as low as 2 min to 1 hr. Consequently, the resin inventory for this process is low and that helps reduce the capital cost. On exhaustion, the short beds are regenerated in a countercurrent mode for maximum efficiency. The entire Recoflo system is assembled in a compact skid-mounted unit (Fig. 13). Poor kinetics and the relatively high price of chelating exchangers tend to limit their use for metals recovery. The improved kinetics (due to smaller particle size) and short-bed height characteristic of the Recoflo process greatly enhance the performance and economic viability of the chelating exchangers. They are now being used to recover metals from electroplating and hydrometallurgical wastestreams.[49] Grinstead has also used this principle for removing heavy-metal cations—particularly from dilute wastewater streams—and concentrating the heavy metals in the spent regenerant by over 1000 times.[28]

Continuous Annular Chromatography

We have discussed how metal ions can be removed from a dilute wastewater stream. Frequently, we come across a situation where the contaminated water contains several heavy metals. The methodologies outlined earlier can be effectively employed to remove all the heavy-metal cations, but the corollary is that the regenerant solution will have a mixture of all the heavy-metal cations. In other words, the heavy-metal cations are not separated in the regenerant stream. Such a mixture of salts of toxic metals has only a limited commercial value and there is a pressing need for separating the heavy-metal cations. Commonly encountered toxic metal cations, such as Cu^{2+}, Pb^{2+}, Ni^{2+}, Cd^{2+}, Zn^{2+}, etc., exhibit very similar physical and chemical characteristics and, therefore, separating one from another poses an obvious difficulty. A separation technique known as continuous annular chromatography (CAC) developed at Oak Ridge National Laboratory (ORNL) seems to show promise. In CAC, separation is achieved by using a slowly rotating annular bed of ion exchange resin, where feed is continuously introduced at a stationary point, while the eluent flows over the remainder of the annulus. The rotation of the sorbent bed coupled with the passage of the eluent causes the separated solutes of the feed to appear as helical bands, each of which has a

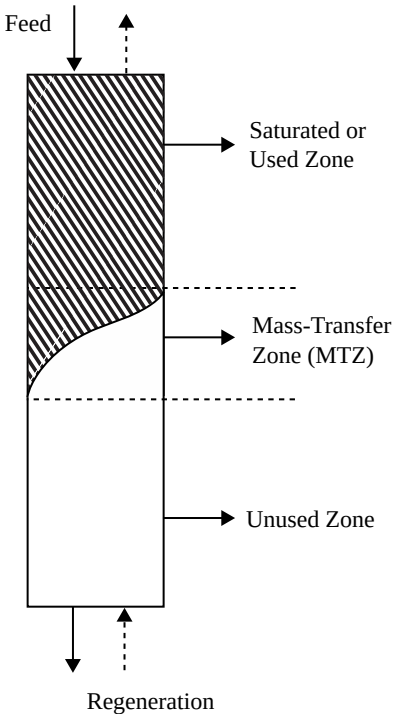

Fig. 12 Presence of three different zones in a fixed-bed column.

characteristic stationary exit point. Fig. 14 shows a conceptual diagram illustrating the key features of CAC, which is capable of achieving multicomponent chromatographic separation for a relatively concentrated mixture of metal salts. Various versions of a CAC apparatus have been constructed and tested experimentally at ORNL.[50–52] Multicomponent systems tried include the separation of Ni, Cu, and Co in ammoniacal solution, iron and ammonium in ammonium sulfate–sulfuric acid solution, and hafnium from zirconium in sulfuric acid solution. For the

above-mentioned examples, Dowex 50W-X8, a polystyrene strong-acid (sulfonic group) cation exchanger resin with 8% DVB cross-linking from Dow Chemical, MI, was used as the stationary phase. Fig. 15 provides

some constructional details of CAC apparatus built for bench-scale testing at ORNL.

Fig. 16 shows separation of Cr(III) from Fe(III) with the CAC apparatus by Byers, Sisson, and Decarli II using ammonium as an isocratic eluent where the feed concentration was fairly high (5 gm/L).[52] Theoretically, elution and resolution of various components being separated can be predicted quite precisely using steady-state material balance and rate-limiting equations. From Fig. 16 one can note the excellent agreement of experimental results with the theoretical prediction (solid lines).

Using gradient elution, Byers, Sisson, and Decarli II have shown that the purity of Fe(III) and Cr(III) in the product can be increased by an order of magnitude.[52] However, all these studies were conducted with a strong-acid cation exchange resin, Dowex 50. Earlier discussion has indicated that chelating functionality may be used to improve the relative selectivity between the two metal ions, especially in the presence of ligands. Use of appropriate chelating exchangers may, therefore, broaden the application potential of CAC in separating heavy metals. Thus, CAC in conjunction with a proper choice of chelating ion exchange resins may be a useful tool in accomplishing this desired goal of heavy-metal–cation separation. Continuous annular chromatography apparatus is practically stationary and hence maintenance-free. Central treatment facilities, where wastewater streams are collected and treated for heavy-metal removal, are gaining momentum because of their overall economy and are being encouraged by the state and the federal regulatory authorities.[53] Using CAC in such facilities for separation and recovery of heavy metals may be a worthwhile venture in the coming years.

CONCLUSIONS

Ion exchange resins have been used in a myriad of applications and based on trends, they will find newer application scenarios in the future. Present research in this field is primarily in the following areas:

1. *Size/morphology of the resin*: Pellicular resins that have diameter in the submicrometer range are being synthesized for applications where faster kinetics (of ion exchange during sorption and regeneration) is of prime importance, such as in chromatographic analysis. Nanoparticles of ion exchange resins are being developed by many researchers and because of their high surface area to volume ratio, their kinetics is faster than of conventional resins. Because of their nanosize, they can also be used in novel scenarios, such as in situ treatment of contaminated groundwater. Modifying the morphology has also been the focus of many researchers with the possibility of ion exchange membranes and composite sheets being used as a filtration material and under chemical/potential gradients.
2. Improving selectivity of the resin for target analytes. Many researchers have attempted to develop new resins that are targeted for certain analytes, such as ClO_4^-, As(V), Cr(VI), NOM, PCP, etc. The primary focus here is to improve the selectivity of the synthesized resin for targeted ion vis-à-vis the competing ions. This enhanced selectivity value is needed because the target ions have an extremely low concentration compared to the competing ions, but are needed to be removed to almost nondetectable levels (the guideline for ClO_4^- concentration in drinking water source aquifer is <1 ppb).
3. *Improving resin regeneration efficiency*: Since the late 1950s when ion exchange resins were used in industrial applications, researchers have tried to optimize regenerant solutions for specific resins operating under specific influent solutions, but presently many researchers have been attempting to increase manifold the regeneration efficiency of a certain resin by taking advantage of specific reactions between specific ions or by manipulating the regenerant dielectric constant.

Latex Processing

Alexander F. Routh
Department of Chemical and Process Engineering, University of Sheffield, Sheffield, U.K.

INTRODUCTION

Latex consists of tiny particles of polymer dispersed in liquid. It is naturally occurring and also made synthetically in large volumes. Latex is the major component of paints as well as being used in paper, textiles and adhesives, with an annual market for these polymer dispersions in excess of $20 billion.

Although available as a natural product from rubber trees, demand has necessitated synthetic production of latex. The major use of latex is in the formation of polymer films and a common problem with latex is ensuring stability prior to use.

This entry describes some common polymers used in latex formulations and standard synthesis methods. Particle interactions and reasons for the loss of stability will be reviewed and mechanisms of film formation will be outlined.

HISTORY OF LATEX

The origins of latex are from the rubber tree (Hevea Brazilliensis), which originated in the Amazon rain forest. From the second half of the 19th century, plantations were developed predominantly in South East Asia to harvest this natural product.[1,2]

Although Dupont had been making polychloroprene rubbers since 1920, synthetic manufacture of latex was extensively developed, during World War II, in the United States. The development was in response to the Japanese conquest of South East Asia and the subsequent shortage of rubber for tyres and inner tubes, with demand greatly exacerbated by the war. Rubber was made a ''strategic and critical material'' on June 28th 1940 and the Rubber Reserve Company was set up to produce raw materials, manufacture and sell synthetic rubbers.[3] By the late 20th century, industrial production of ''artificial'' latex was developed with 500 million kg of polymer produced as latex annually.[4]

USES

By far the largest use for latex is in emulsion paints with a common household paint, being around 50% polymer in aqueous solution. Latex is also used commonly in the manufacture of protective gloves, as an adhesive, as an additive in paper and textiles, and in the manufacture of foam rubber.[5]

DEFINITIONS

Latex is a dispersion of polymer particles in a liquid medium, where the particles will remain suspended indefinitely. This property means that latices are colloidal dispersions. By nature of its origin, latex is classified into *natural* latex for dispersions obtained from plants, and *synthetic* latex for dispersions that are man made, typically by a process called emulsion polymerization. Blackley[2] discusses a number of further classifications including *artificial* latex for dispersions in which the polymer is dispersed after synthesis, and *modified* latex where a chemical modification of existing latex is made.

EXAMPLES OF POLYMERS USED IN LATICES

The range of monomers available and copolymerization in varying compositional blends makes the number of possible polymer variants immense. Acrylic and styrene-acrylic copolymers are the most widely used polymers in paints and other coatings. According to Lesko[4] acrylic polymers ''account for 30% of commercial emulsion polymers.'' Other polymers commonly used in film forming latices are polychloroprene and poly(vinyl acetate). Polystyrene–cobutadiene latices are mixed with cement and sand to form rubberized cement, as well as being used as additives in textiles and paper industries, and in the manufacture of foam rubber.

The mechanical properties of polymers are very sensitive to temperature, hence an important design property is the glass transition temperature of the constituent particles and, subsequently, the final product. Styrene homopolymer has a glass transition temperature of around 100°C and butyl acrylate a glass transition temperature of around –50°C. Hence copolymers of these two monomers have a glass transition temperature in a range from –50°C to 100°C,

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007833

Table 1 Glass transition temperatures of a range of acrylic homopolymers

Monomer	Acronym	Homopolymer T_g (°C)
Methyl acrylate	MA	+8
Ethyl acrylate	EA	−22
n-Butly acrylate	BA	−54
i-Butyl acrylate	IBA	−43
Methyl methacrylate	MMA	+105
Ethyl methacrylate	EMA	+65
n-Butyl methacrylate	BMA	+20
Styrene	S	+100

(From Ref.[4].)

depending on the composition. Table 1 shows the glass transition temperature of a range of acrylate polymers.

A further design consideration is the resistance of each polymer to different environments. For example poly(methyl methacrylate) is highly resistant to the action of sunlight, while polystyrene has low resistance. Conversely, polystyrene has excellent resistance to water where poly(methyl methacrylate) is only fair. (From Ref.[4].)

The chemical structure of a range of common polymers is given in Fig. 1.

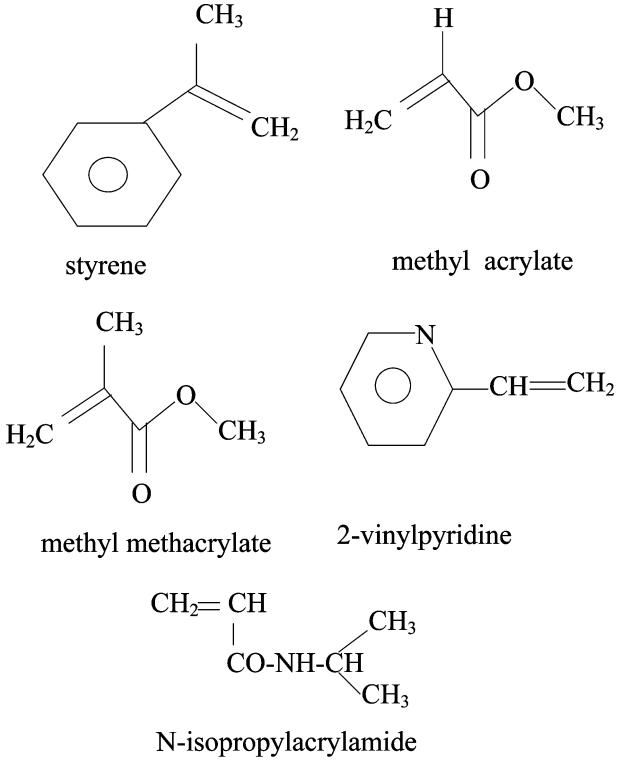

Fig. 1 Monomers commonly employed on latex production.

LATEX SYNTHESIS

The three main particle production methods are *emulsion*, *dispersion,* and *suspension* polymerization. In each case, the monomer is mixed with a continuous phase and an initiator. In addition a stabilizer in the form of surfactants may be required.

Emulsion Polymerization

In emulsion polymerization the monomer is barely soluble in the suspension medium, but the initiator is soluble. The monomer forms droplets of many microns in size that are surrounded by the stabilizing surfactant. Some monomer will dissolve in the bulk liquid and hence come into contact with the initiator, and thereby begin the polymerization. Further monomers will come into contact with the monomer radicals and polymer chains grow. These growing chains form the basis for particles and continue to grow by reacting with monomers in the bulk. The process continues until all the monomer is consumed. An example of emulsion polymerization is styrene in water with potassium persulfate as the initiator and sodium dodecylsulfonate as the stabilizer. For water-soluble monomers, the reaction can occur in organic media. Typically the monomer is present at volume fractions up to 50% and particles in the range of 50–300 nm are produced.[6]

It is not always necessary to use the stabilizing surfactant with surfactant free emulsion polymerization reported by Goodwin et al.[7]. The particles are stabilized by the surface charge on the particles resulting from fragments of the initiator used. In these cases, the monomer concentration needs to be drastically reduced to less than 5%, and particle sizes of between 100 and 1000 nm are reported.

The size of particles obtained from emulsion polymerization is determined by a balance between the rates of particle initiation and growth. The initial concentration of monomer and initiator, temperature, salt concentration, and the amount of emulsifier, affect the particle size. The particles produced are typically monodisperse with a polydispersity of less than 5%.

Dispersion Polymerization

In dispersion polymerization, the monomer and initiator are both soluble in the reaction medium, but the polymer chains are not. As the chains grow, they form micelles and continue growing. These micelles are primary particles and are typically very swollen with solvent and monomer, and hence further polymerization can occur inside the particles. The resulting particles are sterically stabilized by the addition of

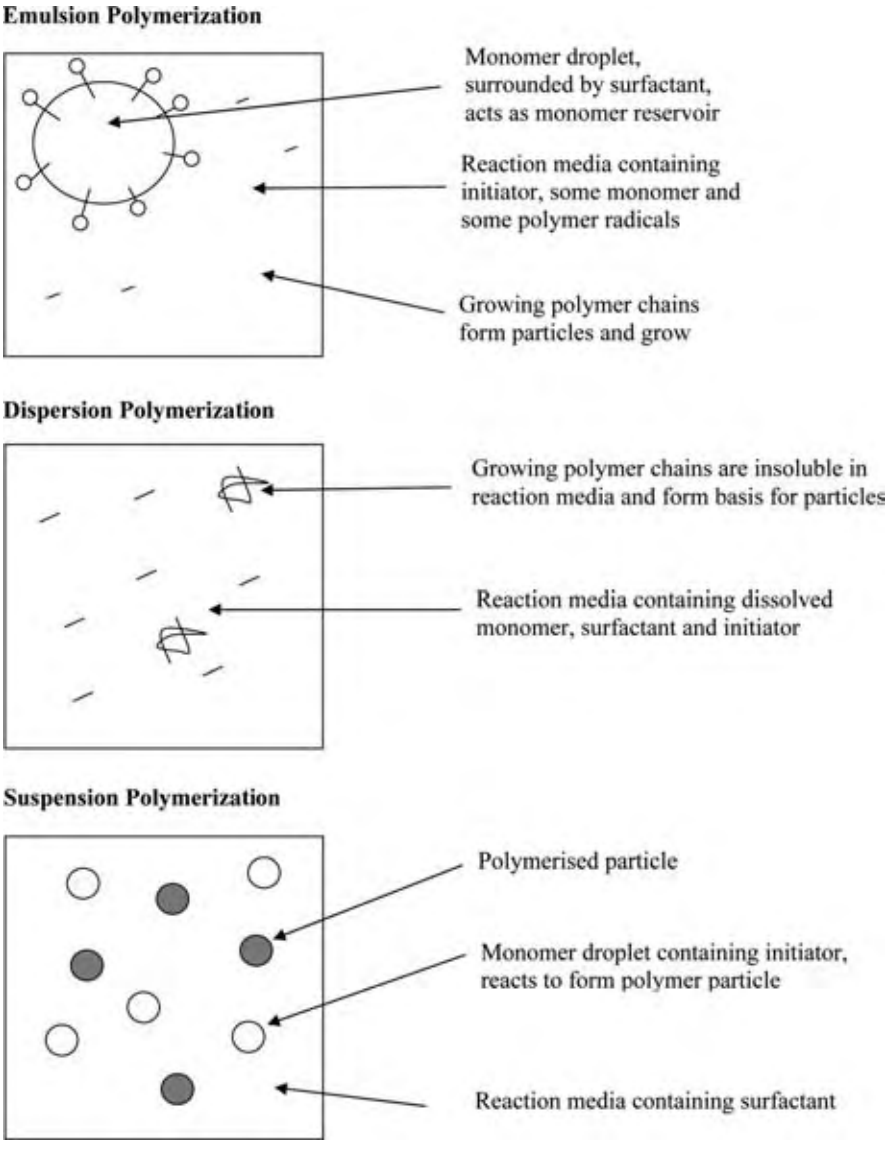

Fig. 2 Three methods to synthesize latex.

surfactants. Resulting particle sizes are in the range from 100 nm to 10 μm, the actual size being determined by the amounts of monomer, initiator and stabilizer, as well as the solvency of the reaction media. A typical dispersion polymerization reaction is styrene in ethanol using polyvinylpyrrolidone as a stabilizer and azo-bis-2-methylpropionitrile (AIBN) as the initiator.[6,8]

Suspension Polymerization

In suspension polymerization, both initiator and monomer are insoluble in the reaction medium, while the initiator is soluble in the monomer. Small droplets of the monomer are formed by stirring and the addition of surfactants whilst the reaction is usually initiated thermally. The polymerization of the monomer droplets leads to polymer particles of the same size as the original monomer droplet. A typical example is styrene and AIBN in water stabilized by polyvinylpyrrolidone and particles in the size range of 20 μm to 2 mm are routinely made. The volume fraction of the monomer is usually kept below 50%. Because of agitation during particle production, the resulting dispersions are generally polydisperse.[6–9]

The three synthesis methods are sketched in Fig. 2.

Pictures of Monodisperse Particles

Remarkable ordering is possible with highly monodisperse particles. This is demonstrated in Fig. 3, an SEM image of 200 nm radius polystyrene particles that were prepared by surfactant free emulsion polymerization.

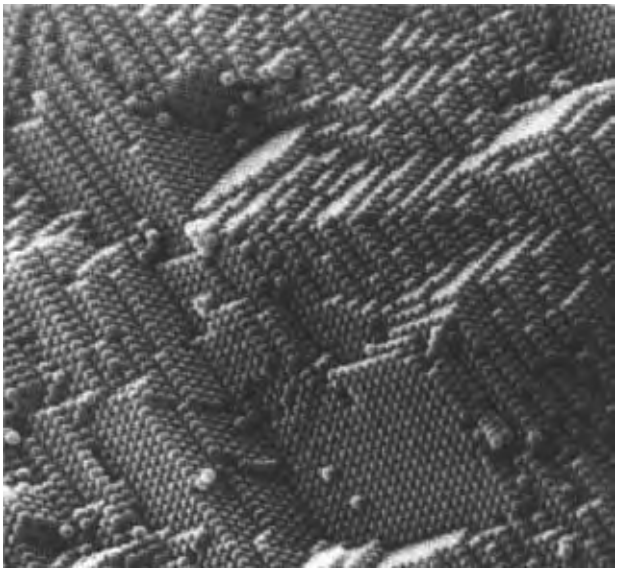

Fig. 3 Monodisperse polymer particles forming an ordered array. (From http://www.idelatex.com/body_pubsandservices.html, copyright Molecular Probes, Inc.).

RESPONSIVE POLYMERS—MICROGELS

A large body of work has recently investigated the properties and uses of responsive polymer latices. These particles, called microgels, swell in response to an external trigger, such as temperature or pH. A common microgel monomer is *N*-isopropylacrylamide, often referred to by its acronym of NIPAM. Particles composed of this monomer, cross-linked with methylene bisacrylamide, display a swelling transition at a temperature of 32°C, with particles being swollen at lower temperatures.[10] Other monomers commonly used to make microgels include styrene, divinylbenzene, acrylic acid, methacrylic acid and vinyl pyridine.[11]

Mechanism for Swelling

Poly NIPAM particles display a swelling below 32°C because water is a good solvent for the polymer at lower temperatures. The polymer chains try to dissolve, restricted only by the cross-linking holding the particles together. Vinyl pyridine based microgels swell below a pH of 3.5 because of protonation of the pyridine nitrogen that establishes a charge inside the microgel. Counter ions flood into the particle to balance the charge and the subsequent increase in osmotic pressure swells the particle. Again, a cross-linker (usually divinylbenzene) is required to stop the particle dissolving.[12] For acidic monomers swelling in the corresponding microgel occurs at high pH because of the osmotic pressure induced by dissociation.

Uses for Microgels

Microgels have found extensive use in the coatings industry as trigger dependent rheological modifiers. There are also reports of the use of PNIPAM particles for the uptake of heavy metals from wastewater and as enzyme supports, resulting in increased reaction rates.[13] The most exciting potential for microgels is as drug delivery agents. The challenges are numerous, with non-toxic responsive monomers required, but the promise of drug release in vivo on application of an external trigger is highly desirable.

STABILITY

A latex dispersion may remain invariant with time, in which case it is referred to as stable, or it may form a lump of polymeric material at the bottom of the container, in which case it is called unstable. It is obviously crucial to keep dispersions stable, at least over long enough time scales to allow their use. The sedimentation rate of a single latex particle is tiny, and Brownian motion is more than capable to keep particles dispersed. However, if particles stick together, or aggregate, they settle very quickly as sedimentation rate increases as the square of the floc size. This is the cause of dispersion instability: particles sticking together and then settling out of solution.

Interaction Potentials

Whether two isolated particles will come together or remain dispersed is determined by the energy of interaction between them. At close contact van der Waals interactions between individual molecules provide an infinite attraction meaning that all colloidal dispersion are, thermodynamically at least, unstable. Latex particles are charged because of electrical charges on their surfaces. This produces a repulsive interaction between particles that can provide a large energy barrier to aggregation and, thus, stabilize latex dispersions.

van der Waals Interactions

Two macroscopic bodies in solution have a mutual attraction. The basis for this is molecular: A dipole in body A will align in a certain orientation. This induces dipoles in body B to align in the opposite direction making charges of opposite sign closer to each other. The result is an attractive force between the two dipoles. When summed up over all possible dipoles in both macroscopic bodies, a net attractive energy is realized. This energy of interaction is dependent on the geometry and separation of the

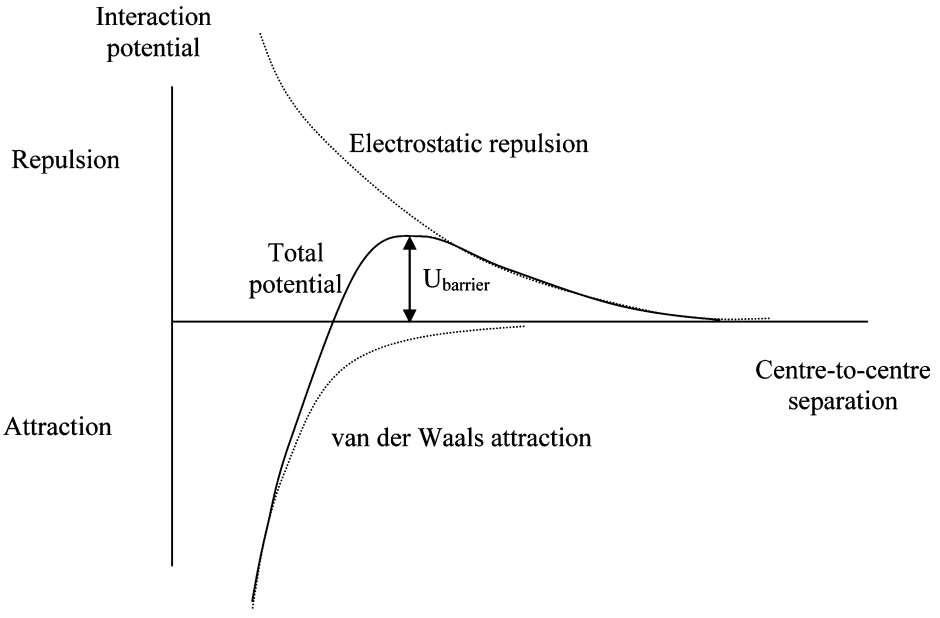

Fig. 4 Electrostatic and van der Waals potentials and a total interaction potential.

macroscopic bodies, as well as the medium they are dispersed in. For two spheres of radius R and center-to-center separation r, the interaction potential U_{vdw} is given by

$$U_{vdw} = -\frac{A}{6}\left(\frac{2R^2}{r^2-4R^2} + \frac{2R^2}{r^2} + \ln\frac{r^2-4R^2}{r^2}\right)$$

where A is called the Hamaker constant and depends on the polarizability of the particle material in the dispersed phase.[14]

Electrostatic Interactions

Two particles that have an electrostatic potential of the same sign will repel each other. The magnitude of this repulsion depends on the size of the potential and the properties of the surrounding fluid. If the surrounding solution contains a large number of ions the surface charge is screened and the inter-particle repulsion diminished. The range of electrostatic interaction between particles is called the Debye length and it is given the symbol κ^{-1}. As argued above, the Debye length is dependent on the local electrolyte concentration. For two spheres of surface potential ψ_s, radius R and center-to-center separation r the electrostatic potential U_{elec} is given by

$$U_{elec} = 4\pi\varepsilon\varepsilon_0\left(\frac{kT}{ze}\right)^2\frac{R^2}{r}\psi_s^2\exp[-\kappa(r-2R)]$$

where ε is the material permittivity, ε_0 the permittivity of free space, kT thermal energy, z the electrolyte valance and e the charge on an electron.[14] Addition of electrolyte reduces the Debye length (makes κ bigger) and reduces the effect of electrostatic repulsions.

DLVO Theory

The central theory for colloidal, and therefore latex, stability is because of the complimentary work of Derjaguin and Landau in Moscow and Verwey and Overbeek in Holland. This has become known as DLVO theory.[14] The idea is to represent a total energy of interaction as the sum of individual attractive and repulsive potentials. Fig. 4 sketches out the van der Waals and electrostatic potentials, as well as the total interaction for a particular particle size, surface potential, and electrolyte concentration.

The range of the electrostatic repulsion is determined by the external electrolyte concentration. If the electrostatics is over a longer range than the van der Waals attraction then the total interaction potential is repulsive at large separations. At short range the van der Waals attraction is always larger than the electrostatic repulsion and the total interaction potential is attractive. Therefore, a barrier to aggregation is present, marked as $U_{barrier}$ on Fig. 4. This is the energy individual particles require when they collide to be able to aggregate. It is analogous to the activation energy in chemical kinetics and depending on its magnitude provides a degree of kinetic stability to a latex dispersion. The addition of salt reduces the range of the electrostatic repulsion, allowing the van der Waals attraction to dominate. This diminishes the magnitude of the barrier to aggregation and destabilizes a latex dispersion.

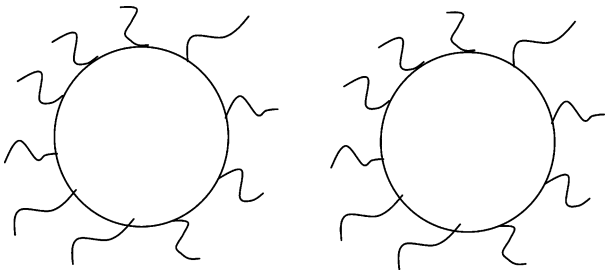

Fig. 5 Polymer chains grafted to particle surfaces provide a stabilizing repulsion: as particles approach, the chains overlap and repel.

Other Potentials

Many other interaction potentials are possible. The most common involve polymers added to systems.

Steric Stabilization

If polymer chains are attached onto the surface of particles they hinder aggregation and provide a degree of steric stability. The polymer chains must extend sufficiently into the solution, preventing approach of particles and hindering aggregation. This form of stability is especially useful in organic dispersions where electrostatic stabilization is not possible. An example is polystyrene particles with poly(ethylene oxide) chains terminally attached.[15] This is shown in Fig. 5.

Depletion Potential

A nonadsorbing polymer added to dispersions will often cause aggregation of particles. Asakura and Oosawa[16,17] were the first to describe the cause of this instability: as two particles approach the finite size of the polymer chains ensures their exclusion from the region between the two particles. The osmotic pressure is dependent on the concentration of macromolecule and hence it is diminished in this overlap region. The excess osmotic pressure in the main bulk fluid causes the two particles to be pushed together. This is called the depletion potential and has been extensively studied.[18–20] This is shown in Fig. 6.

AGGREGATION

If the interaction potential is such that aggregation does occur, then flocs of aggregated particles start to form. The two areas of interest are the rate of aggregation and the structures formed.

Aggregation Rate

The rate is determined by the diffusion of particles toward each other, and the likelihood of an individual collision achieving a stable bond. For strongly attractive potentials, such that every collision results in a stable bond, diffusion of particles towards each other is the slowest step in the aggregation process. In this case, the rate of aggregation is called the Smoluchowski rate[21] and the process called diffusion limited aggregation (DLA). The characteristic time for aggregation τ, scales inversely with the particle volume fraction ϕ as

$$\tau = \frac{\pi\eta R^3}{\phi kT}$$

where η is the viscosity of the continuous phase.

If a significant repulsion exists in the interaction potential then only a small percentage of particle–particle collisions will result in a stable bond. The characteristic time for aggregation is extended by a factor W, called the stability ratio, which takes into account this likelihood of ''reaction:''

$$\tau_{\text{slow}} = W\tau$$

The stability ratio is dependent on the total interaction potential U, such that

$$W = 2R\int_{2R}^{\infty}\frac{\exp(U/kT)}{r^2}dr$$

For very large stability ratios, where only a tiny fraction of collisions between particles result in a stable bond, the process is termed reaction limited aggregation (RLA).

Aggregate Structures

Beautiful fractal images are observed when latex particles aggregate. A fractal is a structure that replicates itself over a number of length scales and is defined by the relation

$$N = \left(\frac{a}{R}\right)^{d_f}$$

where N is the number of primary particles in the floc a is the size of the object and d_f is called the fractal dimension. The two limiting cases of aggregation (DLA and RLA) are found to have fractal dimensions of 1.75 and 2.10, respectively.[22–24]

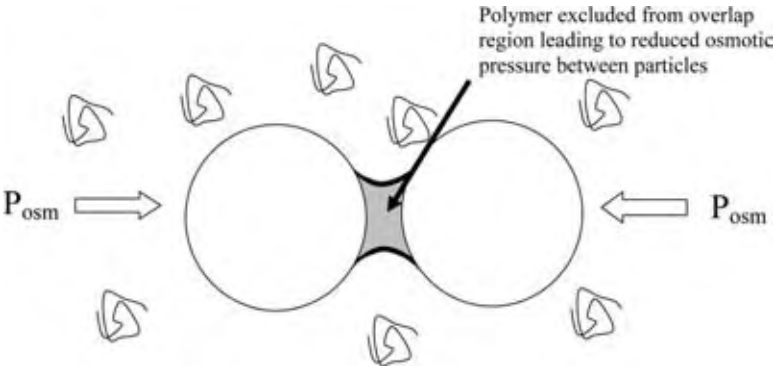

Fig. 6 Free polymer can cause destabilization: polymer, excluded from region between particles, exerts an osmotic pressure pushing particles together.

CHARACTERIZING PARTICLES

It is important to be able to characterize particles in a dispersion. Questions of interest include the particle size and charge. Ways to ascertain the glass transition temperature of the constituent polymer are discussed in the film formation section.

Dynamic Light Scattering

The easiest way to determine the size of colloidal particles is by dynamic light scattering. A laser is shone into a dilute dispersion and the intensity of light scattered at an angle, usually 90°, is followed. This scattered light is found to be self correlated for times shorter than the time it takes for the diffusion of a single particle out of the laser beam. From the self-correlation function the diffusion coefficient is obtained. The Stokes–Einstein relation relates the diffusion coefficient of particles D_0, to the thermal energy kT, fluid viscosity η and particle radius R through

$$D_0 = \frac{kT}{6\pi\eta R}$$

and hence the radius of colloidal particles is readily obtained.

Electrophoresis

Latex particles typically have a charge because of fragments of the initiator located on the surface. Additionally a bulk charge may result from ionizable moieties in the particle core.

In an electric field a charged particle will move towards the electrode of opposite charge. For a given electric field strength E, particles will acquire a velocity V, dependent on their mobility μ according to

$$V = \mu E$$

Moving particles will drag some fluid along with them. This is referred to as the added mass. There exists a radius at which the fluid does not move with the particle and this is called the slip plane. The electrical potential at this plane is lower in magnitude than the surface potential and is called the zeta potential, ζ. The magnitude of this potential determines the mobility. For very low electrolyte concentrations, such that $\kappa R \rightarrow \infty$ the mobility follows as

$$\mu = \frac{\varepsilon\varepsilon_0\zeta}{\eta}$$

Experimental Measurement

For particles large enough to be viewed with a microscope, but small enough that sedimentation is not relevant, an electric field is applied across a chamber and a very dilute sample of particles introduced. The particle motion is then followed visually and the mobility calculated.

For smaller particles, an indirect method is required to measure the particle velocity. The easiest is phase amplitude light scattering. An alternating electric field with a frequency of a few Hertz is applied. The phase shift of scattered light is dependant on the applied electric field and is proportional to the mobility of particles causing the scattering.

Iso-electric points

The source of electrostatic stabilization for latex particles is charged moieties on the surface of particles. At some pH value these groups protonate and the particles lose their surface charge. The pH at which particles have zero charge is referred to as the isoelectric point

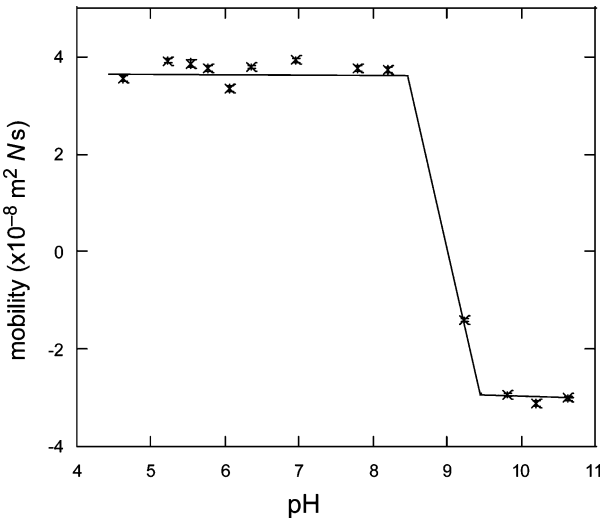

Fig. 7 Mobility versus pH data for polystyrene particles in 1 mM NaCl. The particles were made by surfactant free emulsion polymerization with 2,2-azo-bis(2-methylpropion amidine) dihydrochloride as the initiator.

(IEP) or the point of zero charge (PZC). Fig. 7 shows the mobility of polystyrene particles and an IEP of around pH 9 is seen. At the IEP the particles have very low electrostatic stabilization and readily aggregate.

RHEOLOGY

Latex dispersions display a rich range of rheological properties. The exact behavior of dispersions is dependent on both the volume fraction of particles and the interaction potential.

Shear Thinning

Shear thinning refers to the observation of a decrease in dispersion viscosity as the applied shear rate is increased. It is because of the breakdown of structure in dispersions as the shear rate is increased. For hard sphere latex dispersions, where the interaction potential is zero except at contact, there is found to be a shear thinning behavior for volume fractions above 50%.[25]

Low Shear Viscosity

The viscosity of a dispersion at very low shear rates increases as the volume fraction approaches close packing. For hard spheres a correlation that is found to cover all volume fractions is

$$\frac{\eta_0}{\mu} = \left(1 - \frac{\phi}{0.63}\right)^{-2}$$

where the critical volume fraction of 63% corresponds to random close packing.[25]

Geling

For charged latex particles in water above a critical volume fraction (often about 15%) the dispersion behaves as a viscoelastic solid, being able to support a shear stress. The transition from liquid to solid is found to correspond to the volume fraction of *equivalent hard spheres* being randomly close packed. The size of the equivalent sphere is the particle radius plus the effective size of the electrostatic interaction.[26]

FILM FORMATION

The major use of latex is in the formation of latex films, of which paint is a common example. It is common to split the film formation process up into the three transformations outlined below and the process is sketched in Fig. 8. Although any solvent is possible, water-borne coatings receive considerable attention in the literature, and hence aqueous based dispersions will be considered here. A stable dispersion of particles is concentrated by the evaporation of water. The particles pack and deform under a range of forces to give a structure without voids, although individual particles are still distinguishable. In the final step, polymer chains reptate across inter-particle boundaries, imparting mechanical strength to the film. There have been a number of excellent review articles written recently.[27–29]

Minimum Film Formation Temperature

Film formation requires deformation of polymer particles and reptation of polymer chains, and is strongly temperature dependent. The temperature at which a film will form is commonly measured on a minimum film formation temperature (MFFT) bar. Latex is applied to a metal bar with a pre-assigned temperature gradient. The coating is allowed to dry and a number of transitions are noted. Below a certain temperature the film displays cracks. This is called the crack point MFFT. At a lower temperature there is a transition from cloudy to clear, as the pores between particles become much smaller than the wavelength of light. This is called the cloudy-clear MFFT. A further transition is the temperature at which the film is able

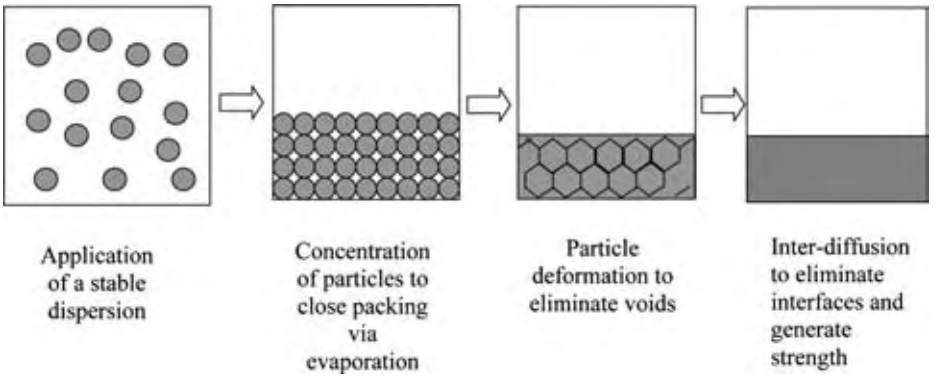

Fig. 8 Four stages of film formation.

to withstand externally applied mechanical shearing. This is called the knifepoint MFFT. The cloudy-clear and knifepoint MFFT are found to move to lower temperatures with time.[30] The MFFT are found to be within a few degrees of the polymer glass transition temperature.[31]

Use of Plasticizers

Particle deformation and polymer diffusion can only occur at temperatures above the glass transition temperature of the polymer. Final coatings, however, are required to be at temperatures considerably below the glass transition temperature. To get around this problem, it is common to add plasticizers to water borne latex dispersions to lower the glass transition temperature of the constituent polymer during the film formation process. Subsequent evaporation of the plasticizer results in a hard final coating. A common plasticizer is 2,2,4-trimethyl-1,3-pentanediol monoisobutyrate, usually referred to as Texanol Ester Alcohol.

Film Formation Mechanism

The final properties of latex coatings are dependent on the mechanism of film formation and how the film forms. For example, the development of mechanical strength is a direct consequence of polymer chain interdiffusion. Prediction of this strength is only possible from an understanding of the transformations occurring on the particle length scale. Here, the three major transformations in latex film formation are briefly outlined.

Transformation 1—Solvent evaporation

An aqueous latex sample initially loses water at a rate that is consistent with the evaporation of pure water. As the particles become more concentrated, two distinct cases have been observed: (1) If the particles consolidate at the top surface and deform significantly, restricting water flow to the top surface, evaporation is found to decrease, and the film becomes vertically inhomogeneous. (2) If the particles are sufficiently rigid, then evaporation is found to continue unhindered.[32]

In addition to the conceptually simple one-dimensional process, evaporating solvent from a latex dispersion is complicated by the presence of drying fronts. A wet film dries first at the thinnest part (normally an edge) and particles pack. Continued evaporation from the packed region causes a transverse flow of solvent in the film, carrying particles to the edge and resulting in a front of packed particles, passing laterally across the film.[33] This means that film formation is inherently two-dimensional and any control over film morphology must consider the lateral dimension.

Transformation 2—Particle deformation

Once particles come into contact, they will begin to deform. If deformation is incomplete then a cloudy film is seen and cracks may appear. The deformation step is, therefore. crucial to film formation, and has received a large amount of attention from academics. A number of driving forces for the deformation have been proposed. All the driving forces depend on the surface tension between the particles and the surrounding medium, or the water–air surface tension. These mechanisms are outlined below:

Wet Sintering. If the particles remain in an aqueous environment after coming into contact, the action of the polymer-water surface tension can cause the particles to consolidate. For this to occur, the deformation must be faster than the evaporation rate, and this was first postulated by Vanderhoff.[34]

Capillary Deformation. As water evaporates, curvature of the air-water interface causes a large negative capillary pressure in the water. Atmospheric pressure

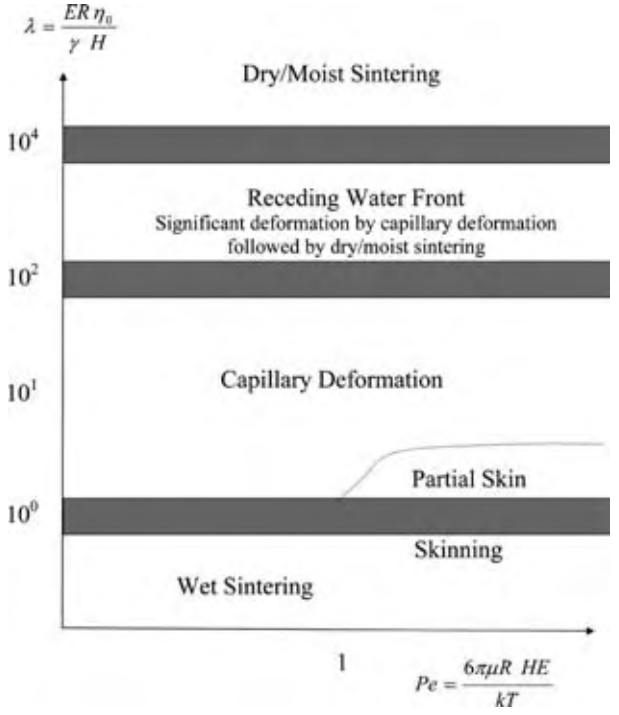

Fig. 9 Regimes of different deformation mechanisms. (From Ref.[32].)

pushes down on the film and can cause the deformation of particles. In this case, deformation is concurrent with evaporation and was first postulated by Brown.[35]

Dry Sintering. Once all the water has evaporated, the action of polymer-air surface tension can cause particles to deform. This is analogous to wet sintering, and was first postulated by Dillon, Matheson, and Bradford.[36] It has been argued that residual water must remain in ''dry'' films to balance residual humidity in the atmosphere, the water being present at the boundary between particles, as pendular rings. The capillary pressure in these rings is large and causes particles to deform. This deformation mechanism has been termed moist sintering.[37]

Receding Waterfront. If significant deformation occurs by capillary deformation, but the voids remain in the film as water recedes, an inhomogeneous film is observed. The deformation is completed by either the dry or moist sintering mechanisms referred to above. This was first identified by Keddie and termed stage II*.[38]

Sheetz Deformation. If the film is inhomogeneous, a continuous polymer layer or skin may form at the top surface. This slows evaporation considerably and allows more time for wet sintering to occur in the consolidated part of the film. This has been termed Sheetz deformation, although the argument about time scales is different to the original postulation by Sheetz.[39]

Predicted Deformation Mechanisms. Recent work has developed maps of the deformation mechanisms expected in films with different properties.[31,32] Two dimensionless groups were found to determine which of the deformation mechanism occurs. The first is the time for particle deformation compared to the time for evaporation, captured in $\lambda = ER\eta_0/\gamma H$, where E is the evaporation rate, η_0 is the polymer viscosity, and γ is the water-air surface tension. The second dimensionless group is the Peclet number, which determines the vertical homogeneity in the film, $Pe = 6\,\pi\,\eta\ R\ H\ E/kT$. The deformation regimes are shown in Fig. 9.

Transformation 3—Polymer reptation

Once the polymer particles have deformed, any free polymer chains will diffuse across particle boundaries. The strength of polymer films has been shown to increase with the depth of polymer interdiffusion, up to size of a single polymer chain.[40]

Design

When designing a film forming latex dispersion, the properties to consider are the final mechanical properties of the film, as well as the ease of film formation: The mechanical properties required, as well as the environment of operation will dictate the polymers suitable for the coating and may well dictate the glass transition temperature of the polymer. The crack points alluded to earlier correspond to the transition from capillary deformation to the receding water front regime. Therefore, a value of λ less than 100 will ensure a well-formed film.

CONCLUSIONS

This article has reviewed latex processing. The polymers used, synthesis of particles, major uses, and reasons for loss of dispersion stability have been outlined. The mechanism of latex film formation has been described, and the different properties resulting from different film forming conditions in latex explored.

INTRODUCTION

This entry briefly describes the use of agitated vessels and reactors to create immiscible liquid–liquid dispersions. A more comprehensive treatment is given by Leng and Calabrese.[1] The term ''immiscible liquid–liquid system'' refers to two or more mutually insoluble liquids present as separate phases. These phases are referred to as the dispersed or drop phase, and the continuous or matrix phase, and their property variables are given subscripts of d and c, respectively. The dispersed phase is usually smaller in volume than the continuous phase, but under certain highly formulated conditions, it can represent up to 99% of the total volume of the system. Immiscible liquid–liquid systems are found extensively throughout the chemical, petroleum, and pharmaceutical industries. The rate of chemical reactions is often mass transfer controlled and is affected by the interfacial area per unit volume of dispersed phase. Examples include nitration, sulfonation, alkylation, hydrogenation, and halogenation. Failure to adequately suspend and disperse drops can lead to undesirable and sometimes catastrophic results.

Mechanical energy, typically supplied through a mechanical device such as an impeller, pump, or rotor–stator device, is required to disperse one phase into the other. Agitation plays a key role in liquid–liquid systems. It controls the break up of drops, referred to as *dispersion*; the combining of drops, known as *coalescence*; as well as the *suspension of drops* within the system. The magnitude and direction of convective flows produced by an agitator affect distribution and uniformity throughout the vessel, as well as the kinetics of dispersion. Agitation intensity is also important. Intense turbulence found near the impeller leads to drop dispersion, not coalescence. Lower turbulence or laminar/transitional conditions found beyond the impeller region, promote coalescence by enabling drops to remain in contact long enough for them to coalesce.

Coalescence, dispersion, and suspension phenomena are complex, inter-related, and scale dependent. For example, dispersion tends to dominate in small vessels and coalescence in large equipment. Nevertheless, industrial processes can be semi-quantitatively analyzed if they are either noncoalescing or slowly coalescing. This simplifies design and scale-up. Coalescence can usually be neglected, for practical purposes, in applications where the volume fraction of dispersed phase, $\phi \leq 0.1$. This is particularly true if surfactants and/or interfacial contaminants are present. However, scale-up is complicated by the time it takes to create dispersions. Small vessels reach a terminal state of dispersion much faster than large ones. If scale-up is done to form equal interfacial area, the large vessel will take much longer to achieve the task. Stirred vessels, rotor–stator mixers, static mixers, decanters, settlers, centrifuges, homogenizers, extraction columns, and electrostatic coalescers are examples of industrial process equipment used to contact liquid–liquid systems. Although this entry emphasizes stirred vessels, the fundamentals of phase behavior are applicable to a broad range of other equipment types. In the case of stirred vessels, for any given system, the mean drop size and drop size distribution depend on the selection, placement, and operational speed of the agitator. Excessive speed leads to hard-to-separate emulsions. Inadequate speed can cause phase separation. Both coalescence and dispersion are fluid motion dependent rate processes. Drop sizes depend on flow, shear, turbulence, and dispersion time, as well as physical and interfacial system properties.[1]

SELECTION AND CONFIGURATION OF LIQUID–LIQUID EQUIPMENT

Any impeller capable of pumping fluid and providing shear can produce liquid–liquid dispersions. Commonly

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120041244

used impellers include disk turbines, pitched-blade turbines, propellers, hydrofoils, paddles, retreat-curve impellers, and other proprietary designs. High-shear, high-speed devices such as rotor–stator mixers are also commonly used to produce emulsions containing finely dispersed, micron-size droplets. These devices are discussed in detail by Atiemo-Obeng and Calabrese.[2]

If the application requires high interfacial area (i.e., small drop diameters), a high-shear impeller, such as the Rushton or radial disk turbine (RDT), is a good choice (Fig. 1). Acceptable substitutes include the Scaba and Chemineer's BT-6 and CD-6 impellers, commonly used for gas–liquid dispersion. If moderate, yet gentle shear is required, such as for emulsion polymerization, the retreat-curve impeller is commonly chosen. When larger drops of a narrow size distribution are required, the loop impeller is a reasonable choice. Broad-blade paddles are also used.

Recommended impeller diameter-to-tank diameter (D/T) ratios, for liquid–liquid operations vary from 0.25 to 0.40 for radial disk turbines, from 0.4 to 0.6 for hydrofoils and propellers, and from 0.5 to 0.8 for retreat-curve, glassed-steel impellers. Vertical placement of the impeller depends on the vessel shape and the application. For dispersion by continuous addition of a dense phase fluid into a less dense fluid, the impeller should have a relatively small impeller clearance off the reactor bottom, C, with respect to the final height of the dispersion, H, i.e., the impeller should be placed low in the vessel ($C \approx H/4$ to $H/5$). For dispersion of light liquids, it is good practice to place a single impeller between $0.20 \leq C/H \leq 0.50$.

Multiple impellers are recommended if $H/T \gg 1.2$ or if $\Delta\rho > 0.15\,\mathrm{kg/m^3}$. Assuming a less dense dispersed phase, the second or top impeller often is a hydrofoil impeller placed midway between the radial disk turbine and the surface of the liquid. This impeller produces high flow at low power, provides effective circulation, and complements the flow pattern produced by the radial disk turbine. The diameter of the second impeller is usually greater than the radial disk turbine, typically $D/T \geq 0.45$. A good practice is to distribute the total power to ≈20% for the hydrofoil and ≈80% for the radial disk turbine. Table 1 lists equipment options for different drop sizing objectives.

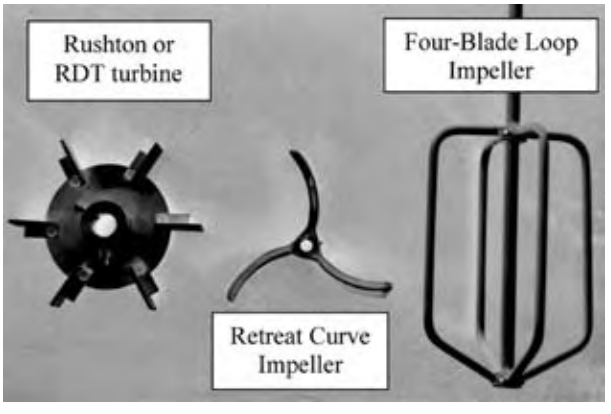

Fig. 1 Some impellers used for liquid–liquid dispersion. (From Ref.[1].)

The geometry for liquid–liquid processing is typically a cylindrical dish bottom vessel. It should be provided with four equally spaced baffles having a width between $T/12$ and $T/10$ and located at least $T/72$ off the wall. Other vessel and baffle arrangements are possible, as discussed by Hemrajani and Tatterson.[3] In all cases, it is essential to avoid stagnant regions in liquid–liquid operations, regardless of the process. This means that the use of flat and cone bottom tanks and tall slender vessels is not recommended. Placing baffles away from the wall, to permit flow between the wall and the baffle, prevents dispersed phase buildup in stagnant areas. Internal heating coils and ladders should also be avoided, if possible. Optimum flow patterns normally develop when the overall vessel shape is $1 < H/T < 1.2$.[1]

FORMING LIQUID–LIQUID DISPERSIONS

Both initial and final conditions affect dispersion formation (see Figs. 2 and 3, where oil is the lighter or the upper phase). If the lower phase is to be dispersed in the upper phase, the radial disk turbine should be placed in the upper phase and an upward-pumping axial flow turbine is placed in the lower phase, as shown in Fig. 2. When the upper oil layer is to be dispersed in the lower water layer, the arrangement shown in Fig. 3 is recommended. Here the axial flow turbine pumps downward. Both figures show the use of a radial disk turbine for dispersion and a propeller to improve circulation. Single impellers can also be used. Often, oil-in-water (O/W) and water-in-oil (W/O) regions initially coexist. The amount of each phase and the relative rates of coalescence (O/W vs. W/O) during transient conditions determine whether the final system is O/W or W/O. Fig. 4 shows the ideal location for a single turbine.

MECHANISMS OF DROP DISPERSION, DROP COALESCENCE, AND PHASE INVERSION

Drop deformation occurs when fluid dynamical forces, often referred to as "shear forces", in the surrounding fluid act on its surface. Surface and internal viscous forces resist it. Drop dispersion (breakage) occurs when the "shear forces" exceed the combined resistance force.

Table 1 Common types of equipment used for liquid–liquid dispersion

Description	Impeller types	Batch/continuous	Desired result	Comments
Stirred tanks; baffles	Flat, pitch, and disk type	Either	$30 \leq d_{32} \leq 300\,\mu m$	General; mass transfer operations
Stirred tanks; baffles	Retreat curve	Either	$30 \leq d_{32} \leq 300\,\mu m$	General; emulsion polymerization[a]
Stirred tanks; no baffles	Paddle, loop, special types	Batch	$100 \leq d_{32} \leq 1000\,\mu m$	Suspension polymerization;[a] suspending agent required
Static/in-line mixers	None	Continuous	$10 \leq d_{32} \leq 200\,\mu m$	Dispersant or protective colloid needed
Rotor–stator mixers	Slotted ring or impeller, along with slotted stator	Either, often continuous	$1 \leq d_{32} \leq 50\,\mu m$	Sparse data for scale-up; need extensive testing
Impingement Mixers	None	Continuous	$1 \leq d_{32} \leq 50\,\mu m$	Sparse data; work with vendors
Valve homogenizers; ultrasonic mixers	None	Usually continuous	$0.1 \leq d_{32} \leq 10\,\mu m$	Sparse data; work with vendors; feed is predispersed

[a]Drop size refers to monomer drops. Latex products are much smaller particles in the range from 0.1 μm to 0.5 μm.
(From Ref.[1].)

Coalescence is the combining of two or more drops, or a drop with a coalesced layer. The two-step process involves collision followed by film drainage. Collision frequency depends on both the agitation rate and the volume fraction of the dispersed phase. The drainage step depends on the magnitude and the duration of the force acting on the drop(s) to squeeze out the continuous phase film separating the drops to a critical thickness, believed to be in the range of ≈50 Å. The coalescence rate is the product of the collision rate and the coalescence efficiency (related to drainage rate). The mobility of the liquid–liquid interface also affects the film drainage rate. Clean, mobile interfaces promote efficient film drainage, and lead to higher coalescence probability. A simple static test for coalescibility is to agitate or shake a sample for 5 min and then watch it settle and coalesce. The results can be interpreted using Table 2. A noncoalescing or slowly coalescing system has a settling time that is greater than 5 min. A rapidly coalescing system has a settling time of less than 1 min.

Coalescence, dispersion, and settling are all affected by dispersed phase concentration or volume fraction, ϕ. Liquid–liquid systems can be categorized with respect to ϕ as follows:

- *Dilute Systems:* $\phi < 0.01$. Dispersion is affected only by hydrodynamics, and each drop is a single entity experiencing continuous phase fluid forces. Coalescence is neglected because few collisions occur.
- *Moderately Concentrated Systems:* $\phi < 0.2$. The behavior of systems in this concentration range depends on coalescence behavior. Ideal dilute dispersion theories may still apply, particularly if the system is noncoalescing. Even in the presence of coalescence, it is possible to roughly predict the droplet size for moderately concentrated systems.

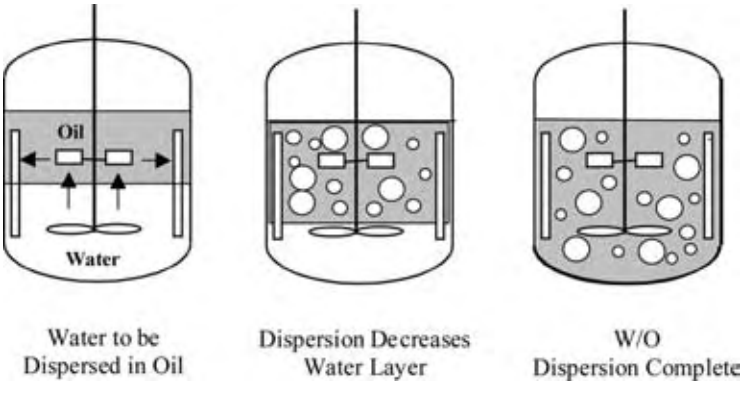

Fig. 2 Dual impeller arrangement for water-in-oil dispersion. Propeller is upward pumping. (From Ref.[1].)

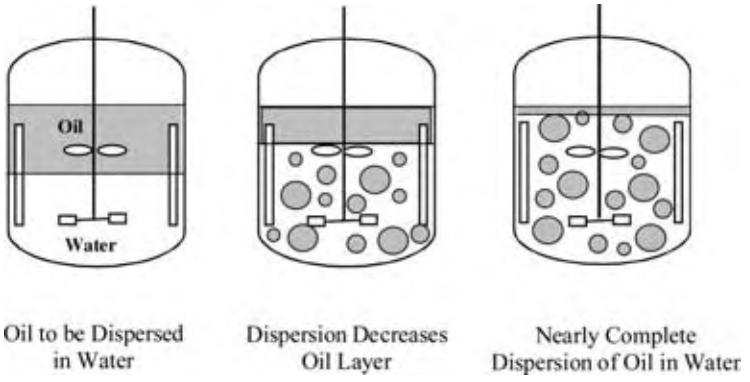

Fig. 3 Dual impeller arrangement for oil-in-water dispersion. Propeller is downward pumping. (From Ref.[1].)

- *More Concentrated Systems:* $\phi > 0.2$. This range is common in industry. Fast coalescence is probable for clean systems. Sprow[4] found that with coalescing systems, drop sizes were position dependent within the vessel. This behavior is very complex and extremely difficult to scale-up, as coalescence and dispersion dominate in different regions of the vessel.

Phase inversion is a commonly observed phenomenon in which the continuous phase abruptly becomes the dispersed phase and vice versa (see Pacek et al.[5,6] and Pacek, Nienow, and Moore [7]). Systematic studies on the effect of surfactant concentration and mixing on phase inversion and emulsion drop size have been carried out by Brooks and Richmond.[8–11] Fig. 5 shows schematically the steps occurring during phase inversion. Although conflicting information exists on the subject, the following conclusions can be made:

- Coalescence, not dispersion, dominates as the controlling mechanism in phase inversion. Factors affecting film drainage rates, such as agitation rate, interfacial tension, interface mobility, film viscosity and contact time, all apply;
- Inversion behavior is property dependent and therefore system specific.
- Surface-active agents play an important role, affecting film drainage rates.
- Every system has an operating region in which the oil phase is continuous, a region in which the aqueous phase is continuous, and an ambivalent region where either phase can be continuous, depending on initial conditions, flow circulation, and agitation intensity. This is shown in Fig. 6, which contains the data of Kinugasa et al.[12]
- The probability for phase inversion increases as drops get closer together.

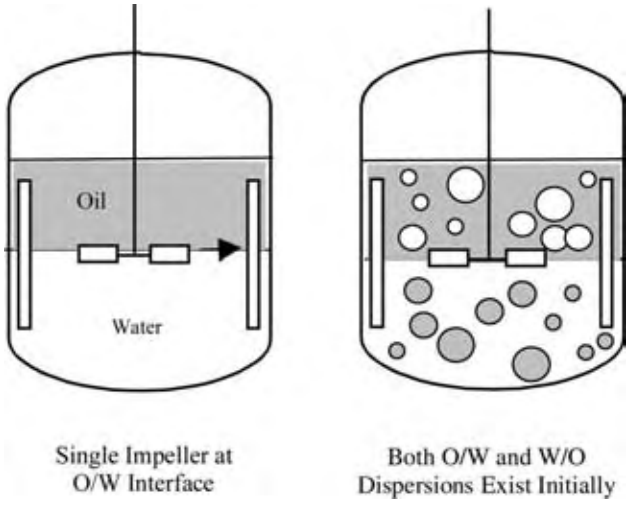

Fig. 4 Single radial disk turbine placed at oil-water interface. (From Ref.[1].)

PRACTICAL ASPECTS OF DISPERSION FORMATION

As previously discussed, placing a radial disk or Rushton turbine in the aqueous or lower phase, close to the interface, can be effective when making oil-in-water dispersions. A central interfacial vortex forms with the commencement of impeller motion. This directs a stream of the lighter oil phase to the impeller where it disperses. The volume of the oil layer decreases with continued dispersion until it is exhausted. Placing the turbine in the oil or upper phase, close to the interface, can result in water-in-oil dispersions, because a water-containing vortex forms, allowing water to be dispersed into the lighter oil phase.

Dispersions may also be formed by the continuous addition of one phase into another under agitated conditions. This method offers a safe procedure for handling exothermic reactions such as nitration and emulsion polymerization. The amount of phase addition will determine if phase inversion occurs.

Listed below are some general recommendations for immiscible liquid–liquid systems:

- Use multiple turbines if the system is rapidly coalescing, to provide additional dispersion capability.

Table 2 Characterization of the coalescibility of immiscible liquid–liquid systems

Time to separate	Characterization	Process implication
<10 sec	Very fast coalescence	Expect severe scale-up problems for agitated vessels; provide more dispersion opportunities. For example, use multiple impellers, provide for strong flow at the top and bottom of the vessel. Consider use of long static mixers
<1 min	Fast coalescence	Scale-up problems can be managed by careful selection of mixing equipment. Use multiple impellers, eliminate unnecessary internals, and provide for complete circulation
2–3 min	Moderate coalescence	Problems are less severe, design for coalescence. Use large impellers for dispersion and flow. Maintain ample flow at the top/bottom surfaces. Often can treat this case as noncoalescing
>5 min	Slow coalescence	Application can be treated as dispersion only

(From Ref.[1].)

Axial flow turbines can also be used to achieve better uniformity in circulation.

- Avoid excessive dispersion in noncoalescing systems. Creation of tiny, hard-to-coalesce drops can become a problem if phase separation is required later. Test the system using bench scale equipment to see if and at what speed undesirably small drops form.
- Use at least one axial flow hydrofoil-type impeller of high D/T (i.e., $0.4 \leq D/T \leq 0.6$) in addition to the Rushton or RDT turbine for systems having large phase density differences.
- Interfacial tension controls the ease of drop breakage. Low interfacial tension ($\sigma \leq 10$ dyne/cm or 0.01 N/m) systems require lower power for dispersion than high interfacial tension ($\sigma \geq 30$ dyne/cm or 0.03 N/m) systems.
- Use dish bottomed vessels with proportions $H/T < 1.2$.
- Baffling is always required for liquid–liquid dispersion, with the exception of suspension polymerization and certain highly shear sensitive emulsion polymerizations.

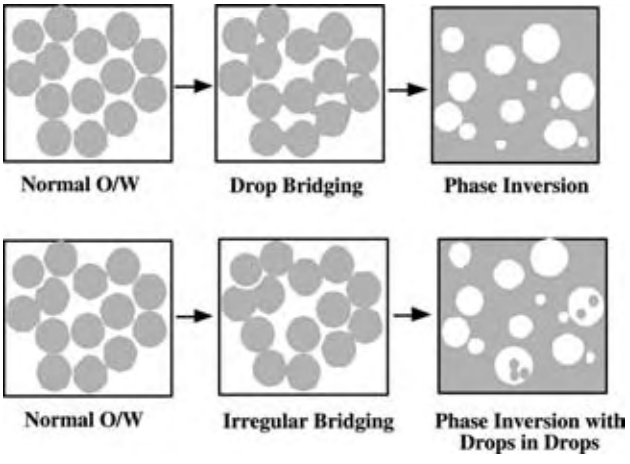

Fig. 5 Sequences in phase inversion. (From Ref.[1].)

Table 3 gives a summary of practical guidelines for scale-up of coalescing and noncoalescing systems.

CALCULATION OF MEAN DROP SIZE IN LIQUID–LIQUID DISPERSIONS

The ability to predict drop size is critical to determining both the interfacial area for mass transfer and the state of dispersion of the system. In dilute systems and in moderately concentrated systems where coalescence can be neglected, the following equation describes the maximum equilibrium (i.e., after a long time) drop diameter of an inviscid or low viscosity dispersed phase:

$$d_{\max} = C_1 \left(\frac{\sigma}{\rho_c}\right)^{3/5} \varepsilon_{\max}^{-2/5} \tag{1}$$

where the constant C_1 must be determined from experimental data. An extensive discussion of drop dispersion theory is given by Leng and Calabrese.[1] Davies[13] showed that values of $d_{\max}$ for a wide variety of dispersion devices could be correlated with maximum local power per mass, if a rough estimate of $\varepsilon_{\max}/\varepsilon_{\text{avg}}$ could be obtained. The results of the analysis for dilute inviscid dispersed phases, corrected for interfacial tension, are shown in Fig. 7. The slope of the line bounding the data is –2/5, as predicted by Eq. (1).

A more practically important drop size than $d_{\max}$ is the Sauter mean diameter d_{32}, defined as:

$$d_{32} = \frac{\sum_{i=1}^{i=m} n_i d_i^3}{\sum_{i=1}^{i=m} n_i d_i^2} \tag{2}$$

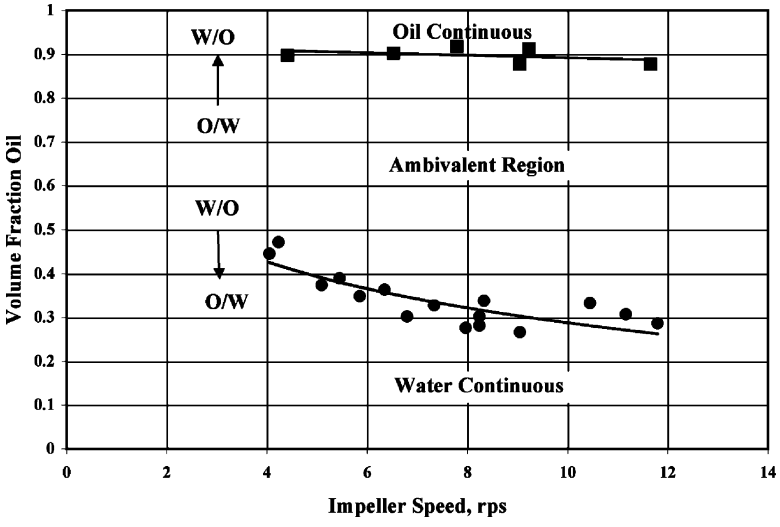

Fig. 6 Phase inversion boundaries for the kerosene-water system showing oil and water continuous regions, and an ambivalent region. (From Ref.[1,12].)

For geometrically similar turbulent systems, $\varepsilon_{max} \propto \varepsilon_{avg}$, which for constant power number gives $\varepsilon_{max} \propto N^3D^2$ (see Zhou and Kresta[14,15]). For a dilute system, the droplets will have sizes equal to d_{max} or smaller. There is considerable experimental evidence that $d_{max} \propto d_{32}$ (see Leng and Calabrese,[1] Wang and Calabrese[16]). Therefore, for geometrically similar systems, Eq. (1) is equivalent to:

$$\frac{d_{32}}{D} = C_2\, We^{-3/5} \tag{3}$$

where the Weber number $We = \rho_c N^2 D^3/\sigma$ is the ratio of inertial (disruptive) to surface (resistance) forces. For Rushton turbines, Chen and Middleman[17] found $C_2 = 0.053$ (Fig. 8) for a broad range of liquid–liquid pairs. Eqs. (1) and (3) show that, at equilibrium, dispersed phase systems created by turbulent flow scale-up by maintaining constant ε_{max}; or for practical industrial purposes, by constant ε_{avg}, which is equivalent to constant P/V_L. Large Weber numbers result in small drops and vice versa. These expressions are valid for dilute, noncoalescing systems of low μ_d, at equilibrium. Many stabilized or noncoalescing industrial systems with $\phi > 0.05$ can also be scaled by the constant P/V_L criterion.

If the drops are viscous, the internal viscous resistance to deformation must be considered. Furthermore,

Table 3 Guidelines for scale-up of liquid–liquid stirred vessels

Feature	Non/slowly coalescing system	Rapidly coalescing system
Scale-up criterion	P/V_L, constant	Circulation time, constant
Scale-up limitation, V_{Large}/V_{Small}	100/1	10/1 to 20/1
Baffles	Yes, but not for suspension polymerization	Yes
Impellers	Radial disk turbine and optional axial flow/ hydrofoil impeller	Multiple radial disk turbines and axial flow/hydrofoil impeller for better circulation
D/T	0.3–0.5	$\geq$0.5
Time to reach terminal drop size	Long times for large vessels	Short times under 30 min for most coalescing systems (all vessel sizes)
Geometric similarity	Maintain close similarity	Use more and larger turbines in larger vessel. Do not try to maintain geometric similarity
Speed/drives	Variable or fixed speed	Variable speed capability is essential. Consider over design to meet unpredicted performance
Risk	Low to moderate risk	High risk

(From Ref.[1].)

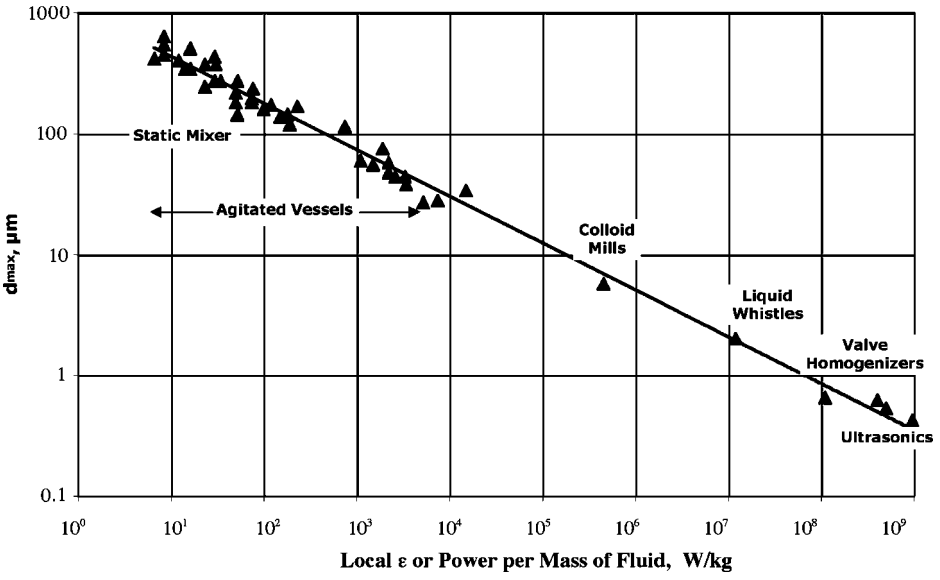

Fig. 7 Dependence of drop size on local power drawn by various dispersion devices. (From Ref.[1,13].)

the effect of ϕ on d_{32} should also be taken into account. In more concentrated systems ($0.01 \leq \phi \leq 0.3$), which can be described as noncoalescing, the relationships given above can be modified to account for both the viscosity effect (in $\mathrm{Vi} = (\rho_c/\rho_d)^{1/2}\mu_d ND/\sigma$) and ϕ to give the following equation for Rushton turbines, obtained by Calabrese, Wang, and Bryner:[18]

$$\frac{d_{32}}{D} = 0.054(1 + 3\phi)\mathrm{We}^{-3/5} \times \left[1 + 4.42(1 - 2.5\phi)\mathrm{Vi}\left(\frac{d_{32}}{D}\right)^{1/3}\right]^{3/5} \quad (4)$$

This equation should be used with some caution. It has only been experimentally validated for dilute dispersions ($\phi < 0.1$) and $D/T = 0.5$. Other equations for d_{32} are discussed by Calabrese and coworkers.[16,18,19]

CALCULATION OF THE MINIMUM IMPELLER SPEED FOR COMPLETE DISPERSION, N_{MIN}, IN LIQUID–LIQUID SYSTEMS

Settling and coalescence are common when the dispersed and continuous phases are of different density, and when agitation provides only minimal circulation throughout the vessel. It is, therefore, important to determine the minimum impeller speed, N_{min} to completely incorporate the dispersed phase, as droplets, into the continuous phase (i.e., to remove the initial stratification of the immiscible liquids in a vessel). Most reported work is semiempirical and follows the approach of the ''just suspended'' state of solids in liquids described in an earlier entry of this book, as well as by Atiemo-Obeng, Penney, and Armenante.[20]

There are analogies between N_{js}, the minimum agitation intensity to suspend solids, and the corresponding variable, N_{min}, for drop suspension. Both depend on density difference, continuous phase viscosity, and impeller diameter. However, N_{js} depends directly on particle size, while N_{min} depends instead on interfacial tension and the other physical properties that determine drop size.

Skelland and Seksaria[21] determined the minimum speed to form a liquid–liquid dispersion from two settled (separated) phases of different density, and included the sensitivity to impeller location. The vessels used were fully baffled. They determined N_{min} for systems of equal volumes of light and heavy phase. Studies included use of single impellers placed midway in the dense phase ($C = H/4$), at the O/W interface ($C = H/2$) and midway in the lighter phase ($C = 3H/4$). They also examined the use of dual impellers located midway in both phases. Several impeller types were tested. Their results are correlated by the following dimensionless equation:

$$\frac{N_{min}D^{0.5}}{g^{0.5}} = C_3\left(\frac{T}{D}\right)^{C_4}\left(\frac{\mu_c}{\mu_d}\right)^{\frac{1}{9}}\left(\frac{\Delta\rho}{\rho_c}\right)^{0.25}\left(\frac{\sigma}{D^2\rho_c g}\right)^{0.3} \quad (5)$$

The magnitude of the constants C_3 and C_4, given in Table 4, is a measure of the ease of suspension formation. Low C_3values indicate dispersions are formed at low speeds. Large C_3 values (single impellers) suggest that higher speeds are required for minimum suspension. Turbines at the O/W interface require lower speed than in other locations. Radial flat-blade turbines placed in the light phase appear to be inefficient.

Armenante and Huang[22] and Armenante, Huang, and Li.[23] found practically no advantage in using

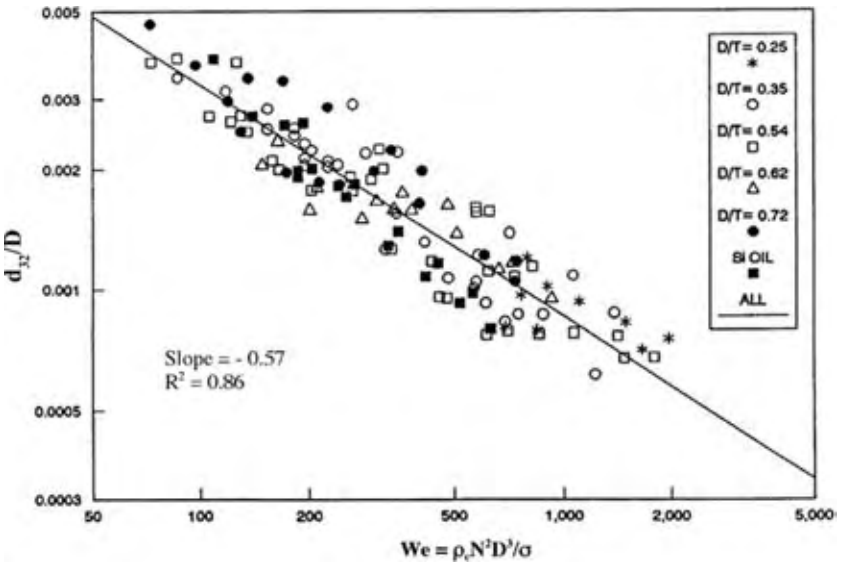

Fig. 8 Experimental data for 14 different liquid–liquid pairs. (From Ref.[1,17].)

multiple impellers for determining N_{min}. This is similar to the result for solid–liquid suspension. However, multiple impellers were useful in improving dispersed phase uniformity.

POWER DISSIPATION IN LIQUID–LIQUID STIRRED REACTORS

As discussed previously, the ultimate drop size is determined by ε_{max}, not ε_{avg}. However, most correlations for drop size use ε_{avg}, because data for ε_{max} are not readily available. The power dissipated by an impeller in liquid–liquid dispersions is:

$$P = N_p \bar{\rho} D^5 N^3 \tag{6}$$

where the volume average density of the liquid–liquid mixture is given by:

$$\bar{\rho} = \phi \rho_d + (1 - \phi)\rho_c \tag{7}$$

Other relevant equations as well as the diagrams to calculate the power number, N_p, are provided in an earlier entry, and by many investigators including Atiemo-Obeng, Penney, and Armenante;[20] Tatterson;[24] Bates, Fondy, and Corpstein;[25] Bates, Fondy, and Fenic;[26] and Armenante and coworkers.[23,27,28] The corresponding value of ε_{avg} for liquid–liquid dispersion is:

$$\varepsilon_{avg} = \frac{P}{\bar{\rho} V_L} \tag{8}$$

An estimate of ε_{max} in agitated vessels can be obtained by replacing V_L in Eq. (8) by the volume swept out by the impeller, as was used by Davies[13] in Fig. 7.

Table 4 Constants for use in Eq. 5

Impeller type	Clearance	C_3	C_4
Propeller	$H/4$	15.3	0.28
Propeller	$3H/4$	9.9	0.55
Propeller	$H/2$	15.3	0.39
Propeller	$H/4 + 3H/4$	5.2	0.92
Pitched-blade turbine	$H/4$	6.8	1.05
Pitched-blade turbine	$3H/4$	6.2	0.82
Pitched-blade turbine	$H/2$	3.0	1.59
Pitched-blade turbine	$H/4 + 3H/4$	3.4	0.87
Flat-blade turbine	$H/4$	3.2	1.62
Flat-blade turbine	$3H/4$	*	*
Flat-blade turbine	$H/2$	4.0	0.88
Flat-blade turbine	$H/4 + 3H/4$	*	*
Curved-blade turbine	$H/4$	3.6	1.46
Curved-blade turbine	$3H/4$	*	*
Curved-blade turbine	$H/2$	4.7	0.80
Curved-blade turbine	$H/4 + 3H/4$	4.3	0.54

*Insufficient data for correlation purposes. (From Ref.[1,20].)

INTERFACIAL AREA IN LIQUID–LIQUID DISPERSIONS

The liquid–liquid interfacial area per unit volume available for mass transfer can be obtained from:

$$a_V = \frac{6\phi}{d_{32}} \tag{9}$$

where d_{32} can be calculated from the equations given previously, at least for non- and weakly coalescing systems.

MASS TRANSFER COEFFICIENT IN LIQUID–LIQUID DISPERSIONS

In principle, the mass transfer coefficient for a *single* liquid spherical droplet in an immiscible liquid flowing with velocity ν_{LL} past the spherical droplet can be calculated from a Froessling-type equation, which was originally derived for a solid particle (see Atiemo-Obeng, Penney, and Armenante.[20]):

$$\mathrm{Sh_{LL}} = 2 + 0.6\mathrm{Re_{LL}^{0.5}Sc^{0.33}} \tag{10}$$

In this equation, the liquid–liquid Sherwood number for a single sphere, $\mathrm{Sh_{LL}} = k_{LL}d_{32}/D_L$, is a function of the liquid–liquid Reynolds number, $\mathrm{Re_{LL}} = \rho_L\nu_{LL}d_{32}/\mu$ and Schmidt number, $\mathrm{Sc} = \mu/(\rho_L D_L)$. This equation is of limited use in mixing vessels where the droplet-liquid slip velocity, ν_{LL}, cannot be determined. Instead, the liquid–liquid mass transfer coefficient can be obtained from empirical equations such as (see Skelland and Xien[29]; Skelland and Moeti[30]):

$$\frac{k_L\, d_{32}}{D_L} = 1.237 \times 10^{-5}\, \mathrm{Sc}_c^{1/3}\, \mathrm{Re}^{2/3} \times \mathrm{Fr}^{5/12}\left(\frac{D}{d_{32}}\right)^2\left(\frac{d_{32}}{T}\right)^{1/2}\left(\frac{\rho_d d_{32}^2 g}{\sigma}\right)^{5/4}\phi^{-1/2} \tag{11}$$

The generic equation for the mass transfer rate is:

$$\dot{m} = k_L a_V V_L \Delta C \tag{12}$$

where ΔC is the concentration driving force across the phases. This equation shows that knowledge of a_V [through Eq. (9)] and k_L [through Eq. (11)] is needed to calculate the mass transfer rate. In general, V_L can be taken as the entire volume of the dispersion, provided that the agitation intensity is well beyond N_{min}.

CONCLUSIONS

Apart from certain formulated products, such as emulsions, liquid–liquid dispersion is rarely carried out for its own sake. It is usually accompanied by heat/mass transfer and chemical reaction, thereby complicating scale-up. Mass transfer and heat transfer are significantly affected by mixing. Hence, mixing is a critical element in the analysis of any liquid–liquid reactor system. The material presented in this entry serves to demonstrate that fundamental knowledge must be coupled with practical insight and engineering judgment to solve problems associated with real industrial liquid–liquid applications.

NOMENCLATURE

A	Interfacial area between phases, m^2
a_V	Interfacial area per unit volume of liquid, m^2/m^3
B	Baffle width, m
C	Impeller clearance measured from the impeller centerline to the vessel bottom off the vessel bottom, m
C_1,C_2,C_3,C_4	Dimensionless empirical constants
ΔC	Concentration driving force for mass transfer, mol/m^3
d_{32}	Sauter mean drop diameter $\left(=\sum_{i=1}^{i=m} n_i d_i^3 / \sum_{i=1}^{i=m} n_i d_i^2\right)$, m
d_{max}	Maximum stable drop diameter, m
D	Impeller diameter, m
D_L	Diffusivity of dissolved component or reactant in liquid, m^2/s
g	Gravitational acceleration, m/s^2
H	Height of liquid in vessel, m
k_L	Mass transfer coefficient, m/s
k_{LL}	Mass transfer coefficient for a single spherical droplet immersed in a liquid flowing at constant velocity past the droplet, m/s
m_L	Mass of liquid, kg
$\dot{m}$	Rate of mass transfer of solute or reactant, kg/s
N	Impeller speed, rotations/s
N_{js}	Minimum speed to just suspend solid particles in vessel, rotations/s
N_{min}	Minimum impeller speed to completely incorporate dispersed phase into continuous phase in liquid–liquid systems, rotations/s
P	Power dissipation, W
t	Time, s
T	Vessel diameter, m
V_{LL}	Liquid velocity past an immiscible liquid droplet (slip velocity), m/s
V_L	Volume of liquid in vessel, m^3
W	Width of an impeller blade, m

Greek Symbols

ε_{avg}	Average energy dissipation rate (or power draw) per mass of mixture, W/kg
ε_{max}	Maximum energy dissipation rate (or power draw) per mass of mixture, W/kg
ϕ	Volume fraction of dispersed phase, i.e., ratio of the volume of dispersed phase to the volume of dispersed and continuous phases
μ	Viscosity, Pa s
μ_c	Viscosity of continuous phase, Pa s
μ_d	Viscosity of dispersed phase, Pa s

ν	Kinematic viscosity, m^2/s
ρ_L	Density of liquid, kg/m^3
ρ_c	Density of continuous phase, kg/m^3
ρ_d	Density of dispersed phase, kg/m^3
$\bar{\rho}$	Average density of mixture, kg/m^3
$\Delta\rho$	Density difference between phases, kg/m^3
σ	Interfacial tension, N/m

Dimensionless Groups

N_p	Power number, $P/(\bar{\rho}N^3D^5)$
Re	Impeller Reynolds number, $\bar{\rho}ND^2/\mu$
Re_{LL}	Liquid–liquid Reynolds number, $\rho_L V_{LL} d_{32}/\mu$
Sc	Schmidt number, $\mu/(\rho_L D_L)$
Sc_c	Schmidt number for the continuous phase, $\mu_c/(\rho_c D_L)$
Sh_{LL}	Sherwood number for a single droplet, $k_{LL}d_{32}/D_L$
Vi	Viscosity number, $(\rho_c/\rho_d)^{1/2}\mu_d ND/\sigma$
We	Weber number for droplets in stirred vessel, $\rho_c N^2 D^3/\sigma$

Lithium–Ion Battery

Chung-Chiun Liu
Xuekun Xing
Electronics Design Center and Department of Chemical Engineering, Case Western Reserve University, Cleveland, Ohio, U.S.A.

INTRODUCTION

The lithium-ion (Li-ion) battery is a large-scale-commercialized rechargeable battery system of the highest energy density to date. Sony introduced the first commercial Li-ion battery in the market in 1991. Following continuous improvement in battery performance, a rapid growth in production volume of this battery has continued unabated. The production volume of various Li-ion batteries approaches about 740 million units with a total revenue of about U.S. $2.4 billion worldwide in 2002.[1] In addition to its high energy density and specific energy, the Li-ion cell has a number of other advantages, such as long cycle life, wide operational temperatures, and reasonable rate performance. All these advantages make Li-ion batteries an attractive power source for many applications, especially for various portable electronic devices such as cellular phones, notebook PCs, PDAs, digital cameras, and audio–video systems. In some traditional applications, the Li-ion batteries will replace the nickel–cadmium (Ni–Cd) and nickel–metal hydride (Ni–MH) batteries, and this trend is expected to continue in the future.

The Li-ion cell has several marked characteristics that differentiate it from most of the other rechargeable cell systems. First of all, the Li-ion cell is a ''high-operation-voltage'' system with an average operation voltage of 3.6–3.7 V, which is about three times that of Ni–Cd or Ni–MH cells. The higher operation voltage becomes practically possible because of the employment of selected nonaqueous electrolytes, which have a much wider electrochemical window compared with its aqueous counterpart, for which the electrochemical window is governed by the water decomposition reaction. Second, there is no metallic lithium used in the Li-ion cell, which thus avoids the difficulties usually associated with the formation of the lithium dendrites on the metallic Li anode during charge–discharge cycles. Third, the cell reaction of the Li-ion cell is not a traditional redox reaction but rather an intercalation/deintercalation process of Li-ions in the anode- and the cathode-active materials, respectively.

Although the commercial Li-ion batteries have been marketed for just about 11 yr, the basic concept and research work related to the development of the Li-ion cell can be traced back to the early 1970s. Whittingham did pioneer work on the mechanism of the intercalation reaction, and various insertion compounds such as TiS_2, MoS_2, V_6O_{13}, etc. were studied and tested as cathode-active materials in nonaqueous solutions.[2–5] Steele suggested the use of graphite and TiS_2 as electrodes for battery applications in 1973.[6] Goodenough's group studied the properties of various lithiated transition metal oxides (Li_xMO_2, M = Ni, Co, Mn) and proposed to use these compounds as the cathode-active material in the early 1980s.[7–10] In the same period of time, the initial concept of the Li-ion cell with two intercalation electrodes in a nonaqueous solution was proposed and studied by Murphy and coworkers.[11] After intense closed-door research and development work, Sony introduced the first commercial Li-ion cell based on a carbon anode and a $LiCoO_2$ cathode in 1991.

CELL COMPONENTS AND CELL CHEMISTRY

Cathode Material and Cathode Reaction

Layered structural $LiCoO_2$ is the cathode-active material being used for most of the commercial Li-ion batteries today. In 1980 Goodenough et al. introduced this compound for the cathode-active material.[7–10] Fig. 1 shows the typical layered structure of $LiCoO_2$, in which the oxide ions form a cubic-close-packed array with close-packed (111) octahedral-site planes alternately filled with Li^+ and Co^{3+} ions. $LiCoO_2$ has good electronic conductivity mainly contributed by the availability of the holes of large O-2p character. On the other hand, Li^+ ions in the structure are in part movable, that is, Li^+ ions can be reversibly extracted from and reinserted to the $LiCoO_2$ structure, as shown in Eq. (1) below:

$$LiCoO_2 \underset{\text{discharge}}{\overset{\text{charge}}{\rightleftharpoons}} Li_{1-x}CoO_2 + xli^+ + xe^- \qquad (1)$$

It is worth noting that the reversibility of the reaction (1) is available only in a range of $0 \leq x \leq 0.5$.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007843

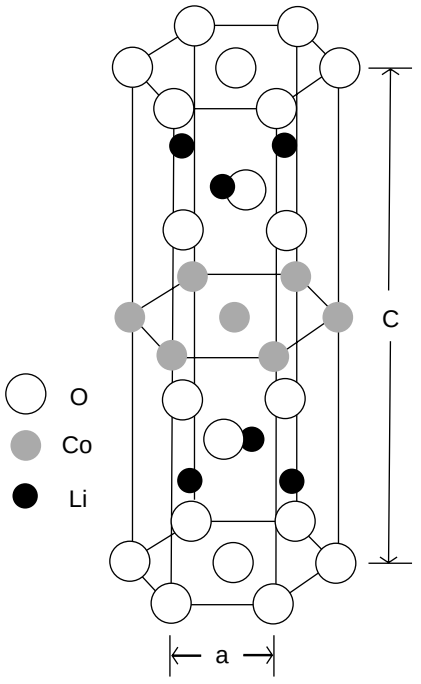

Fig. 1 Schematic diagram of the layered $LiCoO_2$ structure, showing the stacking of the O-Li-O-Co-O-Li-O layers. (From Ref.[10].)

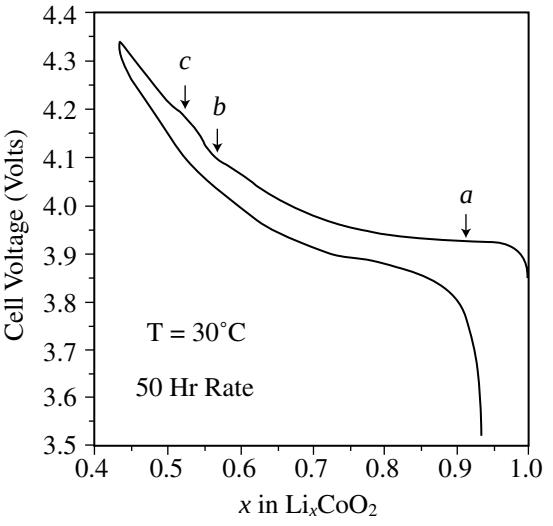

Fig. 2 Cell voltage vs. x in Li_xCoO_2 for the first charge and discharge. (From Ref.[12].)

In the case of $x > 0.5$, oxygen evaluation may take place and the crystal structure may be damaged accordingly.

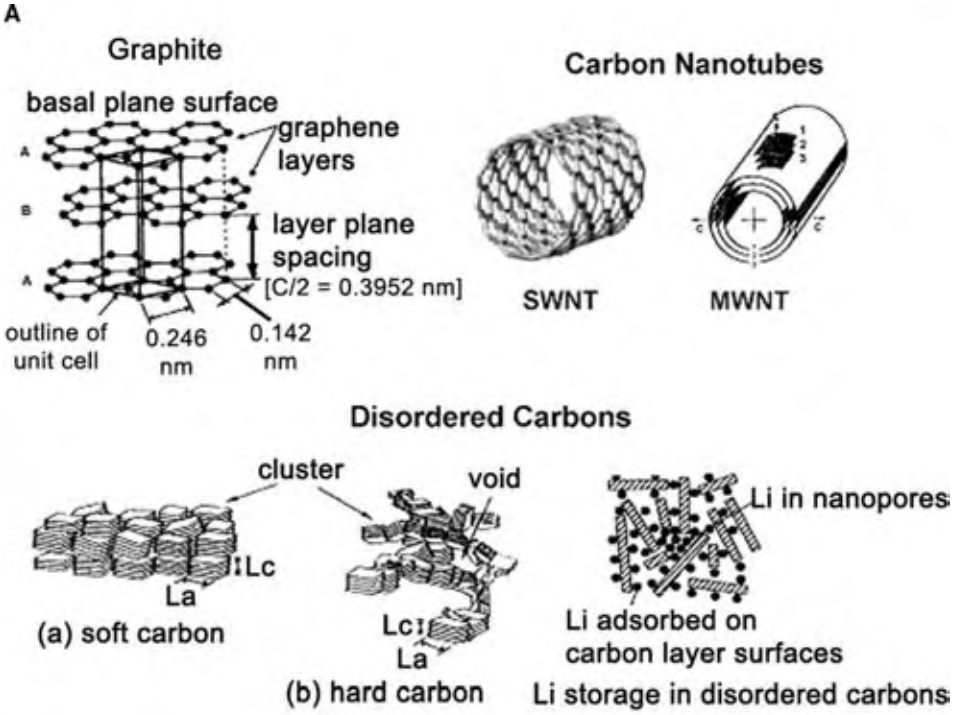
Fig. 2 shows the voltage-composition curve associated with Eq. (1). The three plateaus marked by arrows indicate the occurrence of three distinct phase transitions as x varies from 1 to 0.4 in Li_xCoO_2 during the deintercalation of lithium.[12] The limitation of $x = 0.5$ implies that the reversible specific capacity of $LiCoO_2$ is 137 mA hr/g. As shown in Fig. 2, within the limitation of the compositions, the voltage accompanied with the Li^+ intercalation/deintercalation process is around 4 V (vs. Li), which is much higher than what is shown by cathode materials in all aqueous batteries, and that leads to a much higher energy density of the Li-ion cell.

Anode Material and Anode Reaction

To date, all commercial Li-ion batteries use carbonaceous materials as the anode-active material. Fig. 3A shows the structural schematics of typical carbonaceous materials in the field. Among various carbonaceous materials, graphite and disordered carbons have been employed dominantly in Li-ion batteries.[13] Graphite has a typical layered structure that consists of stacked graphene sheets with an ABAB ... sequence along the C-axis as shown in Fig. 3A. The graphene sheets are bonded together by van der Waals forces with an intersheet gap of about 0.3354 nm, which provides a space and functions as a host for enabling the Li ion intercalation to take place. It has been found that the Li ion intercalation/deintercalation in/out graphite structure during charge/discharge processes is reversible, and the reaction scheme can be described as follows:

$$6C + xLi^+ + xe^- \underset{\text{discharge}}{\overset{\text{charge}}{\rightleftharpoons}} Li_xC_6 \qquad (2)$$

The relationship between the potential and the specific capacity (equivalently, the amount of Li-ions intercalated into the anode) of the graphite anode is shown in Fig. 3B. From Eq. (2), a theoretical specific capacity (372 mA hr/g at $x = 1$) of the graphite can be derived. One important characteristic of the Li-ion intercalation/deintercalation reaction in graphite is that the reaction takes place at potentials close to the metallic lithium potential in the given electrolytes (see Fig. 3B). This characteristic makes graphite act as an anode having an operational voltage similar to that of the metallic lithium while avoiding any cycling difficulty associated with the latter because of the formation of lithium dendrites in the cell charging process. The good reversibility and unique potential characteristics make graphite a good substitute for the metallic lithium and an ideal anode material for Li-ion cells that can provide both good charge/discharge cycle life and high energy density.



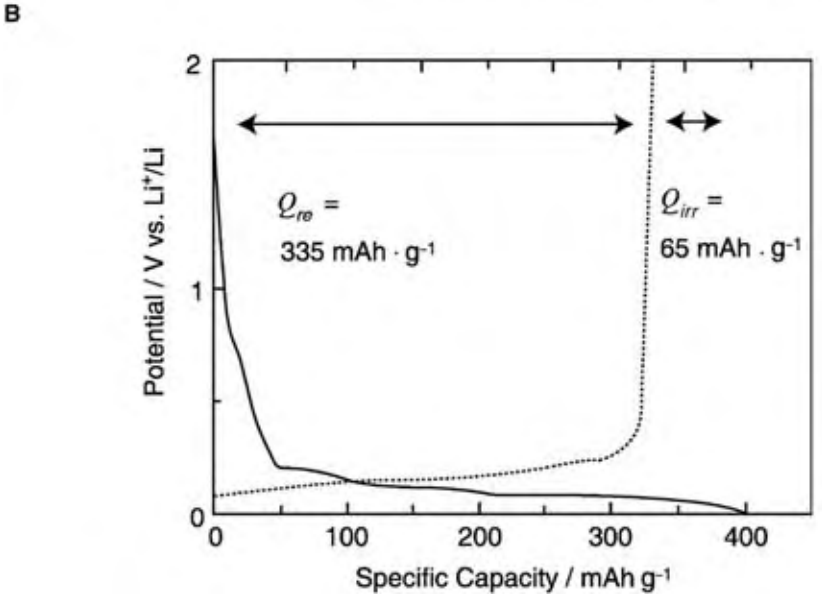


Fig. 3 (A) Schematic of structures of various types of carbons that can insert lithium reversibly. (B) Charge and discharge characteristics of natural graphite powder (NG-7) at the first cycle in the 1 M $LiClO_4$/EC + DEC (1 : 1 vol/vol). (From Ref.[17].)

The mechanism of lithium electrochemical intercalation into graphite has been substantially studied. The intercalation process is characterized by the staging phenomena and the lithium–graphite intercalation compounds have a staging structure. This means that the lithium intercalate layers undergo a successive distribution of stages with respect to graphite host layers following the progress of the intercalation, as schematically shown in Fig. 4. The stage structure changes from a higher to a lower stage during the charge (lithium intercalation), and an opposite order is followed during discharge (lithium deintercalation).

There is always some irreversible capacity loss during the first charge/discharge steps (Li intercalation/deintercalation) of a Li-ion cell. The irreversible capacity loss is attributed to the formation of a solid electrolyte interface (SEI) layer on the graphite surface at the initial stage of the lithium intercalation process.[14] The formation of the SEI layer is crucial to maintain the stability of a graphite anode for the long-term charge/discharge cycles.

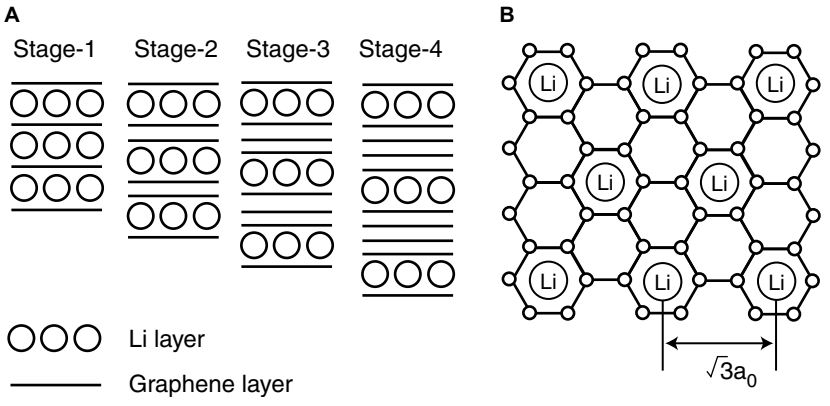

Fig. 4 Schematic of stage structures of lithium intercalation in graphite: (A) stage structures of Li-GICs and (B) in-phase structure of stage-1 LiGIC. (From Ref.[13].)

Overall Cell Reaction

The overall cell reaction of the Li-ion cell can thus be described as follows:

$$6C + LiCoO_2 \underset{\text{discharge}}{\overset{\text{charge}}{\rightleftharpoons}} Li_xC_6 + Li_{1-x}CoO_2 \qquad (3)$$

This cell reaction is the base of the high average operational voltage of 3.6–3.7 V for the Li-ion cell, which is substantially higher than any other available rechargeable battery systems.

Electrolyte and SEI Layer

The Li-ion cell uses a nonaqueous electrolyte as the ionic-conductive medium that consists of a Li salt and a combination of two or more organic solvents. The majority of commercially available Li-ion batteries use a mixture of solvents consisting of a cyclic alkylene carbonate [typically, ethylene carbonate (EC) and propylene carbonate (PC)]; and a linear alkyl carbonate [such as diethyl carbonate (DEC), dimethyl carbonate (DMC), and ethyl methyl carbonate (EMC)]. Two properties, among others, of the solvent are crucial to its application to a Li-ion cell. The first one is its electrochemical window, which should be sufficient to meet the requirement of the high operation voltage of a Li-ion cell. The second one is the ionic conductivity of the electrolyte, which should be large enough to meet the requirement of the rate capability of a Li-ion cell. The electrochemical window of a solvent can be determined from its oxidation potential and its reduction potential. Generally, organic solvents undergo oxidation at its oxidation potential with CO_2 and other small organic compounds as the oxidation products. On the other hand, organic solvents undergo reduction if the potential is low enough to approach its reduction potential. A comprehensive summary on the liquid electrolytes used in Li-ion cells has been presented recently.[15]

The solvent reduction takes place usually at the anode, and it is closely related to the formation of the SEI film on the surface of the anode. The SEI film is an electronic insulator but an ionic conductor, which covers the active surface of the anode and functions as a passivation layer to stabilize the anode-active material (e.g., blocking the solvent cointercalation into the anode-active material) for sustaining a long-term charge–discharge cycle life. The mechanism of the SEI formation at the anode has been studied in depth in recent years. It has been generally agreed that the SEI formation results from complex reactions involving solvents, salt, atmospheric impurities (e.g., O_2, N_2, CO_2, H_2O), and additives, if any.[16] It has been established that $(CH_2CO_2Li)_2$ is a major surface species formed on carbon electrodes for EC-based electrolytes. Usually, the SEI films involve other reaction products such as LiF, Li_2CO_3, Li_2O, LiOH, etc. Aurbach has provided a comprehensive summary for the formation and the composition of the SEI films in various electrolytes.[17] The SEI film formation and its properties (e.g., its adhesive property on the carbon surface, its forming potential and film smoothness, etc.) are crucial to maintain the long-term stability of graphite electrodes in Li insertion/deinsertion processes. The quality of the SEI film is dependent on many factors including solvents, salts, impurities, polarization current, and additives, and the latter has especially attracted substantial effort in recent years (see the following section).

Electrolyte Additives and Functional Electrolytes

The first major effort to bring additives into the electrolytes of a Li-ion cell is driven by overcoming the problems of PC-based electrolytes, which fail when used for the Li-ion cells with a graphite anode (large irreversible capacity loss at the first charge–discharge step, and poor charge–discharge cycle life).

One argument is to relate this failure to the co-intercalate of the PC solvent molecules into the graphite structure together with the solvated Li-ions.[18,19] This co-intercalation process may lead to an exfoliation of the graphite structure. In addition, co-intercalated PC molecules may undergo reduction within the graphite and its reduction products could block Li-ion to enter into the graphite lattice. As a result of these effects, the battery cycle life is adversely affected. Aurbach and coworkers have proposed a different mechanism, and they attribute the failure of the graphite electrode in the PC-based electrolytes to the failure in forming a smooth, cohesive SEI layer on the graphite surface mainly because of the structure hindrance caused by the methyl group on PC molecules.[17,20] Furthermore, the formation of propylene gas during PC reduction could cause higher internal pressure within graphite crevices and split the particles, which could result in the loss of electrical contact with the current collector because of isolation by surface films.

It has been found that the addition of some cyclic ethers, such as 12-crown-chromium-4 (12Cr4), to PC-based electrolytes can significantly improve the reversibility of a graphite electrode.[21,22] Crown ether is a strong complex agent for Li-ions, and the preferential formation of the Li^+–crown ether complexes shields PC out when the Li ions approach the electrode.

Separator

Similar to other battery systems, the Li-ion cell needs a separator to electronically separate its cathode and anode to avoid any electrical short circuit between them, while keeping a good ionic pathway through the electrolyte absorbed in the pore structure of the separator. An adequate separator material needs to meet the following requirements among others: 1) a good electronic insulator; 2) a high degree of porous structure that is able to absorb a sufficient quantity of the electrolyte ensuring a good ionic conductance; 3) a good chemical resistance to the electrolyte and good electrochemical stability in the cell operation conditions; 4) an adequate mechanical and physical strength; and 5) a good wettability to the electrolyte used. To date, the most commonly used separator materials for Li-ion cells are single-layer porous polyethylene (PE) and polypropylene/polyethylene/polypropylene multiple-layer (PP/PE/PP) films (Celgard type). These separators have a thermal shutdown function. The PE porous film will melt down partly when the temperature approaches its melting point (typically 130–140°C). This partial melt-down process leads to pore closing while maintaining the film integrity, which results in maximizing the internal resistance of the cell while minimizing the current and thus avoiding continuous increase in the cell temperature. This function is especially important to protect a Li-ion cell from overcharge and short circuit, because any abnormal current can be automatically cut off because of the rapid increase in the cell resistance.

Li-Ion Cell Construction

The first generation of the Li-ion battery manufactured by Sony is a cylindrical structure, and it is known as model 18650 (cell diameter: 18 mm, cell height: 65 mm). This cell has been manufactured on a very large scale and is widely employed in notebook PCs and other electronic devices. With the rapid growth of cellular phones, PDA, and other thin, light, portable electronic devices, a large portion of Li-ion batteries are being produced with a thin prismatic configuration to meet the market needs. A prismatic cell usually has a rectangular and/or square-shaped metal case (stainless steel or aluminum) and, to some extent, a porch envelope made of aluminum/polymer laminate. This laminate, which is initially employed for a Li-ion polymer (LiP) battery and has been extended to the so-called advanced Li-ion batteries, has a lighter weight and thus improves the cell's specific energy.

Both the cylindrical and the prismatic cells use a wound core structure that is usually referred to as a "jelly-roll." Fig. 5 shows the typical structure of a cylindrical Li-ion cell.[23] Prior to making the jelly-rolls, the anode and cathode films will first be prepared by coating the corresponding slurry consisting of selected active material, conductive material, binder, and solvent on the thin metal strips (copper foil for the anode, aluminum foil for the cathode, respectively), followed by drying, calendaring, and slitting operations. Then, an anode strip, a cathode strip, and the separator strips with adequate length, width, and thickness are combined together and wound into a tight coil, jelly-roll, via a winding machine. It is crucial to maintain close contact without a void or gap between electrodes and separators to ensure good performance of the Li-ion cells fabricated. The coil fabricated is then inserted into a metal casing of adequate dimension and shape, which functions not only as a container to house the electrodes and the electrolyte, but also to provide a hermetical seal from the atmosphere. This container also provides constant internal pressure to further closely hold the electrodes and the separators together. After a thorough vacuum-heat drying to remove any water inside the container, the casing with the jelly-roll is then filled with a selected electrolyte solution of adequate quantity. The electrolyte filling process is usually carried out with a precision pump under vacuum conditions, and it is operated in a dry-room or a dry-box to

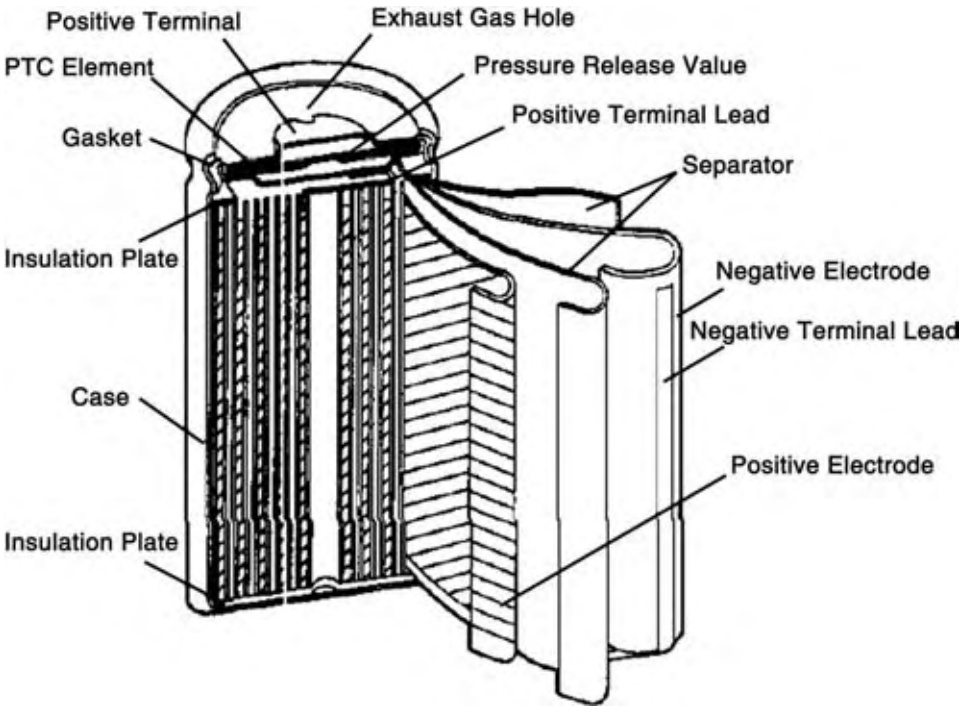

Fig. 5 Typical structure of the cylindrical Li-ion battery. (From Ref.[23].)

minimize moisture absorption. The final step in this assembly is to seal the cell casing by a controlled compression of a polymer gasket located between the cell casing and the casing cap. The sealed cell can then enter a first charging step, namely, the cell formation process.

LI-ION CELL PERFORMANCE CHARACTERISTICS

Charge Characteristics

The most common charging mode of Li-ion cells is the ''constant-current/constant-voltage'' (CCCV) method, by which the cell is charged first at a selected constant current (e.g., $c/2$, $1c$, or others); once the cell voltage approaches a predetermined value (typically, 4.1–4.2 V), the charging continues at this constant voltage until the charging current decreases to a predetermined cutoff value (e.g., $c/20$ or so). Fig. 6 shows a typical charge voltage–current-capacity profile of a cylindrical 18650 Li-ion cell. Unlike Ni–Cd cells, Li-ion cells usually have a near-100% charging efficiency at normal conditions; overcharging is not necessary and actually should be avoided. The charging voltage at the constant-voltage stage is crucial to ensure good performance of Li-ion cells. If the charging voltage is too low, the cell design capacity may not be fully used because of a lesser amount of Li extracted from the cathode at a lower cell-charging voltage. On the other hand, if the charging voltage is too high, it may cause structure damage of the cathode-active material because of overextracting Li. Besides, it may also cause metallic lithium deposition at the surface of the anode because of excess lithium over the intercalation capacity of the anode. All these may adversely impact the battery cycle life and may also induce safety concerns.

Discharge Characteristics

Li-ion cells can be discharged under different modes depending on the needs of the user. Constant current discharge is one of the most commonly used, by which the Li-ion cell undergoes discharge at a wide range of selected currents depending on the applications. The pulse current discharge [such as Global System for Mobile Communication (GSM) operation mode for cellular phones, etc.] is another mode widely employed in the mobile phone applications. The constant-power discharge is typically used in notebook PCs. Fig. 7 shows the typical voltage–current curves under two constant-power conditions for cylindrical 18650 cells. The cutoff voltage of discharge is usually in the range of 2.7–3.0 V. A lower cutoff voltage may shorten the cycle life of the cell because of the possible oxidation of the copper anode current collector.

Energy Density and Specific Energy

Li-ion batteries belong to the high-energy battery systems and have a substantially higher energy density and specific energy compared to other rechargeable

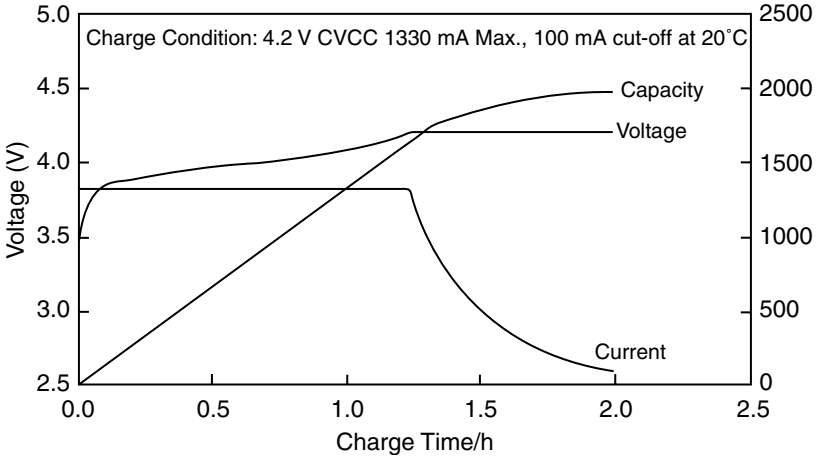

Fig. 6 Charge profile (current, voltage, and capacity) of Panasonic's CGR 18650A Li-ion battery (standard capacity: 2000 mA hr). (From Ref.[23].)

batteries such as lead–acid, Ni–Cd, Ni–MH, etc. The energy density of Li-ion batteries is related to the battery size, and it increases with increasing battery size. Typically, a single Li-ion cell of small to medium size used for normal cellular phone applications has an energy density approximately 350 W hr/L and a specific energy of about 170 W hr/kg, which are significantly higher than those of a lead–acid and a Ni–Cd battery.

Rate Capability

Li-ion batteries have a reasonable rate capability, which can meet the power requirement of various portable electronic devices. On the other hand, because Li-ion cells use nonaqueous electrolyte and the cell reaction involves a Li-ion solid diffusion process, its overall rate capability and power density/specific

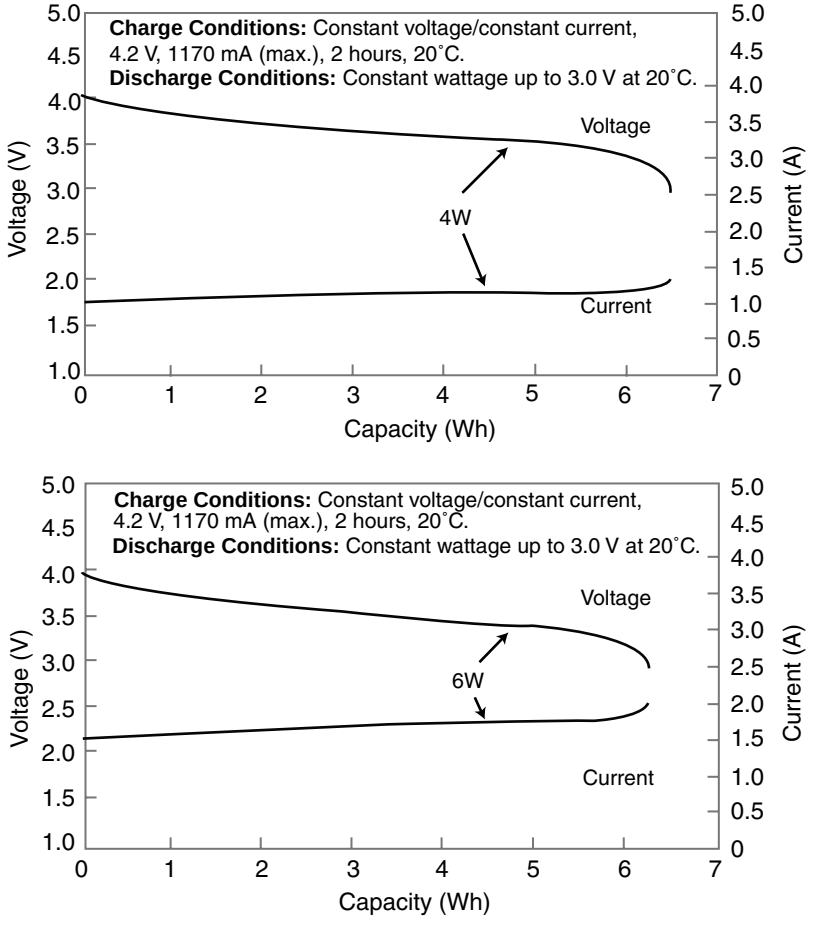

Fig. 7 Voltage–current profile at constant power discharge of Panasonic cylindrical CGR18650HG Li-ion batteries (standard capacity: 1800 mA hr). (From Ref.[23].) *(View this art in color at www.dekker.com.)*

power are lower than for its aqueous counterparts such as lead–acid and Ni–Cd cells. Fig. 8 shows the typical discharge curves of a prismatic 533048 Li-ion cell at various drain rates at room temperature. The rate capability of Li-ion batteries can be improved through cell design such as reducing the electrode thickness, selecting adequate separators and electrolytes, and others.

Cycle Life

Li-ion batteries are known to have a long charge–discharge cycle life because the cell reactions do not involve large structural changes of active materials at both the anode and the cathode. At the normal charge/discharge conditions, a Li-ion battery can be cycled at 100% the depth of discharge (DOD) over 500 cycles, still remaining over 80% of the initial capacity. Fig. 9 shows the typical charging–discharging cycle performance of a prismatic 633450 Li-ion cell. Cell cycle life is strongly dependent on the cell design, the active materials, the electrolyte, and others. Manufacturing conditions, such as electrode coating quality, battery casing sealing quality, moisture control, etc., also play an important role in the impacting of the cycle life of a cell.

Storage Life and Self-Discharge

In addition to its long cycle life, Li-ion batteries have a low self-discharge rate and a long storage life as well. Figs. 10A and 10B show the typical storage performance of Li-ion cells. Another advantage of Li-ion batteries, compared to Ni–Cd batteries, is its lack of memory effect. Although a Li-ion cell can be stored at various states of charge (SOC), it is recommended to store it at a half-charged state, because a fully charged state may promote oxidative side reactions associated with the electrolyte, while a fully discharged state may lead to a possible copper oxidation. During long-term storage, Li-ion cells are expected to lose a portion of their original capacity because of the self-discharge. Although the major portion of this capacity loss can be restored after a few charging–discharging cycles (see Fig. 10B), there is always a portion of the capacity loss that cannot be totally recovered because

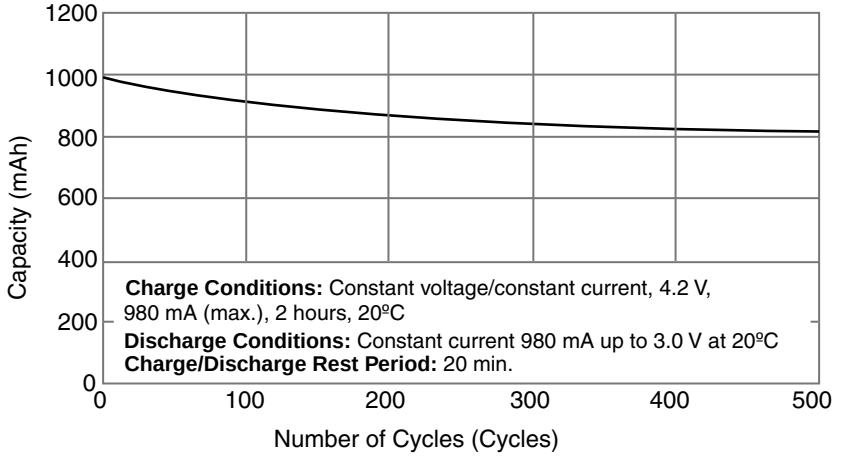

Fig. 9 Cycle life characteristics of Panasonic CGA633450A Li-ion batteries (standard capacity: 1035 mA hr). (From Ref.[23].)

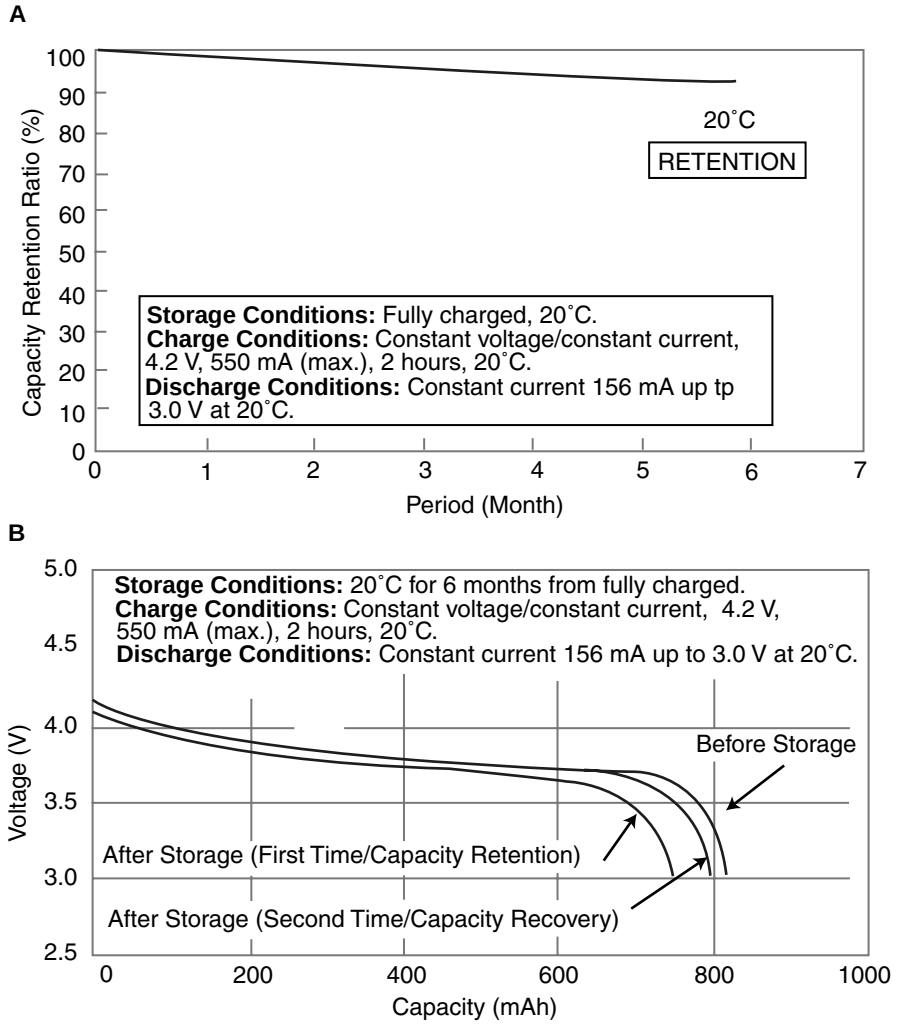

Fig. 10 Storage characteristics of Panasonic CGR17500 cylindrical batteries (standard capacity: 830 mA hr). (From Ref.[23].) *(View this art in color at www.dekker.com.)*

of the side reactions taking place during the storage. The time length of the storage and, more importantly, the temperature of the storage determine this ''irreversible capacity loss.''

Temperature Effect on Discharge and on Self-Discharge and Storage Life

Li-ion batteries can be discharged over a wide temperature range, typically −20°C to 60°C. The discharge capacity decreases with decreasing temperature, as shown in Fig. 11. The battery performance at low temperatures is to a large extent determined by the electrolyte employed. Some batteries are designed for applications at extremely low temperatures (e.g.,−40°C or lower), which require specially designed electrolytes to meet the requirements of the application.

The self-discharge rate of a Li-ion battery is usually lower compared to those of other rechargeable batteries. The capacity loss during storage is largely dependent on the storage temperature as well as the length of the storage time. A noticeably higher self-discharge rate is observed at an elevated temperature. It should be mentioned that the self-discharge rate is also impacted by the SOC of the battery, and the battery at the fully charged state usually shows the highest self-discharge rate.

Safety Issues Related to Li-Ion Batteries

Li-ion batteries use flammable organic electrolytes and work at a voltage range significantly higher than that of other aqueous rechargeable batteries, and safety becomes an important issue in their applications. Various inadequate operations such as overcharge, overdischarge, hard short circuit, abnormal high-temperature environment, impact, and others may cause the battery to catch fire or smoke. There are several industrial standards of safety tests for Li-ion batteries, such as Underwriter Laboratory (UL) 1640, International Electrical Committee (IEC), and others, which regulate Li-ion battery safety requirements.

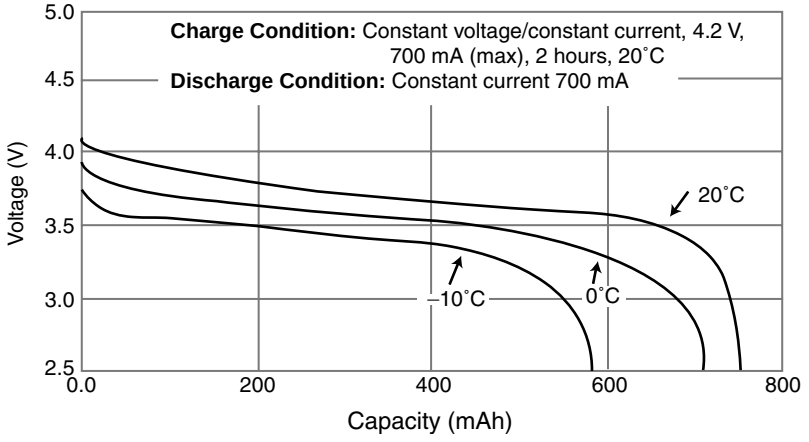

Fig. 11 Discharge characteristics at various temperatures of Panasonic CGA533048 batteries (nominal capacity: 750 mA hr). (From Ref.[23].)

These standards have been widely used by the Li-ion battery manufacturers and users to evaluate the battery safety characteristics to ensure battery safety in applications. Various safety devices including thermal control devices such as the positive temperature coefficient switches and electronic control devices such as various IC protection circuits have been successfully used for Li-ion batteries and battery packs. With an adequate combination of various safety devices, one can protect a Li-ion battery from overcharge, overdischarge, hard short circuit, impact, and other safety concerns throughout its applications.

Li-Ion Polymer Batteries

Commercial Li-ion batteries use liquid nonaqueous electrolytes. One of the new developments is to use a polymer electrolyte. The use of a polymer electrolyte provides several advantages over its liquid counterpart, such as avoiding any electrolyte leakage, making thin format batteries, implanting lightweight metal–plastic laminates as battery package material, etc. The most practical systems of LiP batteries to date are those with ''gelled polymer electrolyte.'' The gelled polymer electrolyte usually consists of a polymer matrix and a certain amount of liquid electrolyte absorbed in the polymer network. In general, there is no visible free liquid electrolyte in the gelled polymer electrolyte. Based on the type of polymers commonly used for the polymer matrix, the gelled polymer electrolytes can be categorized as polyethylene oxide (PEO) based, poly(vinylidene fluoride) /hexafluoropropylene (PVDF/HFP) based, poly(acrylonitrile) (PAN) based, and others. The PEO-based gelled polymer electrolyte received first attention in the development of the rechargeable batteries with metallic Li as the anode. This attention was then extended to other gelled polymers such as PAN, poly(methylmetacrylate), and PVDF. A common characteristic of these gelled polymer electrolytes is the direct trapping of the liquid electrolyte in the polymer network forming a gel-type membrane. In general, the gel-type membrane can be prepared by dissolving a selected quantity of a polymer and a Li salt in an adequate solvent or solvent-mixture, followed by homogenization, heat lamination, and other necessary processes. The obtained gel-electrolyte membrane has a conductivity around 10^{-3} S/cm or higher at room temperature.[24]

Recently, this type of gelled electrolyte has undergone various modifications in composition and processing, and has been successfully employed for manufacturing commercial LiP batteries.[25] One of the newer developments is to mix a known quantity of a monomer with a selected liquid electrolyte, which is then injected into a cell container with inserted jelly-roll, followed by polymerization under heating or radiation. The advantage of this type of LiP batteries is that it has basically the same manufacturing process as the liquid Li-ion batteries, in combination with an electrolyte gelling process. This process provides a practical means to manufacture LiP batteries on a large scale.

A different type of gel-electrolyte-based Li-ion batteries has been developed by Bellcore (now Telecordia Technologies).[26] The Bellcore plastic Li-ion battery technology has two major characteristics. First, this technology uses a special porous polymer separator that consists of a PVDF–HFP copolymer matrix mixed with a fine inorganic filler, such as the fumed SiO_2, and a liquid electrolyte (e.g., $LiPF_6$–EC–DMC) thoroughly absorbed in the polymer matrix. The PVDF–HFP copolymer matrix has a porous structure and its porosity is controlled by first adding a plasticizer (e.g., dibutyl phthalate) during the polymer/filler/solvent mixing process, and then extracting the plasticizer from the formed film to form a porous structure in a controlled way. The second major characteristic of the Bellcore technology is that the electrodes (anode and cathode, which both use PVDF–HFP as the binder) and separator are fused together by heat lamination or heat

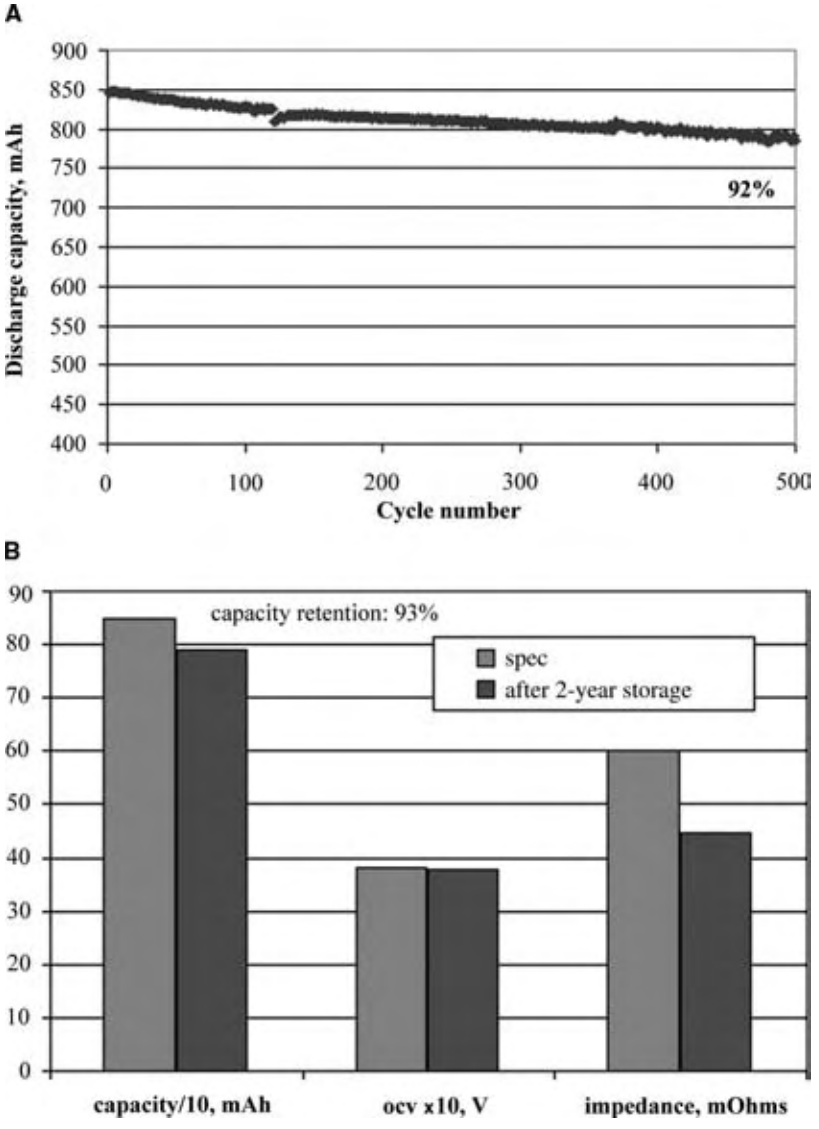

Fig. 12 (A) Cycle characteristics of NTK Powerdex pdx663448 LiP batteries (nominal capacity: 850 mA hr), charge: $c/2$, discharge: GSM, at room temperature. pressing process. This special characteristic makes this technology especially advantageous to batteries with thin format and with stacking structure. Figs. 12A and 12B show the typical charge–discharge cycle performance and the long-term storage performance of the plastic Li-ion batteries based on the Bellcore technology (NTK Powerdex, Inc., unpublished data).

NEW DEVELOPMENTS IN THE LI-ION BATTERY FIELD

Development of New Cathode-Active Materials

Although a very good cathode-active material, $LiCoO_2$ has several disadvantages, such as high cost (due to the limited natural source of the cobalt element), toxicity of cobalt, and limited specific capacity, thermal stability at elevated temperatures, etc. Therefore, considerable efforts have been devoted to the development of new cathode-active materials other than $LiCoO_2$. Among several candidate cathode materials, the layered LiN_iO_2 has a higher specific capacity (e.g., $\sim$180 mA hr/g or higher) and a lower cost, but this material has some issues (such as lower thermal stability at elevated temperatures and the resulting safety concern, and ease of synthesis) that need to be resolved prior to its practical application.[27–29] To overcome these problems various modifications of the compound, such as $LiNi_{1-x}Co_xO_2$, $LiNi_{1-x-y}Co_xM_yO_2$ (M: other metals) and others, are being extensively studied.[30,31] Another promising candidate for the cathode-active material of a Li-ion cell is the Mn-based spinel ($LiMn_2O_4$) and doped-spinel ($Li_{1+x}Mn_{2-x-y}N_yO_4$) compounds.[9,32–36] The main advantages of the spinel compounds are its low cost, nontoxicity, and better safety performance at elevated temperatures. Two of the main problems to be

overcome for the spinel compounds are their relatively poorer cycle life at elevated temperatures and relatively lower specific capacity. Various doped spinel materials have been studied substantially.

Most recently, two new materials have attracted great interest in this development endeavor. One is the layered-structure $LiMn_{2-x}M_xO_2$ (M: other metals, e.g., Ni) compounds, the structure of which is stabilized with the dopant of other metals.[37,38] This group of materials has a higher specific capacity ($\sim$200 mA hr/g) and an operational voltage similar to that of $LiCoO_2$ and they appear to be promising alternates of the cathode-active material, although they are still at a developing stage at this juncture. Another material is the Olivien structured $LiFePO_4$ compound.[39] This material is relatively inexpensive, very stable at elevated temperatures, nontoxic, and has a specific capacity compatible to that of $LiCoO_2$ and an operational voltage about 200 mV lower than that of $LiCoO_2$. One of the major drawbacks of this material is its low electronic conductivity (10^{-8}–10^{-9} S/cm), which significantly impacts the rate capability for the Li-ion batteries with this compound as the cathode-active material. It has been reported that selected dopants can enhance its electronic conductivity by up to 10^8 order of magnitude.[40]

Development of New Anode-Active Material

Carbonaceous materials are widely used in commercial Li-ion batteries. To further improve the battery energy density and reduce the battery cost, the discovery of new anode-active materials with higher specific capacity and lower cost has become a goal in this field. Efforts in this area are mainly devoted to pursuing investigations in two directions: to find and improve the properties of new carbonaceous materials and to develop noncarbonaceous anode-active materials. For the former, several available carbonaceous materials, such as mesocarbon microbeads (MCMB), carbon fibers, are continuously improving in their specific capacity. New anodic materials, such as natural and synthetic graphite of lower cost, have been studied and special carbon materials such as carbon nanotubes are under study and development.[41–43] For the latter, the various alloys, such as silicon-based, tin-based, and intermetallic-based alloys, are of great interest to the field in terms of their feasibility as anode-active materials.[44–47] One of the advantages of the metal alloys as the anode-active material is their high specific capacity (e.g., 600 mA hr/g or more). However, two main drawbacks of these materials must be overcome before their practical usage. One is the large, irreversible capacity loss during the first charging–discharging step. Another is the large volume change induced by the lithium intercalation process, which may result in structure change and damage, and finally hurt the battery cycle life.

Development of Electrolytes

Research on electrolytes has focused on the following two areas: one is the development of new electrolyte additives and the other is the development of new Li salts.

The electrolyte additives can be categorized in three ways. The first additives are film-forming additives such as ethylene sulfite, vinylene carbonate, etc.[48,49] A common property of these additives in the electrolytes is that they are reduced at a relatively higher potential (compared with other alkyl carbonates solvents) on the carbon anode, which promotes formation of a more stable SEI film on the surface of the anode, and thus improves the tolerance of the graphite anode to the PC-based electrolytes and improves the battery performance, such as enhancing the cycle life, reducing the self-discharging rate especially at elevated temperatures. The second type of additives is used to reduce flammability of the electrolyte of Li-ion cells, or to provide nonflammable electrolytes for a Li-ion cell. Several inflammable additives such as trimethyl phosphate and other phosphorus (V) compounds have been studied in depth.[50–52] The third type of additives is used for a special purpose, e.g., as agents to protect battery overcharging.

The development of new Li salts to replace the commonly used $LiPF_6$, which is not stable with water and has low thermal stability at elevated temperatures, continues to draw attention. A newly developed Li salt, lithium bis(oxalato) borate[50,51] shows a number of advantages such as higher thermal stability at elevated temperatures, capability for improving compatibility between the graphite anode and PC-based electrolytes, and lower cost.[53,54]

CONCLUSIONS

As a newly commercialized high-energy battery system developed in the past decade, the Li-ion battery has various advantages over other commercial rechargeable batteries, which can be seen in its increasing number of applications. Continuous improvements in its performance and safety will extend its applications even wider. At present the majority of Li-ion batteries produced are relatively small in size and are focused largely on portable electronic devices applications. Substantial efforts have been made toward the development of Li-ion batteries, battery packs, and modules with larger size, higher power density, and safer performance to meet the requirement of other applications including electric vehicle power sources.

Loss Prevention in Chemical Processing

Joel M. Haight
Pennsylvania State University, University Park, Pennsylvania, U.S.A.

INTRODUCTION

As the chemical process industry evolved and advanced over the last 50 years, it could be said that probably more attention was paid to making the process work than to concerns that might be manifested if it failed. Accidents occur in nearly every facet of our lives. It is no surprise that the chemical process industry has also had its accident difficulties. Some of the watershed incidents that have been the impetus for much loss prevention improvement made over the last 15 years are discussed here. While many in the loss prevention field believe that we should not focus on incidents because they are in the past (and we need to be proactive), much can be learned from these incidents. In fact, it might be said that not only did we learn from these watershed incidents, but they also provided some of the motivation for change in our loss prevention systems. George Washington is credited with saying "We ought not to look back, unless it is to derive useful lessons from past errors, and for the purpose of profiting by dear-bought experience."[1]

BACKGROUND

Some of the historic process incidents are well documented in the literature; however, their impact on today's approaches to loss prevention is so profound that this entry would seem to be lacking if it did not, at least, summarize them. One of the earliest incidents occurred at Nypro Ltd., a caprolactam plant in Flixborough, England, in June 1974. It resulted in 28 fatalities and 89 injuries inside and outside of the plant, and damage to more than 1800 homes and 167 shops and businesses. A deflagration occurred after the failure of a temporary bellows joint and the line between two reactors in a six-reactor series of the operation's cyclohexane oxidation plant. It was installed when one of the reactors was removed for maintenance. When this temporary connection failed, about 35 tons of cyclohexane escaped and subsequently ignited. There were no calculations to determine if this temporary 20 in. line and bellows connection could safely handle the process conditions (120 psig and 145°C) and it failed. This incident highlights the need for a management of change process.[2]

A second incident of note occurred about two years later in Seveso, Italy. Approximately 2 kg of dioxin was released through a reactor's pressure relief valve. It was reported that the operating crew had gone home for the weekend without completing the last step in this batch process, which was to add quench water. Without the water, the unattended reaction continued and the vessel became overpressured. The pressure relief valve did its job and protected the reactor; however, 2 kg of 2,3,7,8-tetrachlorodibenzopara-dioxin was discharged to the atmosphere. Wind carried the contaminant over the countryside where people, animals, and plants were exposed to the dioxin. This incident highlighted the importance of standard operating procedures, training in unknown hazards, and emergency response.[2]

In 1984, one of the most notable process incidents occurred in Bhopal, India, at a plant owned by Union Carbide. On December 3, 1984, methyl isocyanate (MIC) was vented to the atmosphere from a vent gas scrubber after a run away reaction overwhelmed the scrubber. It is reported that more than 2500 people died and 20,000 people were injured as a result of exposure to MIC. The subsequent investigation showed that the run away reaction occurred in the MIC tanks after water was reportedly intentionally added to the tank. The safety systems, a pressure relief valve, a vent gas scrubber, and a flare were reportedly poorly maintained. The relief valve worked to vent the pressure, but the scrubber was overwhelmed, and the flare was down for maintenance. This incident highlighted several loss prevention areas that needed improvement. The first was mechanical integrity. No strong preventive maintenance effort appeared to be in place. The second was emergency preparedness and response. It appears that while the plant was built 1.5 miles away from the community, zoning problems allowed the community to expand to the plant limits. It does not appear that much effort was made to work with the community on communication/notification or evacuation needs.[2]

A fourth incident occurred in 1989 in Pasadena, Texas. An explosion occurred at a high density polyethylene plant, when 85,000 pounds of a flammable mixture of ethylene, isobutene, hexane, and hydrogen was released and ignited. The consequences included 23 fatalities, 314 injuries, and over $715 million in

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007844

capital losses. The investigation showed that a crew, attempting to unplug a settling leg in the polyethylene product take off system, did not follow proper procedures for carrying out the operation safely. This incident highlighted several deficiencies in the system's design, and given that there was no process hazards analysis, they were ignored. Also, the permit-to-work system was ineffective, there were no permanent combustible gas detection devices and alarms available, and building spacing was questionable in terms of both absolute distance and high occupancy (the control room).[3]

There have been several other incidents in the process industry such as an LPG explosion in Mexico City in 1984, a North Sea offshore oil platform explosion in 1988, and a fuel tank rupture in Pittsburgh in 1988. More recently, a 1999 naphtha explosion in California, a 2001 sulfuric acid tank explosion in Delaware, a 2002 hydrogen sulfide leak in Alabama, and a 2003 distillation tower explosion in Ohio all resulting in lower fatality numbers than the earlier incidents.[4]

These incidents have taught us much and, especially, the earlier ones seemed to have provided the motivation for the industry and government to begin to aggressively address the catastrophic loss potential associated with the chemical process industry. They helped spark development of several consensus and regulatory standards that have since become so much a way of life in the chemical process industry.

REGULATORY STANDARDS, CONSENSUS STANDARDS, AND VOLUNTARY PROGRAMS

Much of the impact on loss prevention in the last 12 years has come from the Occupational Safety and Health Administration's Process Safety Management of Highly Hazardous Chemicals regulation (PSM). This regulation, 29 CFR 1910.119, took effect in May 1992 and it was joined in 1996 by the Environmental Protection Agency's Risk Management Program (RMP) (40 CFR Subpart B). These performance standards are similar and had industry input through the former Chemical Manufacturers Association [now American Chemistry Council (ACC)] and the American Petroleum Institute (API), among others. These two standards assist the industry in preventing (and/or minimizing the consequences or likelihood of occurrence) catastrophic incidents like those that occurred in India, U.K., Mexico, Italy, U.S.A., and other countries.[5,6]

The Chemical Safety Board is a relatively recent addition to the loss prevention effort for the U.S. chemical process industry. While it was authorized by the Clean Air Act in 1990, it became operational in January 1998. It is an independent federal agency charged with the mission of preventing industrial chemical accidents. This is done through the accident investigation process: by identifying root causes and issuing recommendations to correct the causes. Their work is well publicized and when they issue an investigation report, it is made available to the public. Through this communication, they promote improvements in the loss prevention effort, and while they are not a regulatory body, their recommendations should be taken seriously.[4]

Several consensus standards and voluntary programs help to support process industry loss prevention efforts. The Responsible Care Program of the ACC helped get companies to address protecting not only their workers, but also their neighbors, their customers, and the rest of the community. This is promoted through practices such as Product Stewardship and Emergency Preparedness and Response. OSHA's Voluntary Protection Program (VPP) promotes the use of a safety management system and employee involvement in the management of safety and loss prevention.[5]

Contributions from consensus and industry organizations to the loss prevention effort are significant. The API developed Recommended Practice 750 Process Hazards Management and Recommended Practice 752 covering facility siting. The American Institute of Chemical Engineers' (AIChE) Center for Chemical Process Safety (CCPS) has developed a complete series of textbooks that address the same major elements of OSHA's PSM standard. They sponsor conferences, publish proceedings, develop and promote seminars, and provide industry with a process safety and loss prevention resource.

REGULATORY AND MANAGEMENT PRACTICES FOR PREVENTING LOSS

While the two main management systems that have driven loss prevention in the process industry are regulations, the way the industry has implemented them since 1992 represents an effective way to manage loss prevention and still comply with the regulations. The regulations are OSHA's PSM and EPA's RMP regulations. While they took effect at different times, they are similar in what they require of industry. Both address many aspects of how business operates. It appears to this author that over the last 12 years, industry representatives have made complying with these regulations more the way business gets done rather than an additional task for the sake of compliance.

OSHA's Process Safety Management of Highly Hazardous Chemicals

The OSHA regulation, 29 CFR 1910.119, addresses 14 elements. Through its list of highly hazardous

chemicals and threshold quantities, it first allows industry to determine if the regulation applies (if they handle a chemical from the list in quantities greater than the threshold quantity). This is determined by following the Applicability section [29 CFR 1910.119 (a)]. This covers many of the process industries as well as other industries, from food to power.[5]

The first major element is *Employee Participation* [29 CFR 1910.119 (c)]. This requires that affected employees (those who could be affected by an incident) not only have access to pertinent Process Safety Management information, but also be allowed to provide input to its development and use. It is expected that affected employees will be trained in the standard's content. Many companies not only welcome employees' input, but also involve them in the development and management of the individual elements. It is expected that all employee participation in PSM implementation will be documented.[5]

The second main element in OSHA's Process Safety Management standard is *Process Safety Information* (PSI) [29 CFR 1910.119 (d)]. This requires the covered operation to produce, maintain, and use information associated with the chemicals used, from raw materials to final products, process technology information such as the process design and batch recipes and covered equipment information. The types of information expected include material safety data sheets (MSDS), piping and instrument diagrams (P&ID), block flow diagrams, relief valve design and sizing information, ventilation system information, data sheets on pumps (pump curve data, etc.), compressors, pressure vessel ratings, and safe operating and design limits for equipment. While there is much information to be covered, space limitation of this entry does not allow complete coverage of PSI. However, the list above should give the reader a general idea of the required information.[5]

Not only must PSI be maintained up-to-date, but it must also be available to employees who work with or on the covered equipment. Many companies use electronic media. Only one copy has to be maintained, and all employees who have access to the organization's computer system should have access to the PSI. In some cases, a real-time electronic P&ID is available in which employees can access a particular piece of equipment on the P&ID and, from there, can access the details of that equipment, such as the MSDS, vessel thickness, the pump curve data, pressure relief valve sizing, design basis, etc. The regulation does not require electronic information; hence hard copies maintained in the control rooms or the supervisor's office are considered acceptable. Irrespective of the format, it still must be maintained up-to-date.[5]

The third major element is *Process Hazards Analysis* (PHA) [29 CFR 1910.119 (e)]. This element requires performing one of several types of analyses to identify process hazards that could lead to a catastrophic incident. The techniques one can use are What if studies, What if Checklists studies, Hazard and Operability (HAZOP) studies, Failure Mode and Effects Analysis (FMEA), and Fault Tree Analysis (FTA), among others. An initial PHA must be performed on the covered process, and it must be revalidated every five years after the initial PHA. In these studies, analysts are expected to identify failure potential, determine the potential consequences of that failure or hazard, identify existing safety systems, determine the risk associated with each hazard, and recommend corrective action if warranted. This corrective action is evaluated by the management team, resolved, and then implemented as deemed necessary. These studies are done by multidisciplinary teams. In each case, one of the representatives on the team must be an expert in the process itself and at least one member (preferably the leader) should be trained in the analytical method used.[5]

The next element is *Operating Procedures* [29 CFR 1910.119 (f)]. This requires that the operation of a covered process be directed by written operating procedures that are accessible to and used by the employees who operate that process. They must be up-to-date and must cover normal operations, start up, emergency shutdown, temporary operations, and start up after a maintenance turnaround. They must cover safe operating limits for the critical process parameters as well as how to prevent the process from operating outside those limits (and what to do if the limits are exceeded). These procedures must be certified annually as accurate and up-to-date, have the input of the operators, and they must be trained in their use.[5]

The *Training* element [29 CFR 1910.119 (g)] requires that anyone expected to operate a covered process must be trained in its safe operation. They must receive initial training when assigned and then receive refresher training at least every three years following initial training. The training must include the use of the Operating Procedure and trainees must show that they have understood the training. Any changes to the process covered by the Management of Change element (discussed later) must be incorporated into the training material, and operators must receive training in these changes.[5]

Contractor Safety programs have been in existence for many years, but the PSM Standard required that the program become formalized and more far-reaching than traditional contractor safety programs. The *Contractors* [29 CFR 1910.119 (h)] element requires that those considering the use of contractors must partially base their selection of a particular contractor on their safety performance. Covered process owners, once they select a contractor, must ensure that not only are the employees of the contractor qualified to do the

work for which they were hired, but also they understand the process and the hazards where they will be working. Owners are also required to regularly audit the performance of their contractors and keep incident records.[5]

If a covered process is started up for the first time or undergoes a maintenance turnaround, it must receive a *Pre-Start up Safety Review* (PSSR) [29 CFR 1910.119 (i)]. This element is most often integrated with the Management of Change element (discussed later) and is intended to help ensure that anytime there is a change to the process, it is reviewed and documented by representatives from appropriate disciplines. During this process, the people performing the PSSR check to ensure that necessary changes to operating procedures have been made and that operators have been trained as needed. The PSSR reviewer checks to ensure that required updates to the PSI have been made, that corrective action recommendations made by a PHA team have been resolved or completed, and that all required design specifications have been followed. These checks are to be made prior to start up, and any noted deficiencies that may jeopardize a safe start up are required to be followed up until resolution and/or implementation.[5]

The *Mechanical Integrity* [29 CFR 1910.119 (j)] element addresses requirements to maintain existing equipment in safe and working order. This requires identification of critical equipment and implementation of inspection, testing, and preventive maintenance programs to ensure that not only was the equipment built properly and to specifications, but also that it is maintained safe throughout its life. The type and frequency of inspections, testing, and preventive maintenance routines are not specified, but one can rely on manufacturer recommendations and internal company expert input to develop and establish these routines. The standard also addresses the need for all employees, whether contract or regular, to be trained to perform the intended maintenance, inspections, and testing. In addition to the maintenance aspect of mechanical integrity, the standard also requires that a quality assurance program be established to ensure that all new and existing equipment, spare parts, lubricants, and other consumable maintenance materials meet required specifications for dimensions, metallurgy or materials of construction, composition, strength, etc. Deficiencies found during inspection and testing routines must be managed.[5]

The *Hot Work Permit* [29 CFR 1910.119 (k)] element addresses a permit-to-work system for hot work in flammable areas and energy isolation for work on covered equipment. This element supports existing regulations, specifically 29 CFR 1910.252, on hot work. Hot work permits are important for any work that increases the risk of contact between a flammable vapor and an ignition source. It is a system in which the permits convey safety-related information (protective equipment requirements, special atmospheric testing, approval signatures, etc.) and involve transmission and posting that forces those involved in the task to, at least, review the permit if not approve and sign it.[5]

A number of incidents in the past occurred because a change made to a covered process was not adequately reviewed for unintended consequences. The case in Flixborough is an example. The element that governs this is *Management of Change* [29 CFR 1910.119 (l)]. This element requires evaluation of each change to be sure that the appropriate type and level of review has been done to ensure that it is safe and will not produce undesired consequences. It also requires that any information that is different after the change is revised and that employees are informed of the change or trained to use the new system. This involves input from many disciplines and extensive coordination by the change coordinator. It applies to changes in equipment, raw materials, intermediates and products, and methods or procedures and can even apply to changes in consumable supplies such as lubricants, gaskets, O-rings, etc.[5]

Even with all PSM elements in place, incidents still occur. When they do, the *Incident Investigation* [29 CFR 1910.119 (m)] element applies. An incident is a catastrophic loss event that occurred (or could have occurred) such as a fire, explosion, or toxic release in which people are injured or killed, and/or equipment, facilities, and/or the community are damaged. An investigation must begin within 48 hr of the incident's occurrence. The investigation must be done by a multidisciplinary team with the appropriate expertise to understand the process involved in the incident. This could involve operators, process and/or design engineers, instrumentation and/or electrical experts, materials experts, safety and/or fire experts, and those familiar with investigation techniques. The team determines the causes and develops recommended corrective actions to ensure that the incident does not recur. The team puts together a report of the findings, conclusions, and recommended corrective actions, along with the details of the incident. This report is to be made available to all employees who may be affected by this or a similar incident, or who may have a vested interest in the outcome of the corrective actions.[5]

Should an incident occur, there may be a need to interact with the outside community. If there is a potential for the incident to impact the community, the *Emergency Preparedness and Response* [29 CFR 1910.119 (n)] element will be important. This element relies on two other sections of the OSHA regulations to define compliance: 29 CFR 1910.38 (Emergency Action Plans) and 29 CFR 1910.120 (Hazardous Waste and Emergency Response). In addition, there

must be provisions in this element of the program for addressing small releases. The basic objective is to help ensure that everyone is prepared in the areas of alarms and alarm notification, actual response to the incident (fire fighters, toxic vapor monitoring specialists, etc.), notification of the community response organizations, evacuation plans and procedures, damage assessment, and clean up after the incident. The program must be written, and training and practice must be carried out for all employees involved in or affected by the emergency. Practice drills should be critiqued to ensure that weaknesses in the response system can be identified and corrected before a real incident occurs.[5]

Once all the elements of the Process Safety Management system are in place and are being implemented, the *Compliance Audit* [29 CFR 1910.119 (o)] element provides a means to evaluate the program's compliance level. Every three years, the program must be audited to ensure that it is being implemented as per the regulation. The audits can be done internally, but some companies hire outside consultants to get the viewpoint of an unbiased expert.[5]

There is also a *Trade Secret* [29 CFR 1910.119 (p)] element to help companies protect competitive advantage due to their chemical formulations. However, while this provision does offer some protection in that regard, the representatives of a covered process must still disclose their PSI for any hazards associated with that process or process materials.[5]

Environmental Protection Agency's Risk Management Program

The Environmental Protection Agency's Risk Management Program (RMP) Regulation (40 CFR Subpart B), which took effect in June 1996, is similar to OSHA's PSM standard. Its intent is also to prevent accidental releases of toxic or flammable materials. One difference is that it is directed at preventing off-site impact on the public, as opposed to OSHA's goal of protecting the on-site worker. The RMP regulation applies to companies using or handling materials from a list similar to OSHA's highly hazardous chemicals list above certain threshold quantities. The major elements of RMP include Hazard Assessment, Prevention Program, Emergency Response Program, and documentation maintained on-site and submitted to federal, state, and local environmental authorities.[3]

The *Hazard Assessment* element is a consequence analysis applied to a worst-case event (entire contents of a covered process released in 10 min. under the worst atmospheric conditions) as well as to an alternative case (generally more likely to occur, but usually with less severe consequences). The *Prevention Program* has 11 of the same elements as the PSM regulation, but differs in that it has no Employee Participation, Contractor Safety, Hot Work Permit, or Trade Secret elements, while the PSM standard does not have a Risk Assessment element found in the RMP regulation. The *Emergency Response Element* includes provisions for notifying, involving, and working with local emergency response organizations. While much of the PSM information can become public information if an incident occurs, it is not routinely and automatically made available to the public. In fact, since September 11, 2001, anyone requesting access to RMP-related information must apply in person and show just cause for accessing a company's RMP-related information. The results of the Hazard Assessments are available on EPA and state environmental agency websites.[3]

Implementation of these two government regulations accounts for much of the loss prevention effort in the chemical process industry. While these are regulatory, they form the basis of the management systems used by much of the industry to manage the catastrophic risk associated with process conditions that may increase the potential for loss of containment. While these management activities are thought to be effective, there are also a number of engineered approaches that are discussed.

ENGINEERING APPROACHES TO LOSS PREVENTION

There are many engineered systems that help to reduce the potential for catastrophic loss of containment. These engineered approaches are generic in nature in that one or more can be found in and applied to or on almost all process industry equipment. These systems or design specifications and practices include, but are not limited to, pressure relief systems and flares, automated control systems including detection and alarm systems, piping and equipment material specifications, purging and ventilation systems, fire suppression systems, explosion venting systems, positive pressure buildings, and equipment layout and siting practices.

Automated Control Systems (Including Detection and Alarms)

Many operations in the process industry are carried out by automated control systems. While technology is increasing and improving every day, automated control systems are not new to this industry. Computers have long been used to control pressures, temperatures, flows, levels, process stream concentrations, etc. and, to a great extent, these automated systems perform the control function more efficiently, effectively, and safely than humans. For this reason, automated

systems are relied upon extensively for their contribution to the loss prevention effort.[7]

These systems are designed to sense when process conditions are going outside safe limits. For example, if during a tank filling operation, the level goes above a specified limit, a level indicator/controller device (usually a float valve) generates a signal (based on the valve's position) that a transmitter then sends to an inlet control valve to close, to an outlet valve to open, to a discharge pump to start, to a charge pump to stop, etc. This prevents a spill. If a Temperature Indicator Controller senses an increased temperature, for example, a signal may be sent to cooling water or quench nitrogen valves prompting them to open and cool the process, thus preventing a runaway reaction. If there is a leak, a detection system measures the concentration of the material in the air and at a prescribed concentration, sends a signal to an alarm enunciator or control room screen alerting operators to the problem. It can also send a signal to a block valve that can isolate the process stream from the leak, minimizing the risk of overexposure to the leaking chemical.[7]

In large plant upsets, there is a possibility that the control operators are besieged with an alarm flood or shower. In one case in the author's experience, an upset was determined to have resulted in approximately 300 alarm signals in 5 min. Operators are unable to address all of these. A management strategy and technique that can help address this problem during an alarm flood and that seems to be gaining popularity is the practice called abnormal situation management (ASM). An ASM system can be built and integrated into a normal process control system. Control system engineers attempt to design these systems to take the actions that an experienced operator would to head off any equipment damage or incident. These systems contain an alarm priority system intended to suppress low priority alarms while the operators acknowledge and address the higher priority alarms. This is intended to reduce the information overload on the operator while still minimizing the risk of catastrophic incident because of an operator addressing a low priority alarm when a critical one gets lost in the flood.[8]

Automated system contribution to loss prevention is high; however, one must understand the limits of this equipment, its power source, its failure mode (open, closed, on, off, etc.), whether an alarm is registered at the point of the upset (possibly in a location where no one would see or hear it), or at a computer screen occupied 24 hr of the day.[7]

Pressure Relief Systems

Many vessels within the process industry operate at pressures above atmospheric pressure. Each vessel is rated for a certain range of pressures. If this pressure is exceeded, the vessel can potentially rupture, releasing its contents to the environment. A typical way to address this increased pressure potential, whether it is from an internal process-driven increase such as a runaway, exothermic reaction, or an external fire, is to install a pressure relief device. These devices are generally used to protect personnel from exposure to the contents of the vessel, minimize loss of product or other material, and/or prevent damage to the equipment.[3] This pressure relief device can be a spring-operated pressure relief valve or a rupture disk. The choice of which to use and when is beyond the scope of this entry; however, Crowl and Louvar[3] provide an excellent summary of the design issues and advantages and disadvantages.

Pressure relief devices must be properly sized (capacity), and discharge location is critical. These devices are generally sized for the most likely pressure increasing event, e.g., external fire or internal process upset such as an uncontrolled exothermic reaction. The engineer must calculate the temperature and pressure increases associated with the event as well as the expected release volume. He or she must also account for pressure drops across the relief device as well as for friction losses in the lines. A decision must also be made about whether to discharge to the atmosphere or to a closed system that includes a scrubber, a flare, or even as simple as a water tank, such as is sometimes used for venting anhydrous ammonia. Some of these design decision issues are addressed in more detail by Crowl and Louvar.[3]

Piping Specifications

Piping is similar to pressure vessels in that it must contain the pressure and the toxic or flammable material. A difference with piping is that the process stream is almost always flowing and this introduces a dynamic load on the system that must be considered when establishing piping specifications. Piping can rupture, corrode through, leak at a weld, leak at a flange or other connection point, and can even leak through its walls (if the molecular size of the process stream is small, e.g. hydrogen). For this reason, piping for each particular application must be designed to meet the stresses to which it will be exposed. This is most often done through the use of piping specifications. These specifications usually include an identifying number, a description of the safe range of process stream contents and conditions (maximum and minimum temperatures, maximum and minimum pressures, flow rates, etc.), and materials of construction (to minimize the risk of corrosion attack). It also contains information about required wall thickness, type, material and

size of gaskets, O-rings and fittings, and pipe joining technique, e.g., butt welded or flanged. The specifications also provide information about the types of valves to be used and any other types of connections or appurtenances (thermowells or injection points, etc.). All of these requirements, if adhered to, theoretically will help to prevent loss of containment of toxic and/or flammable materials.[9]

Many piping specifications are partially established by consensus standards such as the American National Standards Institute (ANSI), ANSI B31.3, Chemical Plant and Petroleum Piping Code, the American Petroleum Institute's (API) API 5L Specifications for Lined Pipe, or the National Fire Protection Association's (NFPA) NFPA 30 Flammable and Combustible Liquids Code. These can form the foundation for specifications; however, individual plant operating conditions and history should be considered when establishing piping specifications.[9]

Inerting, Purging, and Ventilation

Often, vessels and other process containers must be opened for inspection or maintenance. The container must be drained and cleaned, but often, residual toxic or flammable vapors can remain. Occasionally, work must be performed in this environment, while the flammable concentrations remain (e.g., some catalysts cannot be water washed or steamed). Because of this, protection methods must be applied to help minimize human exposure, and techniques such as inerting, purging, and ventilating are often used. If all the flammable material cannot be removed, a vessel is inerted with a material such as nitrogen or carbon dioxide to reduce oxygen concentrations to a point where ignition is not possible. If workers are expected to enter these vessels, a confined space entry permitting process must be used and additional attention must be paid to respiratory protection in this oxygen deficient environment. Hot nitrogen purges are sometimes applied to remove heavier hydrocarbons from catalysts or vessel internals. Other general types of purges such as vacuum and pressure purges are used to remove toxic or flammables from a work environment as well. When purging is used, one must decide what to do with the purged material, as it may not be safe to discharge it to the atmosphere. It may need to be routed through a collection medium such as a bag house, electrostatic precipitator, incinerator, or flare system.[3]

General dilution as well as local exhaust ventilation is also used to remove contaminants (toxic or flammable) from a work area. This is done more to protect individuals or small groups of employees than the public. Ventilation systems are sized based on space dimensions, expected contaminant concentration (emergency release or continuous emissions), physical and chemical properties of the contaminant, and extent and time of the occupancy. In each case, similar to purging, ventilation system discharge must be appropriately managed.[10,11]

Explosion Venting and Explosion Proof Equipment

Process operating areas are often designated as explosion proof (XP) or non-XP. An XP designation means that flammable vapors could be present under upset or other intermittent conditions. In these areas, many equipment-related measures must be taken, such as elimination or factory sealing of ignition sources, installing explosion proof housing around electrical equipment (housing can withstand an internal explosion), or installing explosion venting capability. Explosion venting does not prevent an explosion; it only minimizes potential damage by venting the overpressure. This could be in the form of a weak seam welded or riveted panel on a bag house filter or a weak seam weld on a tank roof-to-wall seam. In each case, the panel or roof plate opens to vent the overpressure and protects the rest of the equipment.[3]

When electrically driven equipment is to be operated in an XP and/or an electrically classified area (meaning flammable vapors are, or could be, present), it must be rated to operate in that environment. This means that the ignition source associated with the electricity used to power the equipment must be sealed to prevent the flammable vapors from infiltrating the housing (usually done by the manufacturer). The robustness and the integrity of these seals dictate whether the equipment can be operated in an environment where flammable vapors are always present [National Electric Code (NEC) Class 1 Division 1 area] or where flammable vapors could be present (NEC Class 1 Division 2).

Fire Suppression Systems

If a fire occurs in a process plant, the consequences can be devastating. Therefore, even though the main focus is on preventing fires, some attention must be paid to controlling and suppressing fires as well. There are many types of fire suppression systems in use in the chemical process industries, so decision making is necessary. One must decide between water-based and nonwater-based systems, between automatic and manual systems, or between wet pipe and dry pipe systems. How to make these decisions is beyond the scope of this entry; however, the *National Fire Protection Association's Fire Protection Handbook* and the *Society of Fire Protection Engineers Handbook of Fire*

Protection Engineering offer extensive additional reading in this area. The information available in these two sources is enough to rely upon for designing a fire suppression system.

In general, process plants are protected by the availability of fire hydrants, water monitors, and hose reels. In most cases, a fire will be fought manually by operators and other fire fighters. In some cases, with liquefied petroleum gas vessels, for example, a deluge system is installed over the vessel to help keep the vessel cool in case of a fire for preventing a Boiling Liquid Expanding Vapor Explosion (BLEVE). Sprinkler systems are sometimes found over critical motor-operated isolation valves, in compressor buildings or critical pump rooms. Nonwater-based systems are found in control rooms where computer equipment is located and in records retention areas. Automatic, water-based sprinkler systems are sometimes found in plant office areas.[12,13]

Facility Siting and Equipment Spacing

When conducting a process hazard analysis for an OSHA covered process, one must consider facility siting, also described in the American Petroleum Institute's Recommended Practice 752. It focuses on equipment and building spacing. Facility siting involves consequence analyses to determine the vulnerability zone associated with the extent of the potential damage from toxic vapor clouds, blast overpressure impact, or radiant heat effects. One determines which release scenarios should be considered, then decides on the extent of a vulnerability zone associated with a particular release scenario, and identifies buildings or facilities inside that zone. Once the buildings in the vulnerability zone are identified, one must determine if that building is occupied to the level (number of people hours) reaching unacceptable risk. Once the risk of impact is determined and it is considered unacceptable, a decision is made to remove the building activity to a location farther away from the release source, dismantle the building and build it in a location farther from the release source, pressurize the building, change the process to minimize the likelihood of the release scenario's occurrence, strengthen the blast resistance or vapor tightness of the building, or install a barrier between the source and the occupied building. This is a decision making process based on the extent of the risk and the feasibility of the countermeasures.[2]

Equipment spacing is a practice of determining safe distances between equipment in a process plant. The evaluation and input is most feasibly applied during the design phase and it is based on the expected vapor cloud travel distance, the presence of an ignition source in the equipment and the compatibility between materials handled in each piece of equipment or facility considered. The safest approach is to provide as much distance as possible between individual pieces of equipment; however, this uses more real estate and involves more cost associated with longer piping runs and process inefficiencies. There are trade offs and if one can install rated electrical equipment near a flammable vapor source, this may be less expensive than doubling the distance between them and be just as safe. Proper application of protective spacing principles can lower the risk of fire and explosion.

Other Protective Systems

Other loss prevention systems and devices that should be considered include:

- Static electricity controls—bonding and grounding, relaxation, and increasing process stream conductivity with additives.[3]
- Corrosion prevention—material selection, corrosion inhibition, cathodic protection, galvanic corrosion prevention, and extensive nondestructive and destructive inspection protocols.[9]
- Remote impounding flammable liquids—containment and drainage away from process equipment.

One can consult the references for this entry to learn more about these and other types of protection systems.

CONCLUSIONS

Loss prevention in the chemical process industries has come a long way in the last 15 years. It is now, thanks to regulatory and industry input, a much better managed function than it ever was. The OSHA PSM standard and the EPA RMP have become an integral part of the effort to reduce or prevent catastrophic loss incidents. We have learned much over the last 15 years, and the engineering and management systems approaches to loss prevention have contributed much to the loss prevention effort in the chemical process industries.

Low-Pressure Cascade Arc Torch

Hirotsugu Yasuda
University of Missouri–Columbia, Columbia, Missouri, U.S.A.

INTRODUCTION

Arc discharge is a kind of DC discharge that is characterized by low voltage and high current, which is generated by a pointed small wire (cathode) and surrounding metal surface (anode).[1–7] The cathode and the anode are contained in a small nozzle (arc generator). The luminous gas phase created in the gap between the cathode and the anode is blown out of the arc generator by the flow of the carrier gas, which forms a jet of the luminous gas. The pressure of the carrier gas is generally superatmospheric at the entrance of the arc generator. When the luminous gas is blown into atmospheric pressure, the temperature of the flame is very hot, and the high-pressure arc torch is used as a heat source for cutting metals and welding processes. Cascade arc is the arc that is created by a special mode of arc generation, in which the cathode and the anode are separated by a series of conducting walls that are separated with each other by insulators.

CASCADE ARC GENERATOR AND LOW-PRESSURE CASCADE ARC TORCH REACTOR

Fig. 1 depicts the structure of a cascade arc generator. A disk of copper or brass, e.g., with diameter ~6 cm and thickness ~1 cm, which has a center hole, e.g., ~3 mm in diameter, is the major element of the cascade arc generator. Roughly, 7–10 rings are assembled with insulating gasket between rings so that 7–10 electrically floating conducting walls are aligned in the 2 mm diameter nozzle. Circulating temperature-controlled water cools each ring. A metal wire with low sputtering yield, typically tungsten wire, is used as the cathode, and the last ring is typically used as the anode.

When electrical voltage is applied between the cathode and the anode, the breakdown of the gas in the interelectrode space, which is surrounded by numbers of electrically floating conducting surfaces, occurs. The first arc discharge occurs between the cathode and the first ring, which establishes its electrical potential that is higher than the next ring. The discharge propagates from the first ring to the second ring, and so on to the anode surface in a cascading mode. Because of this mode of the propagation of arc discharge, this type of arc is termed as cascade arc or wall-stabilized arc. The advantage of cascade arc over other types of arc is in the ease of generating arc and the stability of the arc generation process.

A single monoatomic gas, e.g., argon, helium, etc., is used as the carrier gas of the cascade arc discharge. When the luminous gas is injected into an expansion chamber in low pressure, e.g., 1 torr or less, the flame extends a significant length (e.g., 1 m), which depends on the flow rate, input power, diameter of the nozzle, and the pressure of the expansion chamber. This mode of cascade arc torch is termed low-pressure cascade arc torch (LPCAT), which is useful in the surface modification by means of LPCAT treatment and LPCAT polymerization.

Low-pressure cascade arc torch can be used without employing the second gas that is injected into the expansion chamber, or with addition of a single or multiple gases or vapors. Because of a very high velocity of luminous gas jet stream, the location of the second gas injection is not a critical factor because the second gas is sucked into the jet stream. However, the second gas is generally introduced near the nozzle. Fig. 2 depicts the assembled cascade arc generator that can be attached to a vacuum system. In this configuration, the second gas injection port is integrated into the cascade arc generator. A pictorial view of an LPCAT reactor is shown in Fig. 3, which displays a stream of luminous gas injecting from the nozzle into the expansion chamber in vacuum.

As seen in Fig. 3, the LPCAT flame is relatively narrow implying that a uniform luminous gas phase is not created in the expansion chamber. Consequently, the treatment that can be achieved by an LPCAT is governed by the line of sight process, regardless of whether the substrate touches the luminous gas flame or not, and limited to a relatively small area that is exposed to the flame or near the tip of flame. When a substrate is placed along the line of the jet stream, the well-identifiable flame is destroyed, and gaseous species scatter in the downstream of the substrate. The scattered species could cause surface treatment effects; however, their extents are much smaller than that by the jet.

Plurals of integrated cascade arc generators, which are strategically placed on an expansion chamber, can be used to achieve a wider and uniform treatment.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120008055

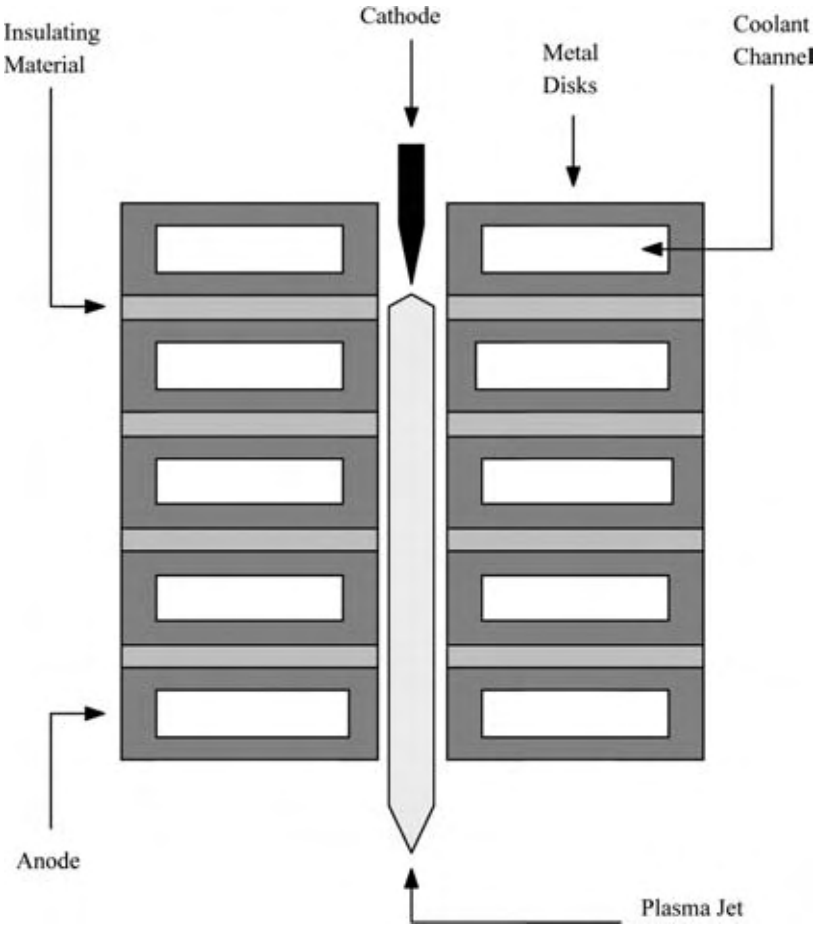

Fig. 1 General schematic of the cascade arc generator.

The relative motion of substrate with respect to the luminous gas jet is more or less mandatory for the uniform treatment. Fig. 4 depicts a reactor equipped with three cascade arc generators, of which two are used to treat substrates placed on a rotating plate.

Another mode of LPCAT processing is that the integrated cascade arc generator, such as the one shown in Fig. 2, is placed in a vacuum chamber held by a robot arm. In this mode, LPCAT jet could scan over a complex-shaped substrate by the robotic operation.

With low-pressure cascade arc, plasma formation (ionization/excitation of Ar) occurs in the cascade arc generator, and the major body of luminous gas is blown into an expansion chamber in vacuum. The majority of electrons and ions are captured by anode and cathode, respectively, of the cascade arc generator, and there is no external electrical field in the expanding plasma jet. Consequently, the photon-emitting excited neutrals of Ar cause the majority of chemical reactions that occur in the plasma jet. The luminous gas coming out of the nozzle interacts with gases existing in the space into which it is injected or the surface that is placed to intercept the jet.

Low-pressure cascade arc torch can be utilized in the following three modes in the surface modification of materials:

1. Without addition of the second gas or vapor, i.e., jet of excited argon neutrals.
2. With addition of the second gas that does not form the deposition of material (nonpolymer forming gas), i.e., jet of excited neutral species of the second gas.
3. With addition to the second gas that causes the deposition of material (polymer-forming gas and monomer), i.e., plasma polymerization by means of excited neutral species of argon.

The second gas is introduced in the expansion chamber. Because of an extremely high velocity of gas injecting from a small nozzle (e.g., 3 mm in diameter), the second gas injected into the expansion chamber in vacuum cannot migrate into the cascade arc generator, that is, the activation of Ar in the cascade arc generator and deactivation of the activated species of Ar in the expansion chamber, which activate the second gas introduced in the expansion chamber, are temporally

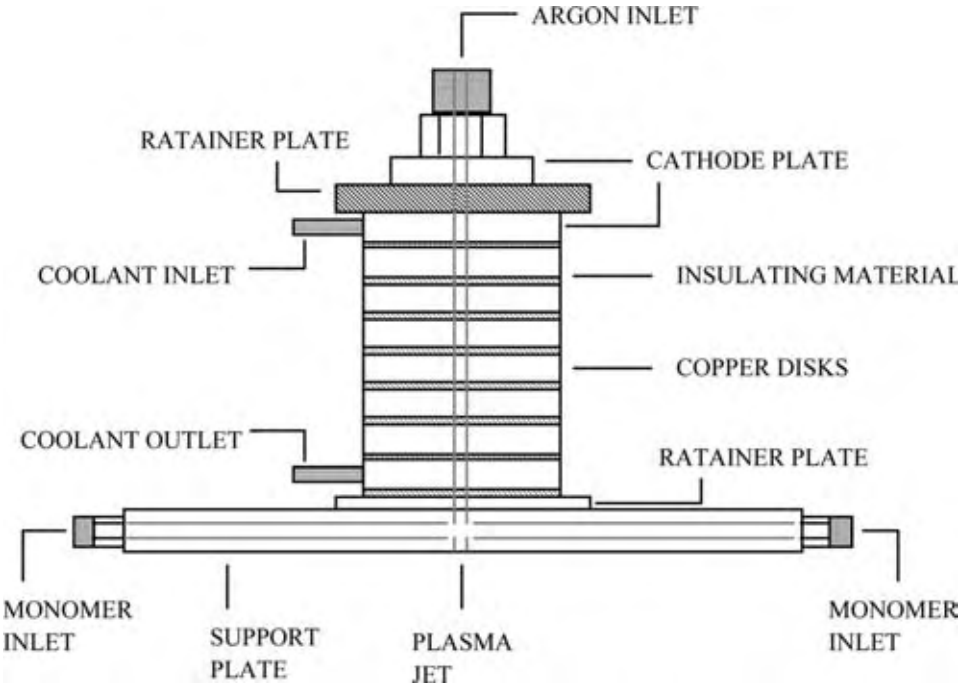

Fig. 2 Assembled cascade arc generator, which can be attached to a vacuum chamber.

and spatially separated. The LPCAT treatment and polymerization occur under such a totally (temporally, spatially, and kinetically) decoupled activation/deactivation system.

CREATION OF LUMINOUS GAS IN A CASCADE ARC GENERATOR

In LPCAT process, only an inert gas, such as Ar, exists in the cascade arc generator, and DC voltage is applied between the cathode and the anode. Therefore, it is a DC discharge of Ar, but it occurs under much higher pressure than most low-pressure DC discharges, and the gas travels very fast uniaxially in the generator. The basic process of ionization of Ar takes place in the cascade arc generator, which can be depicted as follows:

The ionization of Ar by high energy electron, e^*,

$$Ar + e^* \longrightarrow Ar^+ + 2e \quad (1)$$

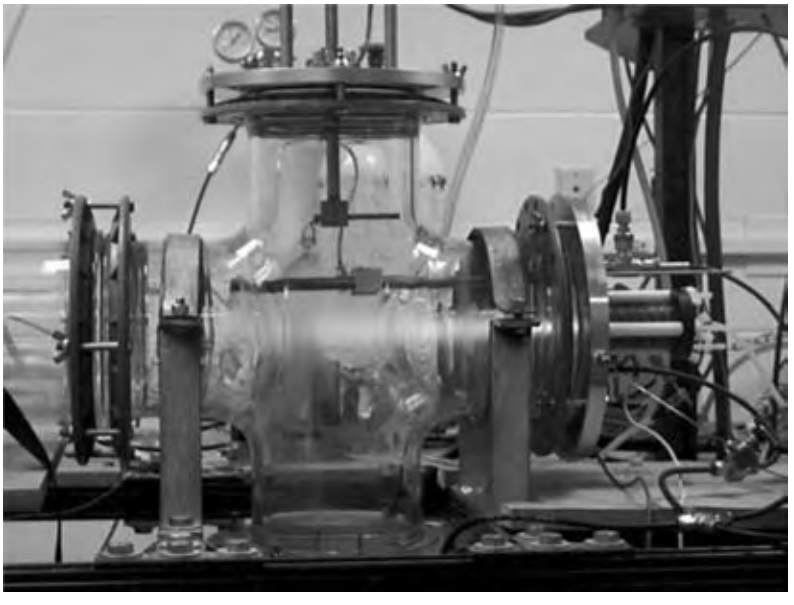

Fig. 3 Pictorial view of cascade arc torch reactor. *(View this art in color at www.dekker.com.)*

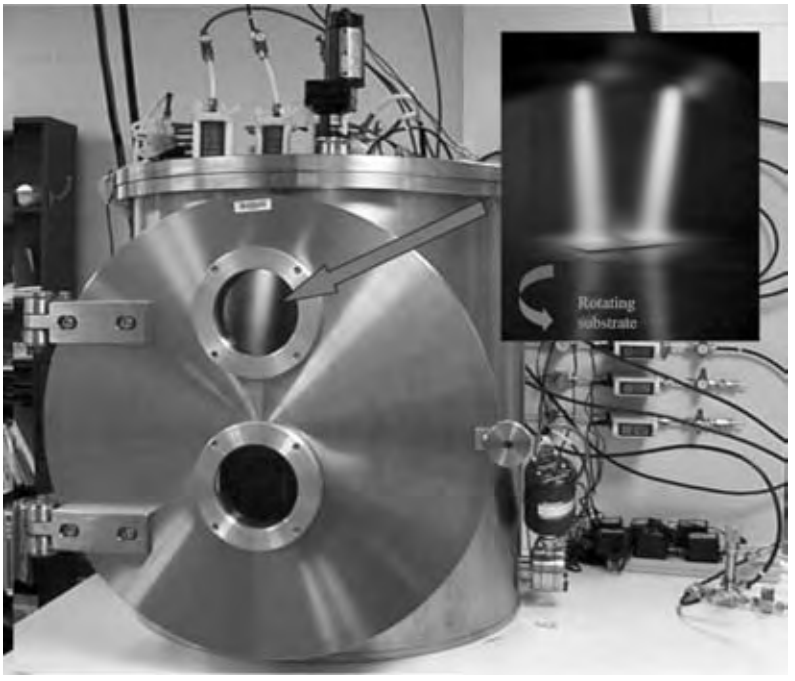

Fig. 4 The LTCAT model reactor with multiple cascade arc generators. *(View this art in color at www.dekker.com.)*

The creation of excited neutrals by an electron having the same level of energy also occurs simultaneously

$$Ar + e^* \longrightarrow Ar^* + e \quad (2)$$

The cathode captures most of Ar^+, and the anode captures the majority of electrons. When the luminous gas phase created in the cascade arc generator is blown out of the nozzle, the majority of species in the luminous gas jet are excited Ar neutrals and some strayed electrons.

In an expanding cascade arc plasma jet, the main characteristic is that electrons have very low kinetic energy (low electron temperature). The electron temperature estimates range from 0.3 to 1.5 eV in argon plasma jets by Langmuir double probe measurements.[5,8] As the double probes sample only the higher energy electrons, and not the bulk of electron distribution, the average electron temperature could be significantly lower than the above reported values. Because ions cannot be created at such low electron temperatures in the expansion chamber, only neutral lines are emitted in a pure argon or helium luminous gas jet.

In the expansion chamber, no electrical field exists, and no acceleration of electrons occurs. In such a passive environment, the number of electrons follows typical first-order decay as a function of the distance from the nozzle (Fig. 5).[8] Excited Ar neutrals outnumber electrons and dominate subsequent dissociation/excitation phenomena. The cascade arc luminous gas jet could be viewed as a jet stream of excited neutrals of the carrier gas.

Low-Pressure Cascade Arc Torch (Without Addition of the Second Gas)

In the expansion chamber without addition of the second gas, excited species Ar^* decay by emitting photons

$$Ar^* \longrightarrow Ar + h\nu_3 \quad (3)$$

The typical emission spectra of argon and helium are shown in Fig. 6 from 310 to 920 nm with few significant emissions outside of this region observed over the 200–1050 nm range. The emissions from the argon and helium plasma jets correspond exclusively to neutral argon or helium excited species, with no argon or helium ion lines.[8]

Some representative emission lines from the luminous gas jets are summarized in Table 1. The dominant features for argon plasma jet correspond to 4p $\rightarrow$ 4s transitions, with higher energy levels, such as 5p[2.5] $\rightarrow$ 4s[1.5], being quite clearly observed, as well. The excited atoms in a helium luminous gas jet have much higher energy levels than those in an argon luminous gas jet. With such a high energy over 23 eV, the excited helium neutrals can ionize nearly any molecular gases (excluding organic vapors, which mostly dissociate) injected into the expansion chamber.

The ratio of the concentration of excited species (energy carriers such as Ar) to that of the unexcited carrier gas is proportional to the power input

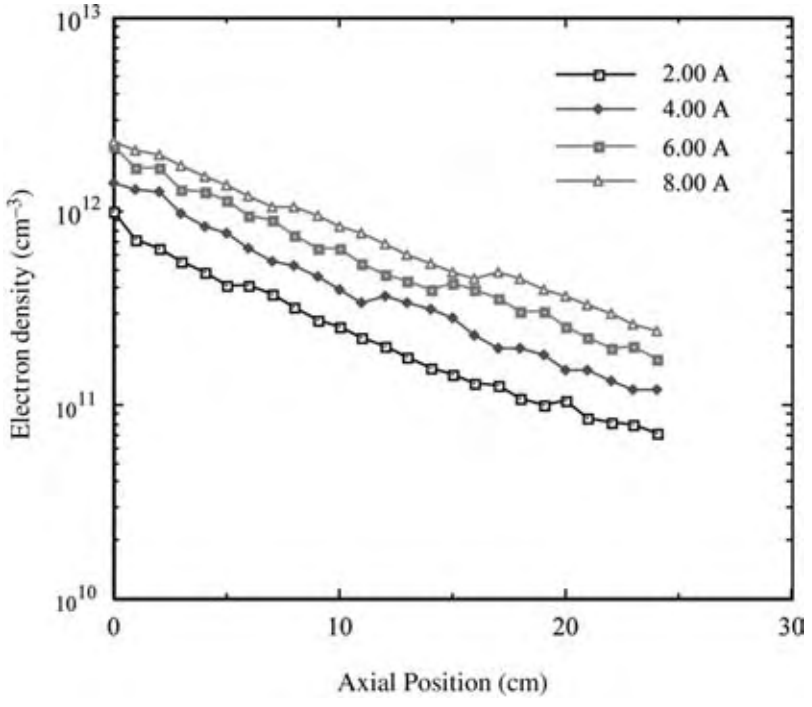

Fig. 5 Electron density (cm^{-3}) as a function of axial position and arc current. Other conditions are 2000 sccm argon and 560 mtorr (75 Pa). *(View this art in color at www.dekker.com.)*

given by *W*. This relationship can be expressed in Eqs. (4) and (5).[9]

$$\frac{[\text{Energy carrier}]}{[FM]_c} = \frac{[FM]_c^*}{[FM]_c} = \alpha_1 W \quad (4)$$

where α_1 is the proportionality constant (sec/J).

$$[\text{Energy carrier}] = [FM]_c^* = \alpha_1 W [FM]_c \quad (5)$$

In Eqs. (4) and (5), [Energy carrier] is the concentration (mass density) of excited species of the carrier gas in the jet stream blown out from the arc column into the expansion chamber (not the concentration in the chamber). The subscript "c" represents the carrier gas, and superscript "*" represents the excited carrier gas. *F* is molar flow rate, and *M* is the molecular weight of the gas. *FM* is the mass flow rate.

Fig. 7 shows the change of argon emission (763.5 nm) intensity against a combined experimental

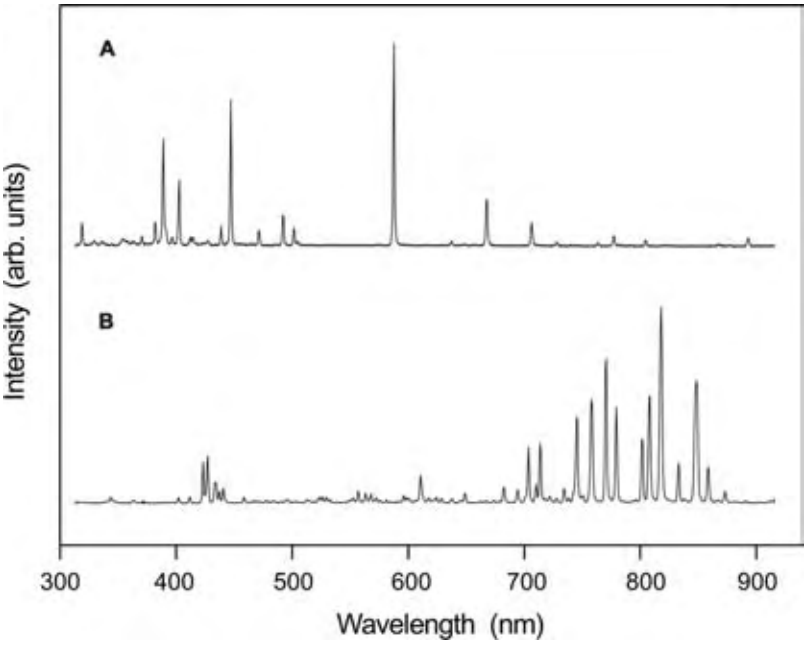

Fig. 6 Typical optical emission spectra of (A) helium plasma jet and (B) argon plasma jet; the spectra were obtained at an axial position 2.7 cm from the jet inlet; conditions are: (A) 3000 sccm helium, 1.35 kW, and 89 Pa; (B) 2000 sccm argon, 0.64 kW, and 75 Pa.

Table 1 Most intense emission lines observed in argon and helium plasma jets

Species	Emission wavelength (nm)	Transition	Energy of emitting state aboveground state, E_B (eV)
Ar	420.1	$5p[2\frac{1}{2}] \rightarrow 4s[1\frac{1}{2}]^0$	14.50
	696.5	$4p'[\frac{1}{2}] \rightarrow 4s[1\frac{1}{2}]^0$	13.33
	750.4	$4p'[\frac{1}{2}] \rightarrow 4s'[\frac{1}{2}]^0$	13.48
	763.5	$4p[1\frac{1}{2}] \rightarrow 4s[1\frac{1}{2}]^0$	13.17
	772.4	$4p'[\frac{1}{2}] \rightarrow 4s'[\frac{1}{2}]^0$	13.33
	794.8	$4p'[1\frac{1}{2}] \rightarrow 4s'[\frac{1}{2}]^0$	13.28
	811.5	$4p[2\frac{1}{2}] \rightarrow 4s[1\frac{1}{2}]^0$	13.08
	842.5	$4p[2\frac{1}{2}] \rightarrow 4s[1\frac{1}{2}]^0$	13.09
He	388.9	$3p^3P^0 \rightarrow 2s^3S$	23.01
	402.6	$5d^3D \rightarrow 2p^3P^0$	24.04
	447.2	$4d^3D \rightarrow 2p^3P^0$	23.73
	587.6	$3d^3D \rightarrow 2p^3P^0$	23.07
	667.8	$3d^1D \rightarrow 2p^1P^0$	23.07

parameter $W(FM)_c$, where W is the power input applied to the arc column and $(FM)_c$ is the carrier gas mass flow rate. The other argon emission lines, such as 706.7 and 604.3 nm, also showed similar trends. The argon emission intensity was proportional to the arc current at a fixed argon flow rate, and proportional to the argon flow rate at a fixed arc current. In other words, if the emission intensity was plotted against W or $(FM)_c$, the number of straight lines corresponding to values of $(FM)_c$ or W, respectively, were obtained, which are the similar dependences observed for the deposition in glow discharge on the discharge wattage and flow rate of monomer.[10]

The argon emission intensity showed a linear dependence on the combined parameter, $W(FM)_c$, i.e., the total energy applied to the monomers in the LPCAT process, as described by Eq. (5), can be expressed by this combined experimental parameter, $W(FM)_c$.

Addition of Nonpolymer-Forming Gases

The introduction of the second gas into the expansion chamber causes two significant visible changes: 1) the shrinking of the flame and 2) the change of color of the flame. These phenomena indicate that the excess energy carried by excited Ar neutrals are consumed

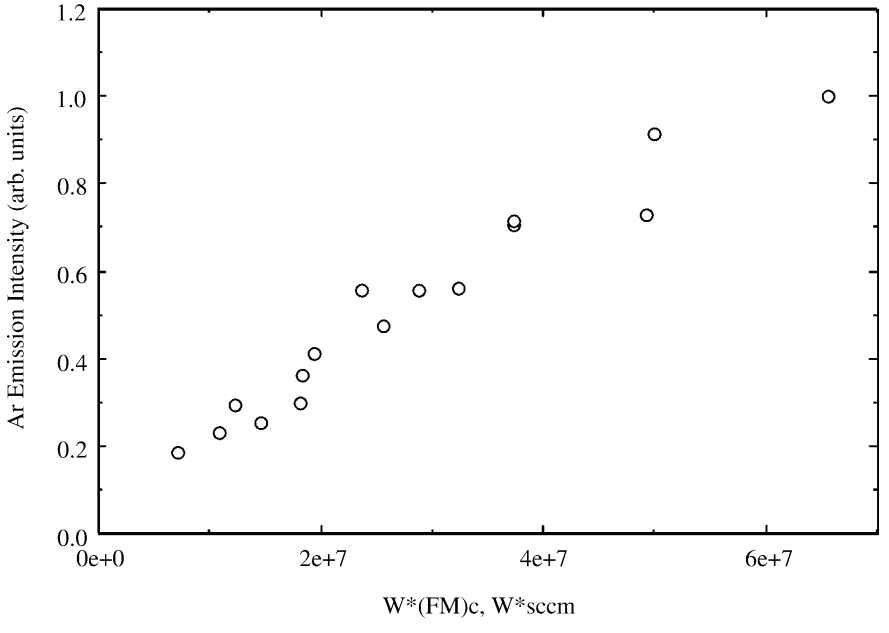

Fig. 7 The argon emission (763.5 nm) intensity as a function of the combined experimental parameter; W is the power applied to the arc column.

Table 2 Identified emission lines and bands

Species	λ(nm)	Transition	E_B(eV)	Remarks
N_2	337.1	$C^3\Pi_u \rightarrow B^3\Pi_g$	11.1	Second positive
	662.3	$B^3\Pi_g \rightarrow A^3\sum_a^+$	7.4	First positive
N_2^+	391.4	$B^2\Sigma_u^+ \rightarrow X^2\Sigma_g^+$	18.7	First negative
O	777.2	$3p^5P \rightarrow 3s^5S^0$	10.7

in creating a new luminous gas phase, which consists of a mixture of the second gas and Ar (carrier gas), and the color depends on the nature of the second gas. The length of the mixed luminous gas flame also depends on the flow rate of the second gas (at a fixed flow rate of Ar), i.e., the higher the flow rate, the shorter the length of flame. Tables 2–4 depict characteristics of the luminous gas phase when a second gas is added to the expansion chamber.[11]

The electron-impact ionization does not occur in the cascade arc torch, and the energy transfer between excited neutrals of the carrier gas and the added gases becomes a dominant reaction, i.e., the Penning-type reactions or resonance reactions between gas molecules and excited neutrals of the carrier gas is the principal generation process for the reactive species.[12]

On addition of the second gases to the plasma jets, the emission of argon or helium plasma jets are highly quenched. The dominant features in the emission spectra are due to the excited species corresponding to the added gases, with only the strongest argon or helium lines remaining visible.[11]

Nitrogen

When nitrogen is added to plasma jets, all argon or helium emission lines are highly quenched, and a very strong pink flame for argon plasma jet and a green flame for helium plasma jet are formed. The dominant features in the spectra are due to nitrogen species. Fig. 8 depicts optical emission spectroscopy (OES) signals of luminous gas jet of N_2 added to: 1) Ar and 2) He LPCAT.

In radiofrequency (RF) plasmas (see Plasma Polymerization Coatings) that are characterized as low ionization degree and high electron temperature, the emission is mainly due to electron excitation and pooling reaction of the molecular metastable. Fig. 9 depicts various emissions observed in RF discharge of nitrogen. The main ion is N_2^+, which also can be excited by electrons to give the molecular ion emission. In expanding cascade arc helium plasma jet, only the spectrum of the first-negative system of N_2^+ was observed, as shown in Fig. 10, which depicts comparison of nitrogen luminous gas in RF and in LPCAT.

Table 3 Spectra emitted in argon plasma jet with addition of reactive gases

Reactive gas	Visual appearance	Observed spectra
None	Orange	Ar atom lines
N_2	Pink	N_2 second positive
O_2	Orange	O atom lines
Air	Pink	N_2 second positive O atom lines
H_2	Light blue	H_2 molecular continuum H_α, H_β lines
$N_2 + H_2$	Pink	N_2 first and second positive NH band H_α line
NH_3	Light blue	NH band H_α line

Table 4 Spectra emitted in helium plasma jet with addition of reactive gases

Reactive gas	Visual appearance	Observed spectra
None	White	He atom lines
N_2	Green	N_2^+ first negative
O_2	Light blue	O_2^+ first negative O atom lines
Air	Green	N_2^+ first negative O atom lines
H_2	White	NH band H_α, H_β lines

Argon-excited neutrals were consumed by the increasing nitrogen addition, and the emission intensity of the N_2 second-position emission band keeps increasing with increasing nitrogen flow rate from 0 to 60 sccm, which shows that more activated nitrogen species were produced (Fig. 11).

The electronic energy level of the excited argon or helium neutrals plays a dominant role in active nitrogen excitation processes in the plasma jets. As can be seen in Table 1, excited argon neutrals (E_B: ~13 eV) have more than enough energy to excite either state of N_2 first-position (E_B: ~7.4 eV) or state of N_2 second-position (E_B: ~11.1 eV), and excited helium neutrals (E_B: ~23 eV) have more than enough energy to excite any state of N_2 first position, N_2 second position, and N_2^+ first negative (E_B: ~18.7 eV). However, from the emission spectra of low-pressure cascade arc plasmas of nitrogen, a selective excitation of nitrogen species was observed. Only the activated species of N_2 second position (E_B: ~11.1 eV) in argon plasma jets and N_2^+ first negative (E_B: ~18.7 eV) in helium plasma jets were observed, which have the electronic energy levels close to those of excited argon atoms (E_B: ~13 eV) or helium atoms (E_B: ~23 eV), respectively. No excited species of nitrogen with higher or much lower energy levels than that of excited argon or helium neutrals was identified.

In the creation processes of reactive nitrogen species in the low-pressure cascade arc plasmas, only species that have close energy match to the excited species of carrier gas occur, e.g., N_2 second position and excited argon atoms or N_2^+ first negative and excited helium atoms. The selective excitation of nitrogen species was not observed in RF plasmas from either pure nitrogen or its mixture with argon or helium, probably because of the electron-impact ionization rather than the energy transfer type activation predominates in the RF glow discharge of nitrogen.

Oxygen

When oxygen was added into an argon plasma jet at 60 sccm, neither obvious quenching of argon emission

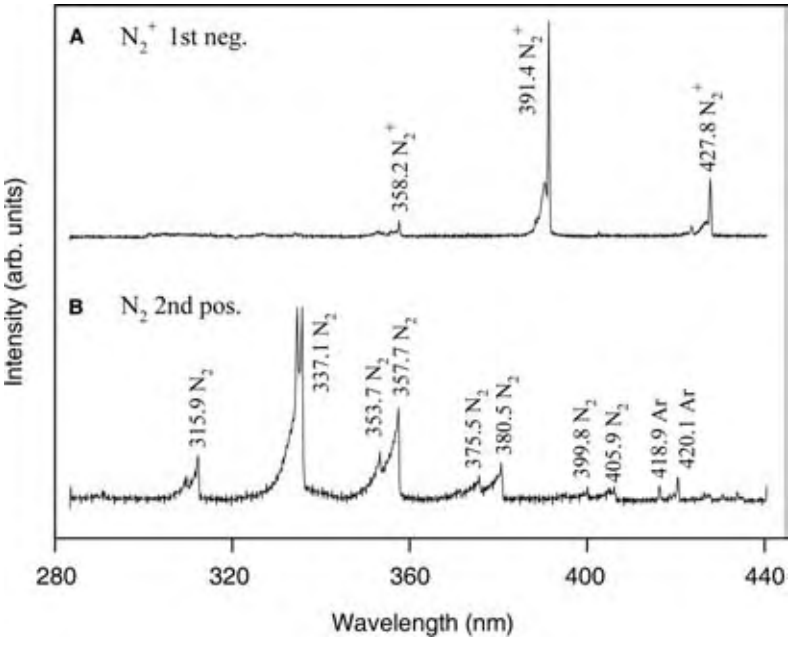

Fig. 8 Typical emission spectra of nitrogen in low-temperature cascade arc plasma jets: (A) N_2 in helium plasma jet and (B) N_2 in argon plasma jet.

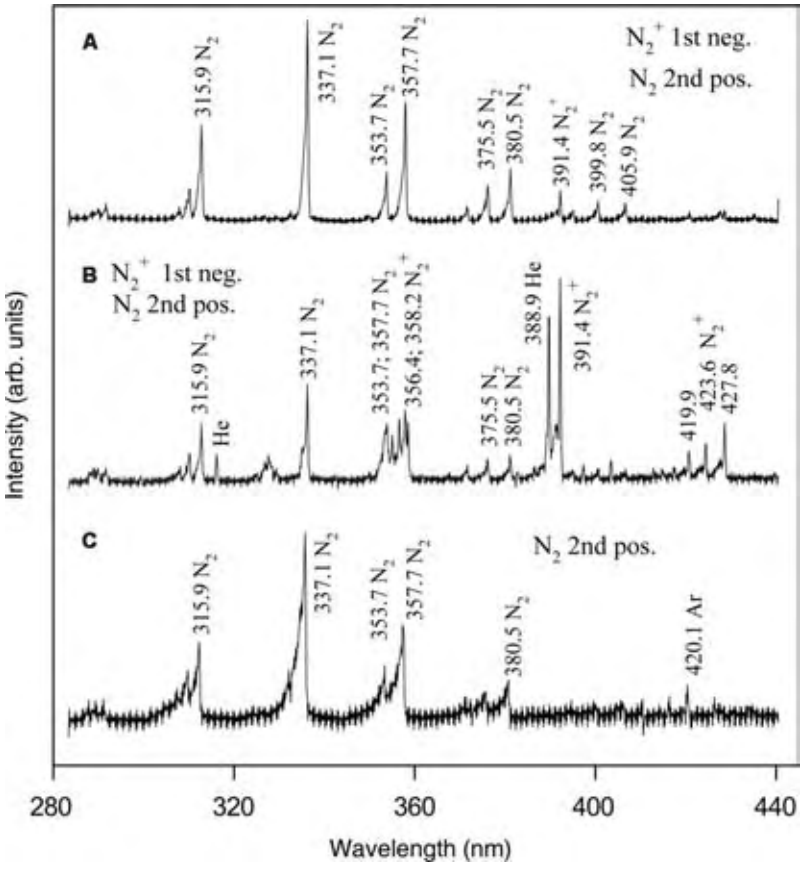

Fig. 9 Typical emission spectra of RF plasmas: (A) pure nitrogen, 60 sccm N_2, 10 Pa, RF power 40 W; (B) mixtures of 60 sccm nitrogen and 2000 sccm helium, 75 Pa, RF power 100 W; and (C) mixture of 60 sccm nitrogen and 2000 sccm argon, 75 Pa, RF power 250 W.

nor color change of the plasma jet was observed. The emission due to Ar atoms dominated the spectrum. However, the optical emissions due to excited oxygen atoms at 777.2 nm (E_B: ~10.7 eV) and 844.6 nm (E_B: ~11.0 eV) were clearly observed.

When oxygen was introduced into a helium plasma jet, rapid quenching of helium emission occurred and a very short light-blue flame was formed, and the emission due to N_2^+ first-negative system (E_B: ~18.2 eV) appeared in addition to the oxygen atom emission. Because of the obvious quenching, the emissions due to He atoms became very weak. This result can be clearly understood from the different energy levels between the excited argon and the helium neutrals, i.e., the excited helium atoms have more than enough energy to ionize oxygen molecules and excite them from the ground state to an excited state, but excited argon atoms do not have enough energy. The following reactions

$$He^* + O_2\left(X^3\sum_g^-\right) \longrightarrow O_2^+\left(b^4\sum_g^-\right) + e + He$$

$$O_2^+\left(b^4\sum_g^-\right) \rightarrow O_2^+\left(a^4\prod_u\right) + h\nu$$

are energetically possible for the production of O_2^+ first-negative system species. The generation process for excited oxygen atoms in argon plasma jet can also be clearly described by the following excitation transfer reaction:[12]

$$Ar^* + O_2\left(X^3\sum_g^-\right) \rightarrow O^* + O + Ar$$

Air

As the main components of air are nitrogen and oxygen, the main feature of the emission spectra of air in argon or in helium plasma jets is also a typical mixture of nitrogen and oxygen emission spectra in the plasma jets. When air was introduced into the argon plasma jet, a strong pink flame was formed and the main emissions were due to N_2 second-position molecules and excited oxygen atoms. When it was added to a helium plasma jet, the dominant emissions were due to N_2^+ first-negative molecular ions and excited oxygen atoms, but no O_2^+ first-negative emission was observed.

Hydrogen

When hydrogen gas was introduced into argon plasma jet, all the argon emissions were strongly quenched and a very short and brilliant flame with a light blue color was formed. The emissions from excited hydrogen atoms (E_B: ~12 eV) and molecules (E_B: ~11.8 eV) were

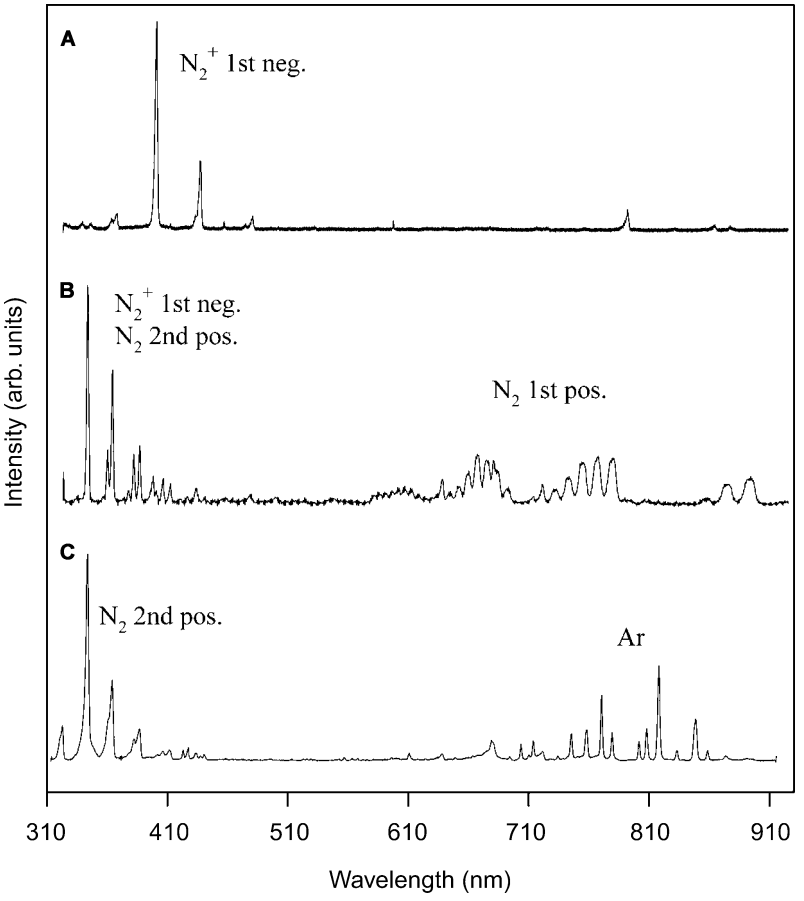

Fig. 10 Typical emission spectra of 60 sccm N_2 (A) in helium plasma jet, (B) RF plasma of pure N_2, 10 Pa, RF power 30 W, and (C) in argon plasma jets.

observed. However, when hydrogen gas was added to helium plasma jet, neither the strong quenching effect nor color change was observed. Only very weak emissions from excited hydrogen atoms were detected, and no emission from excited hydrogen molecules was observed, as the energy level of excited helium atoms exceeds the ionization energy for both H atoms (E_i: ~13.6 eV) and H_2 molecules (E_i: ~15.4 eV).

This system forms highly ionized so-called Penning mixtures.[13,14] The higher excited states of H_2^+ are partly stable and partly unstable, depending on the quantum numbers of the electron present. The stable excited states have, however, only very shallow minima of the potential curves.[15] That is the reason why no spectrum of H_2^+ is observed for the helium plasma jet. The argon excited neutrals, on the other hand, cannot ionize either hydrogen atoms or molecules, but could produce excited H_2 molecules, which can be detected by optical emission spectroscopy.

Ammonia

When ammonia gas was introduced into an argon plasma jet at a flow rate of 60 sccm, all argon emission lines disappeared, and a very short but brilliant light blue flame was formed. A very strong NH emission band was observed. In the ammonia RF plasma, some very weak N_2 emission bands due to N_2 second position appeared, but in the ammonia flame formed in an argon plasma jet, no emission related to N_2 species was observed.

Mixture of nitrogen and hydrogen

Figs. 12 and 13 show the emission spectra of an argon plasma jet with the addition of nitrogen and hydrogen at different compositions. The N_2 emission due to N_2 second-position intensities decreased greatly, even when a small amount of hydrogen existed. At a higher hydrogen composition in the mixture, very weak emission bands due to N_2 second position were observed. Quite strong emissions due to N_2 first position appeared with different levels of hydrogen in the gas mixture. Adding hydrogen to the system can limit the selective excitation of nitrogen species in low-pressure cascade arc plasmas, though the mechanism is not clear.

Addition of Material-Forming Gas

The creation of chemically reactive species from polymer-forming gas (monomer) follows the same

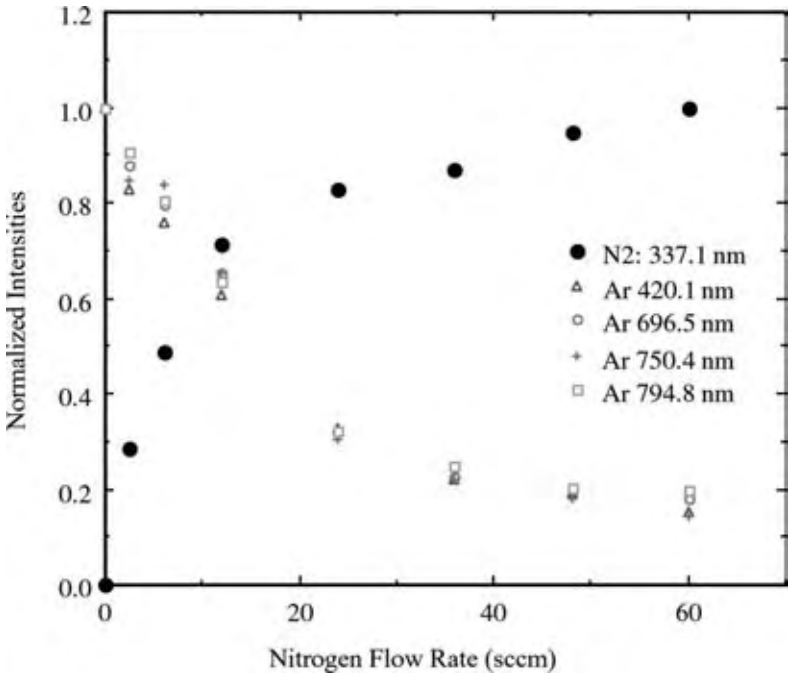

Fig. 11 The dependence of emission argon lines and nitrogen second-position band (337.1 nm) emission intensities at an axial position 2.7 cm from jet inlet on the flow rate of nitrogen added to argon plasma jet. Conditions are 2000 sccm argon, 60 sccm nitrogen, 75 Pa, 0.64 kW. *(View this art in color at www.dekker.com.)*

principle described for nonpolymer-forming gases, i.e., molecular dissociation by energy-transfer mechanism. On addition of monomers to the argon luminous gas jet, the emissions of argon luminous gas are highly quenched. The dominant features in the emission spectra are due to excited species corresponding to the relevant monomers with the strong argon lines remaining visible. Photon-emission aspects of some organic molecules are described below.

CH_4 or CH_3OH

The spectral features of OES spectra of low-temperature cascade arc plasmas of CH_4 and CH_3OH, are identical for both of these systems. Emission bands of CH radicals, emission lines of H atoms constitute the dominant emission characteristics of OES spectra for both the plasma systems. The CH emission ($A^2\Delta \rightarrow X^2\Pi$ at 431 nm) intensities are almost the same for both CH_4 and CH_3OH plasmas, and follow similar trends with the change of arc currents.

If one assumes that the densities of the electronically excited states, from which the observed emissions originate, are directly proportional to those of the ground state, the emission intensity profiles reflect approximately the species concentrations, especially at constant pressure. Therefore, the above results may indicate that, at the same operating conditions, almost the same quantity of CH radicals exist in CH_4 and CH_3OH cascade arc plasmas. From the OES spectra assignment, CH radicals are the only reactive species that could be attributed to the growth of plasma polymers in both CH_4 and CH_3OH cascade arc plasmas.

If one speculates only based on OES data, CH_4 and CH_3OH cascade arc plasmas should give similar deposition rates. However, the deposition rate did not follow the prediction. The deposition rates of CH_3OH in LPCAT are less than 1/10 of that for CH_4. The results of deposition rates indicated that there existed an inverse correlation between OES signals and the deposition rate, indicating that polymerizable species are not photon-emitting species.

CF_4 or C_2F_4

Clear-cut demonstrations for the case, in which polymerizable species that do not emit photons are created exclusively by the molecular dissociation by energy transfer principle, was found with addition of CF_4 or C_2F_4 to Ar LPCAT. The finding implies that the photon emission per se is not the essential indicator of chemical reaction pertinent to plasma polymerization. According to the literature, the CF_4 and C_2F_4 plasmas are the well-investigated fluorinated carbon plasma systems by OES diagnostics with conventional plasma sources. However, without influence of electron-impact ionization in LPCAT, these cases turned out to be the case for the formation of polymerizable species that do not emit photons, which occurs by the energy transfer mechanism.

The OES spectra of low-temperature cascade arc plasmas for carrier gas Ar only and with CF_4 and C_2F_4 addition were identical, although the quenching

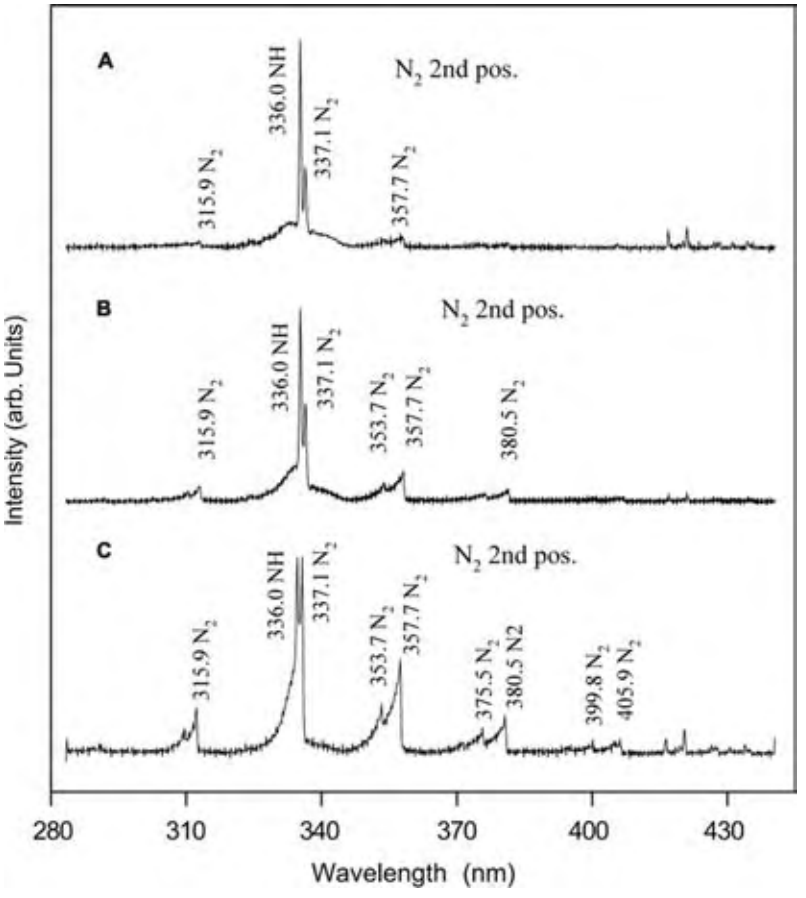

Fig. 12 The optical emission spectra of argon plasma jets (A) with addition of 10 sccm nitrogen and 10 sccm hydrogen, (B) with addition of 60 sccm nitrogen and 2.7 sccm hydrogen, and (C) with pure nitrogen addition, 60 sccm nitrogen. The cascade arc conditions are 2000 sccm argon, 0.64 kW, and 75 Pa.

of the flame occurred when the second gas is added. Low-temperature cascade arc plasmas of CF_4 and C_2F_4 did not show any additional peaks or continuums when compared to the Ar plasmas, like CF_2^+ or the CF lines that were found in the OES spectra for ($Ar + CF_4$) and ($Ar + C_2F_4$) RF plasmas. None of the species previously reported for CF_4 RF plasma, i.e., CF_2 and CF bands, as well as fluorine atom emissions, exists in the OES spectra of CF_4 or C_2F_4 LPCAT.[16] The addition of CF_4 or C_2F_4 quenched

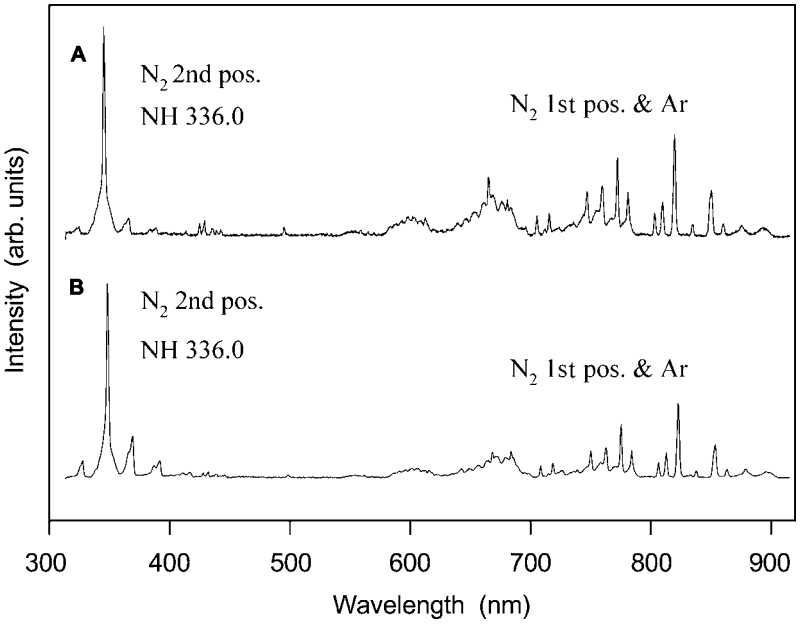

Fig. 13 The optical emission spectra of argon plasma jets with addition of nitrogen and hydrogen mixture: (A) 10 sccm nitrogen and 10 sccm hydrogen and (B) 60 sccm nitrogen and 2.7 sccm hydrogen. The cascade arc conditions are 2000 sccm argon, 0.64 kW, and 75 Pa.

the cascade arc torch flame (the excess energy is transferred to the second gas), but did not create reactive species of the added gas that emits photons, which can be identified by OES.

X-ray photoelectron spectroscopy data, on the other hand, showed that the low-temperature cascade arc torch treatment of (Ar + CF_4) and (Ar + C_2F_4) yielded just as good, if not better, fluorination of PET fibers as RF plasma treatment with these gases.[16,17] These examples clearly demonstrate that the main polymerizable species in plasma polymerization (free radicals) are not photon-emitting species in most cases. This is in accordance with the growth and deposition mechanism based on free radicals, which account for the presence of large amount of dangling bonds in most plasma polymers[10] (see ''Plasma Polymerization Coating'').

The formation and the dissipation of luminous gas phase of organic vapor by excited Ar neutrals in the cascade arc polymerization could be described as follows. A fraction of photon-emitting Ar neutrals (Ar^*), expressed by nA^*, interact with the monomer (M), and cause the dissociation of the monomer yielding fragmented photon-emitting species (A^* and B^*) and hydrogen atom (H) according to the scheme described by Eq. (1):

$$nAr^* + mM \longrightarrow m(A^* + B^*) + xH + (n - m)Ar^* \quad (6)$$

The remaining Ar^* emit photons according to Eq. (3). The photon emission by A^* and B^* can be expressed by the same equation, if these species do not chemically react. A fraction (β) of fragmented photon-emitting species reacts with the monomer or its fragmented moiety (represented by X) to yield polymerizable species (represented by $AX^\bullet$).

$$\beta A^* + X \longrightarrow \beta AX^\bullet \quad (7)$$

In the case in which no photon-emitting species are created, the formation of polymerizable species can be represented by a modified Eq. (6), as

$$nAr^* + mM \longrightarrow m(A^\bullet + B^\bullet) + xH + (n - m)Ar^* \quad (8)$$

The perfluorocarbons injected into Ar LPCAT represent the case represented by Eq. (8). On injection of a perfluorocarbon, such as CF_4, C_2F_4, etc., luminous gas jet shrinks. However, OES data indicate that there is no signal discernible to F-containing species. Radio-frequency discharge of mixtures of Ar and perfluorocarbon shows F-containing species, indicating the route to create polymerizable species in LPCAT is different from that in RF plasma because of the absence of electron or ion impact dissociation of monomer.

DEPENDENCE OF DEPOSITION RATE ON OPERATIONAL PARAMETERS

In the conventional glow discharge polymerization, the normalized deposition rate is given by

$$\text{Normalized deposition rate} = \alpha W/FM \quad (9)$$

where W is the electrical energy input to the discharge system, and FM (mass flow rate) represents the total mass of gases that adsorb the energy[10] (see ''Plasma Polymerization Coating''). W/FM represents the energy input per unit mass of gas involved, whereas W represents the energy input into the electrical circuit. As the carrier gas plasma is the direct energy source for the activation of monomers, the concentration of energy carrier [Energy carrier] represents the amount of energy available to activate LPCAT plasma polymerization in the cascade arc torch (in the expansion chamber).

The deposition rate in LPCAT polymerization can be described by the following expressions by replacing W in Eq. (9) (for general glow discharge polymerization) with [Energy carrier].[19]

$$\text{Normalized(DR)} = \alpha_2 \frac{[\text{Energy carrier}]}{[FM]_m} \quad (10)$$

By virtue of Eq. (5),

$$\text{Normalized(DR)} = \alpha_2 \frac{[FM]_c^*}{[FM]_m} = \alpha_2 \frac{\alpha_1 W[FM]_c}{[FM]_m} \quad (11)$$

where α_2 is a unit-less proportionality constant. Thus,

$$\text{Normalized(DR)} = \alpha_1\alpha_2 \frac{W[FM]_c}{[FM]_m} \quad (12)$$

In Eqs. (9)–(12), subscript ''m'' represents monomer, and the other experimental parameters are the same as described earlier. In essence, $W[FM]_c/[FM]_m$ is an energy-input factor (J/sec), the quantity of which can be considered as the energy applied to monomer per mass unit of monomers in unit time, transported by luminous carrier gas.

First, the energy transfer scheme based on $W[FM)_c/[FM]_m$ can be verified by examining OES spectrum of the second gas added into the expansion chamber of the cascade arc torch reactor as shown in Fig. 7.

The plotting deposition rates of different monomers with different feed rates in Normalized (DR) vs. $W[FM]_c/[FM]_m$ coordinates would give rise to the most objective comparison of their tendencies with regard to deposition. In LPCAT, a very important fact is that the polymerization (material formation) is ''atomic'' rather than ''molecular'' processes, implying that the depositing entities are fragmented species of the original monomer molecule.[10] Therefore, the deposition rate in LPCAT polymerization is determined largely by the type of atoms contained in the monomer structure, rather than by molecular structures.

Fig. 14 depicts the deposition characteristics of LPCAT polymerization. In this diagram, different monomers, different flow rates, and different electrical power inputs are all pooled together. The figure shows that: 1) the deposition rate in cascade arc torch can be well represented by Eq. (12), and 2) the deposition characteristics of silicon-containing monomers and hydrocarbon monomers are significantly different.

The silicon-containing monomers exhibited much higher deposition yield than hydrocarbon monomers. The wider scattering among various Si-containing organic molecules is due to the fact that each molecule contains different amount of C-based moieties. It can be estimated, from this figure, that Si-based moieties polymerize nearly seven times faster than C-based moieties. As there is a significant difference in the deposition behaviors of Si–C compounds and hydrocarbons, these results also indicate that the type of atoms contained in the monomer structure plays an important role in plasma polymerization in LPCAT.

Because of the relatively narrow beam of plasma jet, the deposition occurs in relatively narrow area. Deposition rate profiles as a function of axial position are shown in Fig. 15. Experimental conditions are 8.00 A arc current, 2000 sccm argon, 10.0 sccm methane, and 560 mtorr (75 Pa). The centerline deposition rate decreases sharply and the deposition rate at the shoulders of the profile increases with increased axial position, with profile broadening attributed to the diffusion of polymerizable species from the jet axis. The total mass deposition rate over a circle of 50 mm radius is given in Table 5, along with the conversion of methane to plasma polymer. Although the distribution profile broadens as the axial distance increases, the total deposition rate remains nearly constant within the distance examined. This implies that the distance from the nozzle, beyond a certain distance, is not a critical factor in practical deposition process, because the velocity of gas is so large that the variation of the distance is insignificant in the deposition process.

Low-pressure cascade arc torch polymerization or coating could be considered more or less the same as the plasma polymerization or coating by other conventional plasma processes. The ultrathin layers prepared by LPCAT polymerization have the general characteristics of plasma polymers, i.e., amorphous (noncrystalline), high concentration of the dangling bonds (free radicals trapped in immobile solid phase), and the high degree of the internal stress in the layer.

The internal stress follows the general pattern of its dependency on the energy input. Fig. 16 depicts the dependence of the internal stress on the power input

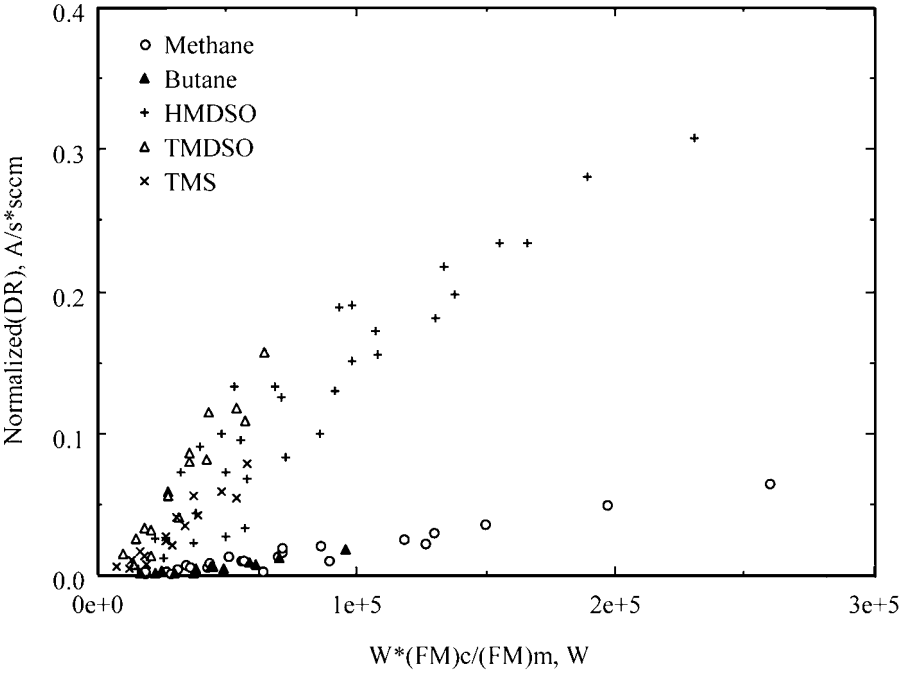

Fig. 14 Dependence of the normalized deposition rate of silicones and hydrocarbon monomers on the parameter $W^*(FM)_c/(FM)_m$ in cascade arc torch polymerization. The deposition rates were obtained at an axial position of 27.5 cm from the luminous gas jet inlet.

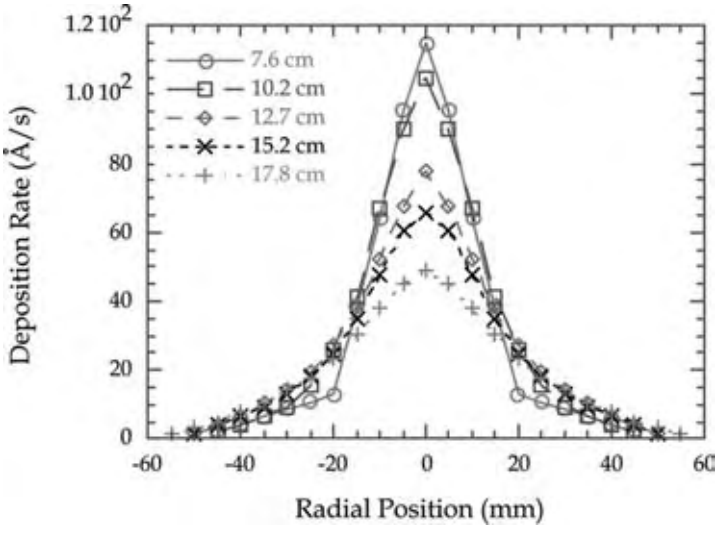

Fig. 15 Variation of the radial deposition rate distribution profile with axial position; conditions: 8.0 Å, 2000 sccm argon, 10.0 sccm methane, and 560 mtorr. *(View this art in color at www.dekker.com.)*

parameter. The larger monomers tend to create the higher internal stress, but in all cases, the internal stress increases with the power input. The internal stress is closely related to the refractive indices, as shown in Fig. 17. Si containing monomers have lesser internal stress and lower refractive indices compared to hydrocarbon (Nobonene), which showed conspicuously different lines in both the figures.

CHARACTERISTIC FEATURES OF LPCAT PROCESSING

The major effects of LPCAT treatment and LPCAT polymerization coating are, by and large, the same as conventional glow discharge treatment and plasma polymerization coating. However, the processing of LPCAT treatment or coating is significantly different in that it is a spray processing that requires the relative motion of the substrate with respect to the torch flame for the substrate larger than the diameter of LPCAT jet. Although the local treatment or deposition rate is high, it does not translate directly to the high overall processing rate depending on size and shape of the substrate.

Table 5 Total mass deposition rates and percent conversion of methane to plasma polymer at various axial positions. Conditions are 8.00 A, 2000 sccm argon, 10.0 sccm methane, and 560 mtorr

Axial position (cm)	Total rate ($\mu g/cm^2/sec$)	Conversion (%)
7.6	9.9	10.2
10.2	11.2	11.5
12.7	11.9	12.3
15.2	11.3	11.7
17.8	11.3	11.7

The process requires nearly three orders of magnitude higher flow rate of the carrier gas than typical flow rates of monomer or a mixture of monomer and a carrier gas in conventional glow discharge processes. The high consumption of carrier gas might necessitate the inclusion of carrier gas recovery system in an industrial scale operation.

The process, therefore, is not an alternative means to carry out conventional plasma processes, and the adaptation of the process should be done with careful identification of the specific goal that cannot be attained by other conventional plasma processes. The major features of the process that could distinguish LPCAT processes from other conventional plasma processes are:

1. The mode of creation of polymerizable or chemically reactive species, i.e., reactions caused by the interaction with excited neutrals of the carrier gas.
2. The short kinetic path length because of the high one-directional transport velocity of polymerizable species.

Whether or not these characteristic features are an advantage or a disadvantage entirely depends on the objectives to be accomplished by the processing. These two characteristic features, however, indicate that LPCAT process is better suited for the surface treatment rather than the surface coating.

The second feature seems to be responsible for the fact that the corrosion protection characteristics of

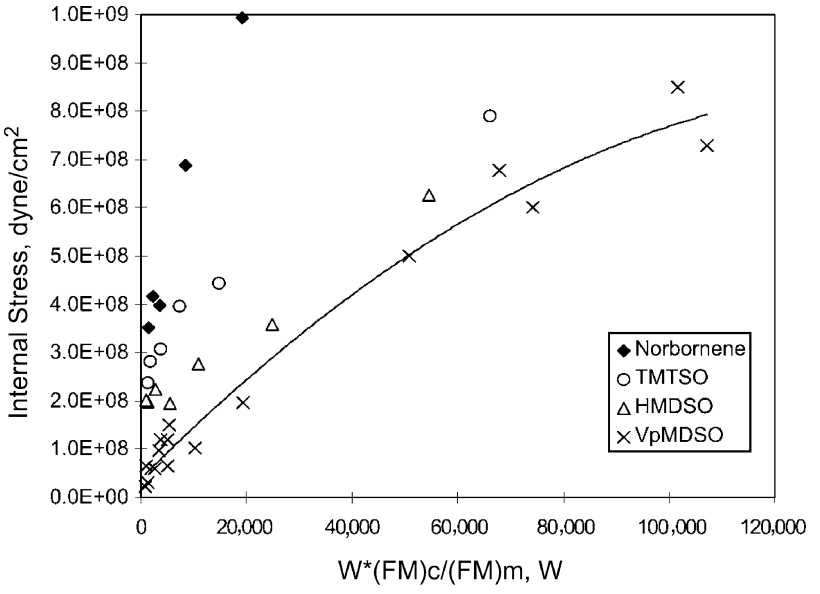

Fig. 16 Dependence of internal stress on the energy input parameter, $W^*(FM)_c/(FM)_m$, for cascade arc torch polymerization.

LPCAT coatings do not match that which can be attained by DC cathodic polymerization. The very high one-directional transport velocity hinders the interaction between polymerizable species existing in the luminous gas phase before they reach the target surface. The velocity of gaseous species leaving the nozzle of the cascade arc generator is estimated to be in the supersonic range, and LPCAT jet is close to the beam of excited species. The short kinetic path length means that smaller or oligomeric species deposit on the substrate. Consequently, the barrier characteristics and the adhesion of the coating become poorer than those that could be obtained by conventional plasma polymerization with a higher degree of kinetic path length. On the other hand, the same feature provides a great advantage when larger species should be avoided, e.g., in the case of deposition onto the surface of nanoparticles, which do not have large enough surfaces to accommodate larger species.

The first feature that chemically reactive species are created by the interaction of molecules (in gas phase or on the surface) with excited neutral species of Ar has a very significant influence in the surface modification of polymers. When a polymer surface is exposed to Ar or O_2 plasma, the energetic ions and electrons (at the level of ionization energy) bombard the surface. The influence on the surface is determined by the energy level. The chemical bonds involved in the molecules that

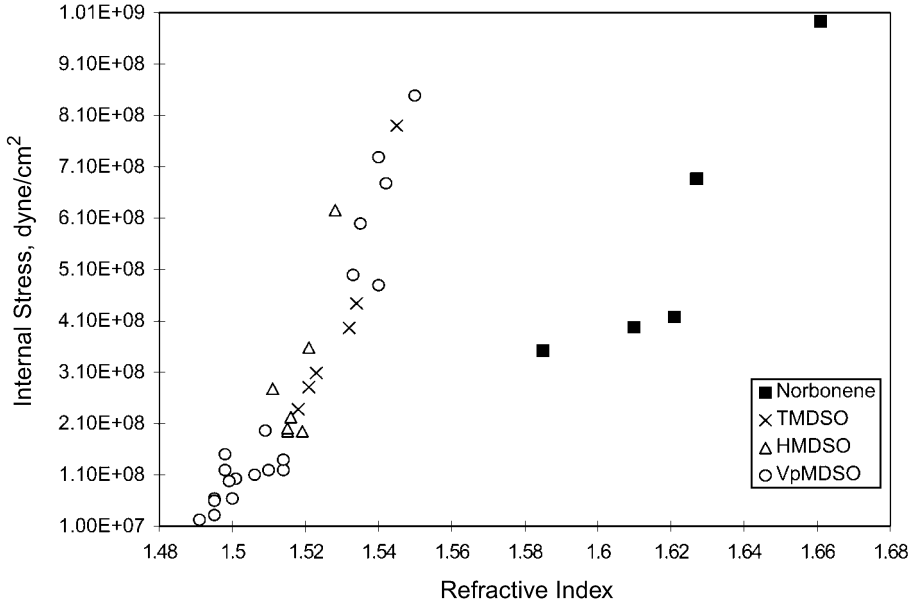

Fig. 17 Qualitative correlation of internal stress with refractive index of cascade arc torch plasma polymer films.

constitute the surface are relatively low (2–3 eV) compared to the ionization energy of the gas used in plasma (over 10 eV).

The cession of a σ-bond yields two free radicals. The free radical on the surface subsequently reacts with ambient oxygen when the treated substrate is exposed to air rendering the surface hydrophilic (in the case of Ar plasma). The high energy of impinging entities (electrons and/or ions) tends to yield excessive cession of bonds, which creates a weak boundary layer below the top surface. This situation could be visualized by the trends that plasma treatment of hydrophobic surface makes the surface paintable, but the paint does not adhere well because the paint could delaminate through the weak boundary sublayer.

In Ar LPCAT treatments, the excited neutrals of Ar, instead of Ar^+ and electrons with over 10 eV, interact with polymer molecules at the surface. The energy level of those excited species are nearly as high as those for ions and electrons; however, the interaction is through the energy transfer process in which the energy matching principle plays an important role. Consequently, the indiscriminate bombardment of highly energetic species does not take place in LPCAT treatment, which leads to a much less damaging surface treatment of polymers. Ar LPCAT treatment of thermoplastic olefins (used as the fascia of automobile bumper) yields much more durable and stable adhesion of paint applied on the treated surface than conventional plasma treatment processes could render.[18] Ar LPCAT treatment of fibrous polypropylene reinforcing materials for concrete also shows the much-improved energy absorbing characteristics of the fiber reinforced concrete by the same principle.[19] Trimethylsilane coating on zirconium oxides, which are used as the radio-opaque pigments in PMMA bone cement recipe, create bonding between the pigments and the polymer matrix and improves the fatigue life of the bone cement.[20]

CONCLUSIONS

Low-pressure cascade arc torch has the unique feature that excited neutral species of Ar that are created in the cascade arc generator are injected into the reaction chamber. The beams of Ar excited species can be used: 1) to cause chemical vapor deposition of the second gas that is injected in the expansion chamber or 2) to modify the surface of substrate, particularly polymers, by letting the excited Ar species react directly with the surface.

Because of the high rate of one-directional movement of the excited species of Ar, the chemical vapor deposition does not yield as well-developed a layer as that which can be obtained with plasma polymerization coating. On the other hand, the direct application of the excited species of Ar on polymeric surface yields excellent surface modifications without damaging the substrate polymers.

Lubrication Performance Factors for Chemical Process Plant Machinery

Jim C. Fitch
Drew D. Troyer
Noria Corporation, Tulsa, Oklahoma, U.S.A.

INTRODUCTION

The need for a maintenance organization to deliver machine reliability at low cost is in continuous demand today. With increasing frequency, lubrication programs are successfully accomplishing this feat by interlacing modern strategies and technologies with amazing skill and dexterity. Unfortunately, complacency is occurring among other organizations in bringing about necessary change to capitalize on opportunities in lubrication to reduce operating costs and production losses.

This entry addresses lubrication in the context of a modern maintenance organization in the chemical process industry. Less emphasis is placed on the selection of lubricants as this subject is expansive and exceeds the scope intended for this entry. Instead, emphasis will be on the activity of lubrication, which falls in the domain of those charged with the responsibility of maintenance and machine reliability. Lubrication deals with stability of the lubricant within the machine in controlling friction, wear, and heat generation, among other things.

LUBRICANT SELECTION

Many books have been published on the selection of lubricants for the numerous machine applications requiring their use. As stated above, it is not the objective of this entry to offer engineering advice on lubricant selection. However, owners and maintainers of equipment in process plants should have a basic understanding of the function of a lubricant. If a current lubricant fails to adequately serve these functions, changing the lubricant may be necessary in order to achieve the desired outcome.

The following are the ways that lubricant formulations may be changed to better serve a particular application:

Base Oil Chemistry: The base oil is the foundational building block of a lubricating oil or grease. The base oil can be derived from various sources including petroleum, oil seeds (vegetable), or synthetics. There are many different options to consider within each of these groups. These choices influence the physical and chemical properties of lubricants as well as the performance in a given condition.

Viscosity and Viscosity Index: Viscosity is the most important physical property of a lubricant. It provides strength for the base oil load bearing. The wrong viscosity, too high or too low, can have devastating consequences in terms of machine reliability. Viscosity index (VI) characterizes the degree to which viscosity changes in relation to temperature change.

Additives: The majority of lubricants on the market today employ the use of additives to enhance, suppress, or alter the properties of the base oil. Numerous additives serve varying formulation objectives, including:

- Oxidation inhibitors
- Pour point depressants
- Corrosion inhibitors
- Foam suppressants
- VI improvers
- Dispersants
- Detergents
- Metal deactivators

Grease Thickeners: Grease has nearly identical properties to lubricating oils, with the exception of the inclusion of a thickener, which gives it a solid or a semisolid consistency. Thickeners are often made of soaps of lithium, sodium, aluminum, or calcium. Like base oils and additives, thickeners possess a myriad of positive and detracting lubricating properties.

By matching base oil type, viscosity, VI, additives, and thickener type (for grease) to the lubrication objectives, the optimum composite performance can result. The primary functions of a lubricant in typical machinery applications include the following:

Friction Control: Friction is the enemy of machine reliability and efficient operation. The lubricant protects machine surfaces through either physical separation by viscous forces or by chemical action whereby additives form a ductile lubricating surface film.

Wear Control: Reducing friction and surface contact minimizes the rate of wear and distress to

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120030626

load-bearing machine surfaces. The rate of wear and life expectancy of a machine and its components is largely influenced by the quality of lubrication.

Corrosion Control: Surfaces that become wetted by a lubricant and its additives are typically much less prone to corrosive damage from water, acids, bacteria, and other similar corrosion agents. Additives can neutralize acids as well as form a barrier film, which repels water and other chemically aggressive contaminants.

Temperature Control: In addition to reducing the generation of heat through friction reduction, the lubricant also serves to transport thermal energy from locations where it is generated to locations where it can dissipate by conduction or convection, typically through a heat exchanger.

Contamination Control: Lubricating oils collect contaminants, such as particles and moisture, and transport them to settling tanks, centrifugal separators, filters, etc. Some lubricants, such as crankcase oils, are formulated with additives to disperse contaminants that reduce the risk of deposit formation, corrosion, or premature filter plugging.

Power Transmission: Hydraulic systems utilize lubricating oils to serve all of the above listed functions plus the transfer of force and motion based on the fluids with general incompressibility.

In selecting a well-suited lubricant for a particular application, dozens of factors must be considered relating to load, speed, duty cycle, machine metallurgy, machine type, relubrication interval, lubricant application method, thermal range, contamination, reliability objectives, safety, and environmental issues.[1] Guidance from the original equipment manufacturer (OEM), industry design standards, lubricant suppliers, and specialists in tribology (study of friction and wear) and lubrication is generally well advised.

GREASE AND OIL APPLICATION METHODS

Once the lubricant type has been selected (base oil, viscosity, and additives), a decision must be made regarding the use of either oil or grease. Here, several more factors come into play. Questions that must be considered include:

- What are bearing speeds and loads?
- What is the operating temperature range for the lubricant?
- What type of bearing designs and sizes are used?
- Will the (lubricated) components operate for extended periods without interruption?
- Will the components be accessible during operation?
- Will the process allow for access during operation?
- Are the components exposed to the environment? Can the components be isolated from the environment?
- Are the components intended to be sacrificial (changed frequently)?
- Are the components highly specialized and sufficiently expensive that extra care must be provided to assure maximum protection available from the lubricant?
- Is there risk of the lubricant leaking onto or into the product being produced (or raw materials)?
- Will the lubricant need to be continuously filtered or dehydrated?
- Will the lubricant need to provide heat transfer?
- Will the lubricant need to seal out the possible ingress of contamination?

The reality for the practitioner and equipment maintainer is that the decision regarding the use of oil or grease and the application method is made well before the equipment reaches the plant floor. Still, for many reasons, lubricant selection and the method of application need to be changed or adjusted to best achieve reliability objectives.

Grease Application Methods

A high percentage of bearings and some gearboxes used in industry are only lubricated once, when the machine or component is built. These lubed-for-life machines are generally low duty with limited operational criticality. Service life varies, but 3–6 yr is typical. The cost of relubrication to extend the service life in such applications is found to exceed the value gained. For example, many companies do not relubricate small electric motors of less than 10–20 hp.[1] These motor bearings are typically sealed to control lubricant leakage and contaminant ingress.

Relubrication of larger bearings and gears can often extend service life by two to four times. However, with the practice of relubrication there are always risks or issues that must be considered. These include:

- Cost to store and handle lubricants
- Labor cost to relubricate machines
- Risk of introducing a wrong or an incompatible lubricant
- Risk of overlubricating or underlubricating the machine
- Safety risk associated with the lubrication technician working near operating equipment

Table 1 shows the advantages and disadvantages of common grease application methods.

Table 1 Advantages and disadvantages of common grease application methods

Grease application method	Advantages	Disadvantages
Grease gun (manual)	Simple to use, low front-end cost, technician can inspect machine	High labor cost, long intervals between relubrication, overgreasing a common problem, safety concerns
Grease cups and single-point lubricators—automatically apply grease slowly over a 3–12 month period	Enables lubrication in remote or restricted access areas, reduced labor cost, reduced grease consumption, increased machine reliability	Disadvantages depend on design and may include inconsistent grease delivery rate, temperature limitations, vibration influences, high costs, plumbing and installation requirements
Centralized automated multipoint lubrication system	Low labor cost, positive displacement delivery, continuous lubricant delivery	High hardware and installation costs, occasional reliability and maintenance problems

Oil Application Methods

Unlike grease, the options for introducing oil to a machine are much more varied and machine type dependent. In general, the larger and more critical the machine is to process operation, the more likely the use of oil, instead of grease, is the best option. Among other things, the use of oil facilitates the following capabilities:

- Ability to filter or separate dirt, water, sludge, and other contaminants
- Heat transfer through the use of heaters or coolers to stabilize lubricant and machine temperature
- Lubricant volume control through oil level gauges and constant level devices
- Simplified and more effective lubricant sampling for periodic analysis
- Ability to circulate the lubricant to insure homogeneous properties

While it is often believed that it is easier to grease a bearing than to reoil, the reliability of lubricated components is often enhanced when oil is the lubricant of choice. Table 2 describes the advantages and disadvantages of common oil application methods.

CONTAMINATION CONTROL

Contamination can be defined as any unwanted substance or energy that enters or contacts the oil. Contaminants come in many forms and may be highly destructive to the lubricant, its additives, and machine surfaces. It is often overlooked as a source of failure because its impact is usually slow and imperceptible. While it is impractical to attempt to completely eradicate contamination from in-service lubricants, control of contaminant levels within acceptable limits can be accomplished and is vitally important.

Particles, moisture, soot, heat, air, glycol, fuel, detergents, and process fluids are all contaminants commonly found in industrial lubricants and hydraulic fluids.[2] However, particle contamination is widely recognized as the most destructive contaminant to the oil and machine. This is the reason why the particle counter is the most widely used instrument in oil analysis today. The central strategy to its success in reducing maintenance costs and increasing machine reliability is proactive maintenance.

Proactive and Predictive Maintenance

While the benefits of detecting abnormal machine wear or an aging lubricant condition are important and frequently achieved with oil analysis programs, they are of low importance when compared to the more rewarding objective of failure avoidance. This is achieved by treating the causes of failure, not just the symptoms. Also, it is the foundation of the popular practice known as proactive maintenance.

Whenever a proactive maintenance strategy is applied, three steps are necessary to ensure that its benefits are achieved. Since proactive maintenance, by definition, involves continuous monitoring and controlling of machine failure root causes, the first step is simply to set a target, or a standard, associated with each root cause. In oil analysis, the most important root causes relate to fluid contamination (particles, moisture, heat, coolant, etc.).

However, the process of defining precise and challenging targets (for example, high cleanliness) is only the first step. The second step is achieving and sustaining control of the fluid's conditions within these targets. This often includes an audit of how fluids become contaminated and then systematically eliminating these entry points. Better filtration and the use of separators are often required.

The third step is the vital action element of providing the feedback loop of an oil analysis program.

Table 2 Advantages and disadvantages of common oil application methods

Application method	Advantages	Disadvantages
Manual methods using hand pad, brush or spray bottle	Low upfront cost, generally easy to apply, machine can be inspected by technicians	High labor costs, excess leakage, over supply immediate after application, difficult to perform on the run, safety risks, contamination risks
Drip feed devices (drop feed, wick feed, etc.)	Simple to use, no moving parts, continuous supply, variable feed rate control, easy to inspect and refill supply bowls	Contaminants can interfere for feed control, viscosity/temperature influences on feed rate, on control of contaminant ingression
Constant-level oilers	Better oil level management, low labor cost, better contamination control	Controlling contamination to the wrong oil level, defective level adjustment devices, tendency for feed supply tube to clog
Oil lifter devices, including oil rings, collars, slingers, paddle gears, and flingers	Machine self-lubricates without additional external hardware, low labor costs	Some devices are highly sensitive to oil level, oil viscosity/temperature, foaming conditions, wear, and operating speed. Also, dry start risks, sediment buildup risks
Bath and splash lubricated machines (typically gearing and bearings)	Machine self-lubricates without additional external hardware, low labor costs	Some are highly sensitive to oil level, oil viscosity/temperature, foaming conditions, and operating speed. Also, dry start risks, sediment buildup risks
Spray and mist lubrication systems–machines being lubricated by a directed spray of oil or oil mist	Low risk of contamination, no oil level control risks, improved machine reliability	High cost of hardware and installation, viscosity/temperature limitations, application limitations
Wet-sump and dry-sump circulating oil systems	Excellent cooling capabilities, enables use of filters and separators, multiple lube points can be supplied at once, low labor cost, the most representative oil sampling, limited oil volume control risk	Expensive hardware installation, leakage risks, large volume of oil required, possible aeration and foaming risks

When exceptions occur (for example, over target results), remedial actions can then be immediately commissioned. Using the proactive maintenance strategy, contamination control becomes a disciplined activity of monitoring and controlling high fluid cleanliness, not a basic activity of trending dirt levels.[3]

Finally, when the life extension benefits of proactive maintenance are flanked by the early warning benefits of predictive maintenance (PMs), a comprehensive condition-based maintenance program results. While proactive maintenance stresses root-cause control, PMs targets the detection of incipient failure of both the properties of the fluid and machine components such as bearings and gears. It is this unique, early detection of machine faults and abnormal wear, which is frequently referred to as the exclusive domain of oil analysis in the maintenance field (Fig. 1).[4,5]

Managing Particle Contamination

There is no single property of lubricating oil that challenges the reliability of machinery more than suspended particles. Very small particles can ride in oil almost indefinitely and, because they are not as friable (easily crumbled) or filterable as larger particles, the destruction can be continuous. Many studies have proven that greater damage is associated with small particles (Fig. 2).[5] Still, most maintenance professionals have misconceptions about the size of particles and the associated harm caused.

These misconceptions relate to the definitions applied to clean oil and dirty oil. It is this definition that influences the setting of appropriate target cleanliness levels for lubricating oils and hydraulic fluids. While there are numerous methods used to arrive at target cleanliness

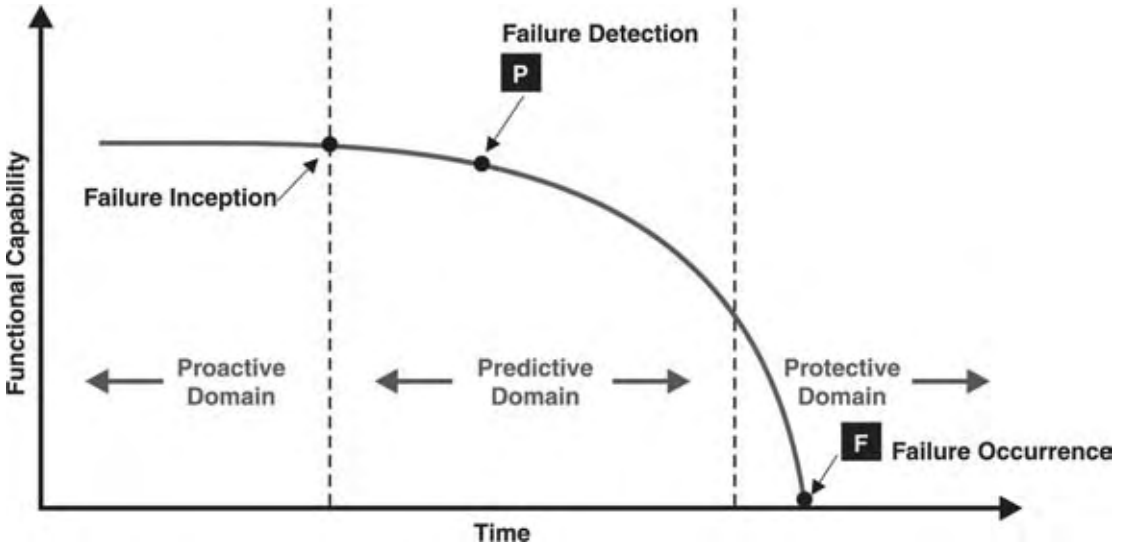

Fig. 1 Condition monitoring domains in the PF interval curve. *(View this art in color at www.dekker.com.)*

levels for oils in different applications, most combine the importance of machine reliability with the general contaminant sensitivity of the machine to set the target.

There are many expensive ways to achieve clean oil but experience has taught us the wisdom of contaminant exclusion—treating the cause not just the symptom. By effectively excluding the entry of contaminants and promptly removing contaminants if they do enter, the new cleanliness targets are frequently achieved. Concerns that filtration costs will increase are not often broached due to the greater overall control, especially from the standpoint of particle ingression.

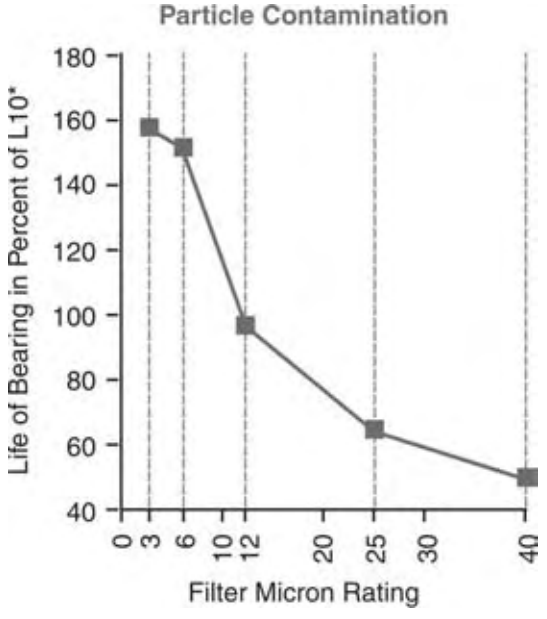

Fig. 2 Particle contamination vs. bearing life. *(View this art in color at www.dekker.com.)*

Managing Moisture Contamination

Moisture, when it contaminates hydraulic and lubricating oils, has a degrading effect on both the lubricant and the machine. For instance, when bearing lubricants are contaminated with less than 0.1% water, more than 75% of the bearings design life can be lost (Fig. 3).[6] Some additives adsorb to the water and are removed when the water separates from the oil while others are destroyed by water induced chemical reactions. Water also promotes oxidation of the oil's base stock, causes rust and corrosion of machine surfaces, and reduces critical, load-bearing film strength.[7] In summary, water represents a serious risk to equipment and should be aggressively controlled.

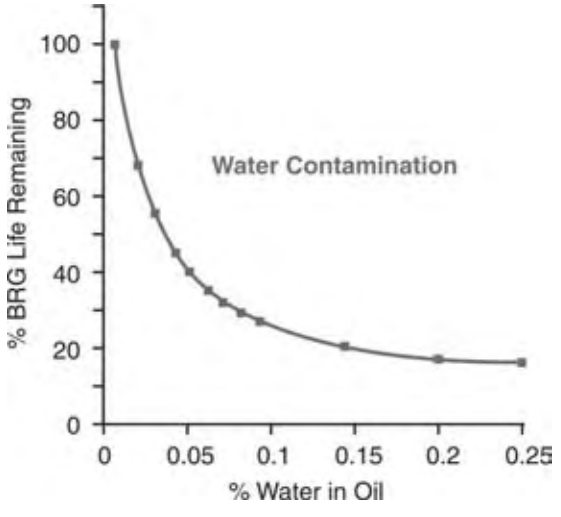

Fig. 3 Moisture contamination vs. bearing life. *(View this art in color at www.dekker.com.)*

Water coexists with oil in either a dissolved state or a free state. In a dissolved state, single water molecules are distributed throughout the oil due to the water's chemical attraction to the fluid. Numerous factors such as viscosity, base-stock type, base-stock condition, impurities, and additive package determine the volume of water that the oil will dissolve. The dissolved volume is a function of the oil's temperature; thus the ''humidity'' is reported as relative humidity, depending upon the temperature. If the oil has dissolved all the water it can at a given temperature, it is saturated. The dissolved water is very difficult to control and does only minimal harm to the machine and oil.[8] Free and emulsified water pose the greatest risk to the machine and they, besides the lubricant, should be placed under strict control.[9]

Along with particle contamination, it is important to monitor the presence of water in lubricating oils. Various methods are available to accomplish this including many simple field techniques. Once an abnormal level of water is observed, corrective action should be performed to dehydrate or change the oil.

Managing Air Contamination

Air may not immediately be thought of as a contaminant, but the presence of air in its various forms may have an impact on the ability of the lubricant to perform its design function. Almost all lubricating oil systems contain some air. Air is found in four phases: free air, dissolved air, entrained air, and foam. Free air is trapped in a system, such as an air pocket in a hydraulic line, and may have minimal contact with the fluid. It can be a contributing factor to other air problems when lines are not bled properly during equipment startup and free air is drawn into circulating oils.

Dissolved air is not readily drawn out of solution. It becomes a problem when temperatures rise rapidly or pressures drop. Petroleum oils contain as much as 12% dissolved air. When a system starts up or when it overheats, this air changes from a dissolved phase into small bubbles. If the bubbles are very small in diameter, they remain suspended in the liquid phase of the oil, particularly in high viscosity oils. This can cause air entrainment, which is characterized as a small amount of air in the form of extremely small bubbles dispersed throughout the bulk of the oil. Air entrainment is treated differently than foam and is typically a separate problem. Some of the potential effects of air entrainment include pump cavitation, spongy and erratic operation of hydraulics, loss of precision control, vibrations, oil oxidation, component wear due to reduced lubricant viscosity, equipment shutdown when low oil pressure switches trip, microdieseling due to the ignition of the bubble sheath at the high temperatures generated by compressed air bubbles, safety problems in turbines (if overspeed devices do not react quickly enough), and loss of head in centrifugal pumps.

Foam, on the other hand, is a collection of closely packed bubbles surrounded by thin films of oil that float on the surface of the oil. Generally, foam is cosmetic, but it must be treated if it makes oil level control impossible, if it spills onto the floor to create a safety or a housekeeping hazard, causes air locks at high points, or is so extreme that the equipment is lubricated with foam. Small amounts of foam do not necessarily need to be treated unless the system suffers from the air entrainment conditions listed here, although the presence of the foam may be symptomatic of a more serious problem.[10–12]

Managing Soft Contaminants (Oxides, Sludge, and Varnish)

The products formed from the oxidation of oil include weak carboxylic acids, sludge, and varnishes. The weak acids can be titrated by acid number (AN) testing and, when quantified, give an indication of the degree of oxidation of the oil. The approach of detecting and analyzing sludge and varnish problems in machinery is not the same as that used in oil analysis. In many instances this is because the evidence is not always in the oil. The sludge and varnish should be analyzed directly, using a different set of tests and evaluation parameters. Still, used oil analysis plays an important diagnostic role in helping to reveal candidate causes, as well as to rule out others.

The conditions that most commonly lead to sludge and varnish problems vary, which complicates the process of identifying the root cause analytically. There are at least 25 unique lubricant degradation mechanisms leading to sludge or varnish formation, including:

- Aeration of the fluid
- Sparking from static electricity
- Bulk thermal degradation
- Antifreeze contamination
- Soot coagulation
- Bulk oil oxidation
- Hydrolysis
- Prolonged cold storage
- Grease-contaminated oil
- Caustic detergent contamination
- Nitration
- Coking on hot surfaces
- Radiological contamination
- Poor engine combustion efficiency and blow-by
- Highly aromatic fuels

- Sulfation (fuel, H_2S, etc.)
- Lead corrosion reactions
- Reactive compressor gases
- Additive incompatibilities
- Base oil incompatibilities

Lubricants degrade in different ways and the products of this degradation are essentially referred to as sludge and varnish. These products are generally unstable in the oil and look for a place to deposit themselves. In certain instances, the deposits form on machine surfaces at the exact location where the oil has degraded, for example, hot surface coking. In other cases, the oil degrades in one location but deposits condense on a surface elsewhere.

The deposits that form on machine surfaces interfere with the fluid performance and the machine's mechanical movements. They can also contribute to wear and corrosion, or simply cling to surfaces. For example, deposits on the spool of a servo control valve can tighten the interference fit between the spool and the bore. Compounding this are the adherence properties of varnish, which can stick particles from the oil to silt lands, thus leading to common silt-lock valve failure. Other types of sludge and varnish-type failures include plugged orifices, damaged mechanical seals, plugged discharge ports on compressors, journal-bearing failure, premature plugging of oil filters, and diesel engine combustion-zone wear.[13–17]

Contaminant Exclusion and Removal

In many machines, the exclusion of contamination is the only way to control contamination. This is because these machines either do not have a filter or the filter in use is coarse, providing no practical protection in the particle size range of critical oil films. When contaminants are not removed by filtration or separators, a lubricant's contaminant level equals the machine's service hours multiplied by the contaminant amount ingressed per hour (ingression rate). For machines exposed to high ambient dust, particle counts can exceed recommended levels in just a few hours.

Even machines with good filters and separators are faced with ingression challenges. To maintain contaminant levels within targets, the filter must remove contamination at a rate equal to the ingression rate (mass balance). The lower the target cleanliness level, the more difficult this becomes. This is because fluids must stay within these high cleanliness targets, but by definition, particles are not densely packed in the oil but rather are sparsely distributed. This means that for every gallon of fluid that enters the filter, there are few particles from that gallon that are available to remove. Yet the filter must still remove particles at a rate equal to the ingression rate, otherwise the contaminant level will rise. This places increasing demand on the quality and capture efficiency of the filter (percent particles removed above a certain size).

The flow rate of the oil entering the filter is also a strong influence. The flow provides the necessary conveyance of particles to the filter. If flow rates are low, filters with even 100% capture efficiency cannot remove enough particles to keep up with ingression, causing contaminant levels to exceed targets. The higher the target cleanliness, the higher the minimum required flow rate for a given filter. After all, a filter can only remove particles it comes in contact with. Some by-pass and kidney loop (off-line) filters have flow rates that are

Table 3 Capabilities of filters and separators in removing contaminants of various types

inadequate for stabilizing target cleanliness levels. Table 3 shows the capabilities of filters and separators in removing contaminants of various types.[18]

It is often said that the cost of excluding a gram of dirt is only about 10% of what it will cost once it enters the oil. Dirt places stress on additives, the base oil, and machine surfaces. Therefore, the cost to filter a gram of dirt from the oil is much higher than that of filtering a gram of dirt from the air intake/breather.

The word ingression refers to the introduction of particles into lubricants and hydraulic fluids regardless of the source (external or internal). Fig. 4 organizes common sources into three subcategories: built-in, ingested, and generated. Depending on the nature of the machine, the ingression rate and sources may vary considerably. For clean-environment indoor equipment, the primary sources can be from process fluids and internal generation (wear, corrosion, etc.).[19]

For many machines, reducing ingression means reducing top-end ingression of the particles entering through fill ports, vents, breathers, hatches, inspection ports, shaft seals, and other headspace openings. There are numerous ways to control top-end ingression in reservoirs, sumps, gearboxes, and bearing housings, as described below.

Purge methods

This involves the introduction of a clean gas or an aerosol into the headspace of the machine. A slight positive pressure is maintained to prevent the entry of ambient air. Examples include instrument air purge, oil mist purge, and nitrogen purge.

Isolation methods

Expansion chambers, piston/cylinder reservoirs, and bladders have been used to isolate headspace air from ambient air to prevent contamination. One disadvantage is that original moisture (humid air) is often unable to escape from the headspace, causing moisture to lock into the oil. In some cases, users have reported that this has led to heavy corrosion.

Filter breathers

If reservoirs and sumps can be tightly sealed so that all air exchanged between the atmosphere and the headspace can be directed through a single port, then high-quality filter breathers can be used to remove dust from incoming air at that port (vent). The quality of the filter (capture efficiency) should be no less than that of the oil filter in use.

LUBRICANT SAMPLING AND ANALYSIS

Lubricant sampling and analysis is a broad field comprising the activities of monitoring, reporting, and responding to information obtained from the analysis

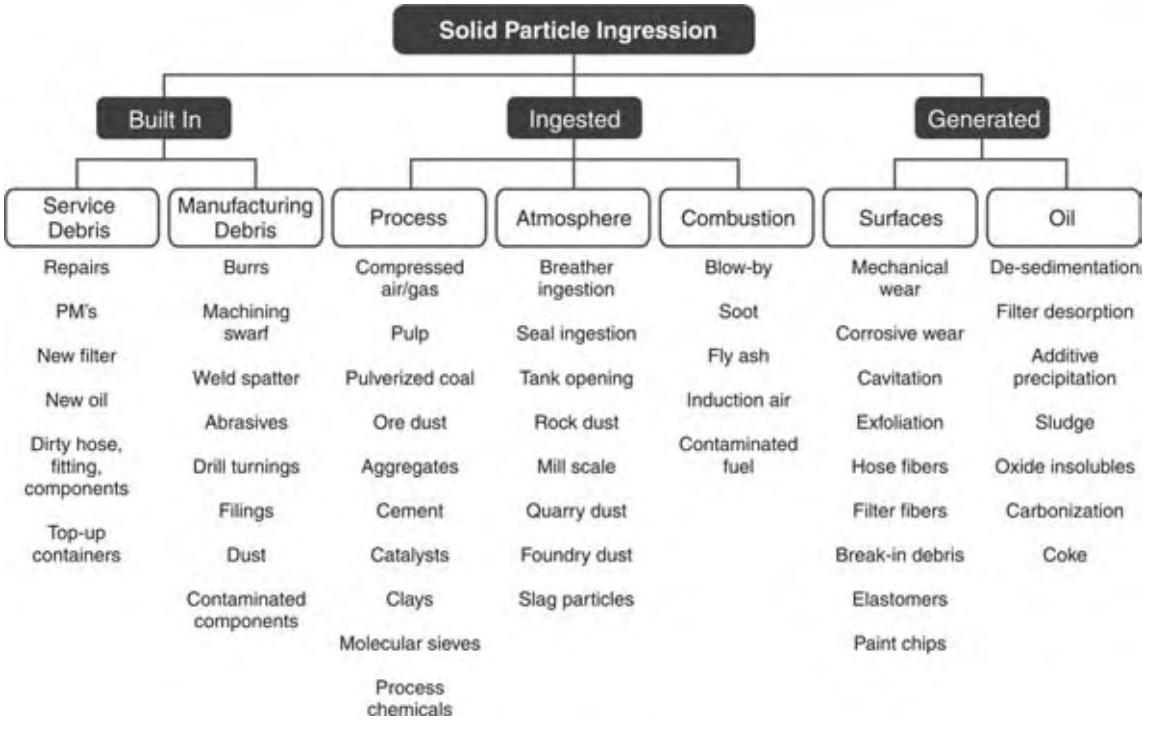

Fig. 4 Sources of particle contamination. *(View this art in color at www.dekker.com.)*

of grease, lubricating oils, and hydraulic fluids. Because the practice also encompasses the analysis of used grease and hydraulic fluids, this discussion will generically refer to the entire practice as ''lubricant analysis.'' Greases, hydraulic fluids, synthetic fluids, and lubricating oils are all lubricants and can be generally analyzed by similar methods.

Lubricant analysis involves numerous activities with the following objectives:

- Optimize machine reliability, productivity, and profitability.
- Reduce maintenance and operating costs.
- Minimize safety risks or related hazards.
- Reduce friction, heat, and energy consumption.
- Protect the environment, including air and water.
- Reduce the consumption of lubricants.

Many different types of conditions can be analyzed and reported through lubricant analysis. Commonly reported conditions include:

- Quality and condition of new oil deliveries.
- Distressed, degraded, or noncomplying in-service lubricant properties.
- Lubricant contamination.
- Abnormal root cause or stressing condition.
- Wear debris composition and physical characteristics.
- Leakage.
- State of lubricants in storage.

The methods of gathering and analyzing lubricant properties and conditions vary widely. Analytical instruments and procedures are often employed in a laboratory to determine important properties of routinely sampled lubricants. Similar instruments can be used remotely in the plant. This practice is often referred to as ''onsite analysis.'' In certain cases the instruments or sensors can be used in real time, dedicated to a specific machine and fluid. The management and reporting of lubricant analysis data is typically conducted with the aid of a computer and software developed for this purpose.

Objectives and Benefits of Lubricant Analysis

Lubricant analysis benefits the organization in several ways before, during, and after the occurrence of machine failure. Before the onset of failure, lubricant analysis confirms that the machine contains the correct lubricant and that the lubricant is physically and chemically fit for service. It also confirms that contamination levels are within tolerable limits. Lubricant analysis can be an important tool in the efforts to ensure the quality of new lubricant deliveries, storage effectiveness, and reclamation activities. Lubricant analysis helps to verify that lubricants are fit for service. These are proactive applications of lubricant analysis that have the potential to extend the life of the machinery.

When a machine fails, wear debris, which is detectable using lubricant analysis, is often produced in advance of any observable operational deterioration (Table 4). The early warning of lubricant analysis provides options for the maintenance professional. Also, lubricant analysis plays a key role in diagnosing problems once they are detected. When a problem is detected, operations personnel can inquire about the projected time interval to failure or the probability that the machine will last until a defined date. Failure prognostics, the process of estimating residual machine or lubricant life, is generally the least precise of the condition-monitoring activities, although it can still provide useful insight. Prognostic forecasts are improved when multiple data parameters are measured and defined.

When a machine fails, users analyze the oil from the failed machine. The oil often contains the remnants of the failure. This information can be used for the deployment of root-cause control measures to prevent similar failures in the future.

Strategic alignment of lubricant analysis to organizational objectives often begins with an audit of the program's component parts. The audit should identify the program's strengths and weaknesses and evaluate how resources are allocated. Often, the audit reveals that a machine was brought into a lubricant analysis program for the wrong reasons. The decision to include a machine for routine lubricant analysis must be based upon the effect a failure will have on production, safety or environmental compliance, the cost to repair or restore the equipment, and/or the likelihood that a failure will occur.

In some cases, the desire to avoid an unnecessary oil change or simply to extend oil drain intervals is an important objective, resulting in reduced lubricant consumption and associated costs. Mission criteria should also influence those machines that should be sampled, the frequency of lubricant analysis, and the types of tests that are conducted. Some machines are more operationally critical than others. They deserve more resources from maintenance technologies. The likelihood that failure will occur and specific challenges (high temperature, risk of contamination, etc.) faced by the lubricant are also factors that influence the type of lubricant analysis and the sampling frequency decision.

Well-implemented lubricant analysis can help optimize the use of maintenance and reliability resources to achieve improved machine reliability and reduced operating and maintenance costs. In certain hazardous

machinery applications, lubricant analysis can help ensure the safety of machinery. When combined with optimum lubrication practices, including the application and selection of lubricants, routine lubricant analysis can reduce energy consumption and waste stream emissions.

Oil Sampling

Oil sampling is a critical factor in successful lubricant analysis. Errors in obtaining a representative sample can impair all further analytical efforts. There are two primary goals in obtaining a representative oil sample. The first is to sample in a way that the information density in the oil is maximized, which is often referred to as maximizing data density. The data could be particles from dust, moisture, additive levels, and wear debris.

The second goal is to minimize data disturbance. Samples should be carefully extracted so that the concentration of information is uniform, consistent, and unaltered by the sampling process. It is important to make sure that the sample does not become contaminated during the sampling. This can distort the data, making it difficult to distinguish what was originally in the oil from what has come into the oil during the sampling process.

To ensure good data density and minimum data disturbance in oil sampling, the following factors should be considered:

Sampling Location: Not all locations in the machine will produce the same concentration of data. Some machines require multiple sampling locations to answer specific questions related to the machine's condition, usually on an exception basis.

Sampling Method: The procedure by which a sample is drawn is critical to the success of lubricant analysis. Sampling procedures should be documented and followed uniformly.

Sampling Hardware: The hardware used to extract the sample should not disturb sample quality. It should be easy to use, clean, rugged, and cost effective.

Sample Container: The type of bottle and cleanliness (ISO 3722) of bottle help ensure that a representative sample is achieved.

It is always advised to expend the necessary resources to equip machinery with proper sampling hardware (valves, access ports, etc.) to ensure that the above goals in oil sampling are achieved.

Testing Strategy

In its simplest and most basic form, lubricant analysis is performed to improve the quality of machine and lubrication maintenance decisions. When analysis is well designed and implemented, many necessary questions about the machine and lubricant can be answered without excessive expense or complexity. This is best accomplished by directing the testing program around three important categories of lubricant analysis:

Fluid Properties Analysis: This category of lubricant analysis deals with the assessment of the chemical, physical, and additive properties of the oil. The testing here confirms that the lubricant is in compliance with the originally specified performance properties.

Contamination Analysis: Contaminants of various types can enter the system and the lubricant from the environment during servicing or by internal generation. Contamination compromises machine reliability and promotes lubricant failure. Lubricant analysis targeting contamination can help ensure that goal-driven targets for contamination control are maintained.

Wear Debris Analysis: When machine surfaces wear, they generate metallic particles that enter the lubricant. Monitoring and analyzing the generated debris enables analysts to detect and evaluate abnormal conditions to assist in directing needed maintenance activities.

Tests selected for routine condition monitoring vary between lubricant types and machine application tests. However, numerous tests are almost always performed (viscometry and elemental spectroscopy for instance) while others are optional or exception tests. An example oil analysis test scheme for a particular lubricant is illustrated in Fig. 5. The following are the types of tests commonly performed in laboratories:

- Viscosity
- Particle counting
- Infrared spectroscopy
- Acid number or base number
- Oxidation stability
- Ferrous density
- Microscopic particle identification
- Elemental spectroscopy
- Water concentration tests
- Flash point

Test results are compared to historic trends and/or alarm levels set to alert equipment owners of nonconforming conditions. Practitioners of modern oil analysis programs receive data from laboratories electronically and only review data on an exception basis.[19,20]

PMS AND ROUTINE INSPECTIONS

Mechanics and/or operators regularly inspect machines. In most cases, the equipment is inspected every day and in some instances, every shift. Such

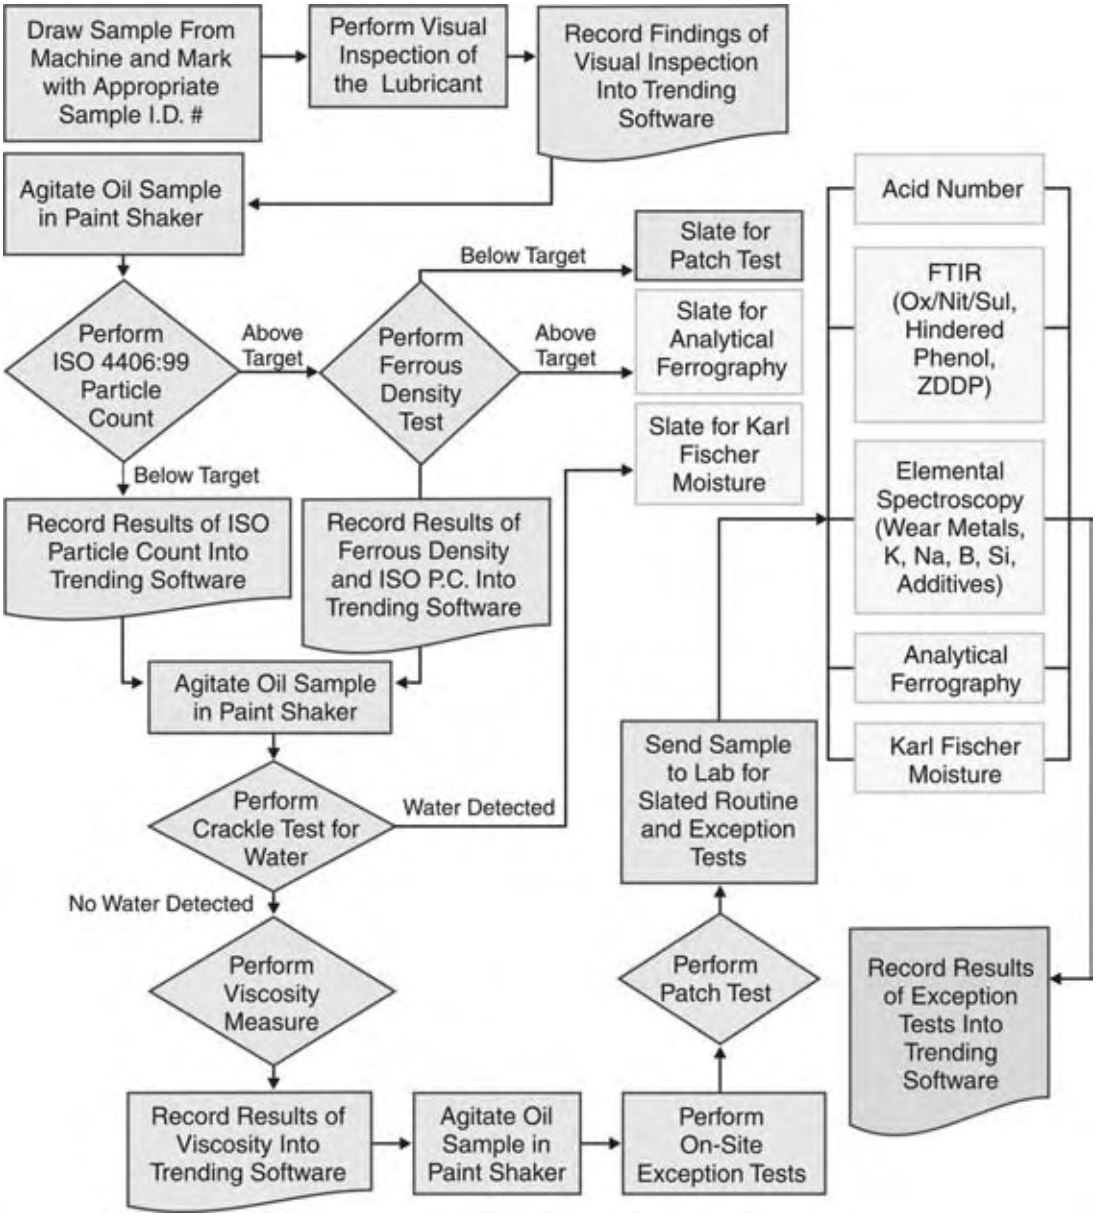

Fig. 5 Example routine and exception test slate. *(View this art in color at www.dekker.com.)*

inspections provide an excellent opportunity to verify that proper machinery lubrication is in order. Many variables can be quickly and easily monitored in a short amount of time. These inspection items can be revealing and will serve as the foundation of a precision lubrication management program.

Every plant, and for that matter every machine, will require a slightly different inspection routine and frequency. Below are six items to consider when setting up an inspection program.

Frequency: Not all machines in the plant are created equal. Some are highly critical and should be inspected on a regular basis, in some cases every shift or every day. Others require only weekly, biweekly, or monthly inspection. Because the lubrication inspection process is simple, it is always advised to err on the conservative side and inspect the machines frequently. The program can always be adjusted at a later time. When deciding on the frequency of inspections, consider the machine's propensity to fail, its impact on production, and the cost, time, and difficulty of restoring it upon failure. Too often, the sump volume is the primary determining factor. Sump volume is an easy way to group machines, but the cost of the lubricant is usually the least of a company's concerns.

Observed Parameters: For many machines, the number of observable parameters can reach into hundreds or even thousands. Obviously some priorities

must be established. It is best to select inspection parameters based upon their relative importance. How will an aberration affect the machine's performance? How frequently do detectable problems occur with a given inspection?

Training: Those performing the inspections must have some understanding about machinery lubrication, contamination control, etc. It is not necessary for them to be experts in the area as long as they have experts to turn to, but they do need a basic understanding. Inspectors also require task-based training on performing the inspection. For example, they must know that the desiccant is deemed failed when it turns from blue to pink. Modern machinery lubrication practices will be new to many of the people performing the inspections. Don't hold the team accountable unless they have been properly qualified to do the job.

Collection Mechanism: The trusty index card will work for performing inspections, but this requires the individual to remember the inspection criteria or refer to an inspection list and make notes about observations. A clipboard with a predefined set of questions (that can be answered "yes" or "no") for each machine is a definite improvement on the index card method. Be sure to leave a space for comments. Both the index card and the clipboard approach require manual entry of the data once they are collected. A more modern approach is to set up the inspection in an industrial-quality personal digital assistant. For each machine, the inspector can answer "yes" or "no," and as required, write short comments. These comments could be selected from a drop-down menu to minimize inconsistency. The data can then be uploaded to a host computer for storage. This speeds the process, ensures that the data will be captured, and reduces transposition errors.

Information Management: Be sure to track inspection findings carefully. Software is the best method because it can keep inspection data where other machine condition information is kept in order to facilitate diagnostics and failure root-cause analysis. Tracking the data helps identify frequently recurring problems, or lubrication "bad actors." It also helps optimize inspection frequency. It may be necessary to assign a number (typically 0 and 1) to the nominal ("yes" or "no") data collected to conform to the requirements of the software used. Some questions will be answered "yes" if things are OK, while others will be answered "no" if things are OK.

Remaining Steps: It seems that anytime a problem is encountered with any part of the lubrication system, an oil change is immediately scheduled with the assumption that the problem will be solved. This is referred to as lazy lubrication maintenance. Indeed, in certain cases the oil must be changed as a part of a complete and a cohesive corrective action. However, in many cases, an oil change is not required. Investigate the problem, identify its root cause, and implement a thoughtful corrective action that addresses the problems and eliminates any unnecessary steps.

Fig. 6 illustrates a list of recommended inspection items. Not all the items listed will be appropriate for all plants, and some additional items might need to be added to meet special needs. Also, some of the items listed are not routine, such as the evaluation of used filters and failed parts; hence, the work will need to be appropriately divided among operators, lubricant technicians, condition-monitoring technicians, and plant engineering.

Ineffective lubrication remains one of the leading causes for machinery failure. Routine inspection of the machine's lubrication system is among the easiest and most productive ways to avoid equipment failure and should play a pivotal role in the pursuit of precision lubrication. This program allows the operators and the mechanics who perform the routine inspections to have a better awareness of the importance of effective lubrication, resulting in the improvement of the quality of lubricant application.[21]

DEVELOPMENT OF PROPER LUBRICATION PROCEDURES

Despite overwhelming evidence suggesting that poor machinery lubrication spells trouble for the plant, most organizations lack clearly defined written procedures for performing basic lubrication tasks. The following outlines reasons why lubrication procedures are important elements of a proper lubrication procedure.[22]

The Importance of Lubrication Procedures

Work Scope: Procedures clearly scope the work an individual is expected to perform. They ensure work is executed the way management or engineering requires. If management wants 12 shots of grease pumped into the bearing, allowing 15 sec to elapse between shots, this desire can be clearly documented in the procedures.

Consistency: In the absence of procedures, five technicians are apt to perform the same task five different ways. In the absence of a procedure, each individual has the freedom to "personalize" the task at hand. Inconsistency produces undesirable results. Documented procedures bring uniformity into the lubrication task while keeping everyone on the same page.

Best Practices: A procedure creates the framework for standardizing best practice. It serves as the

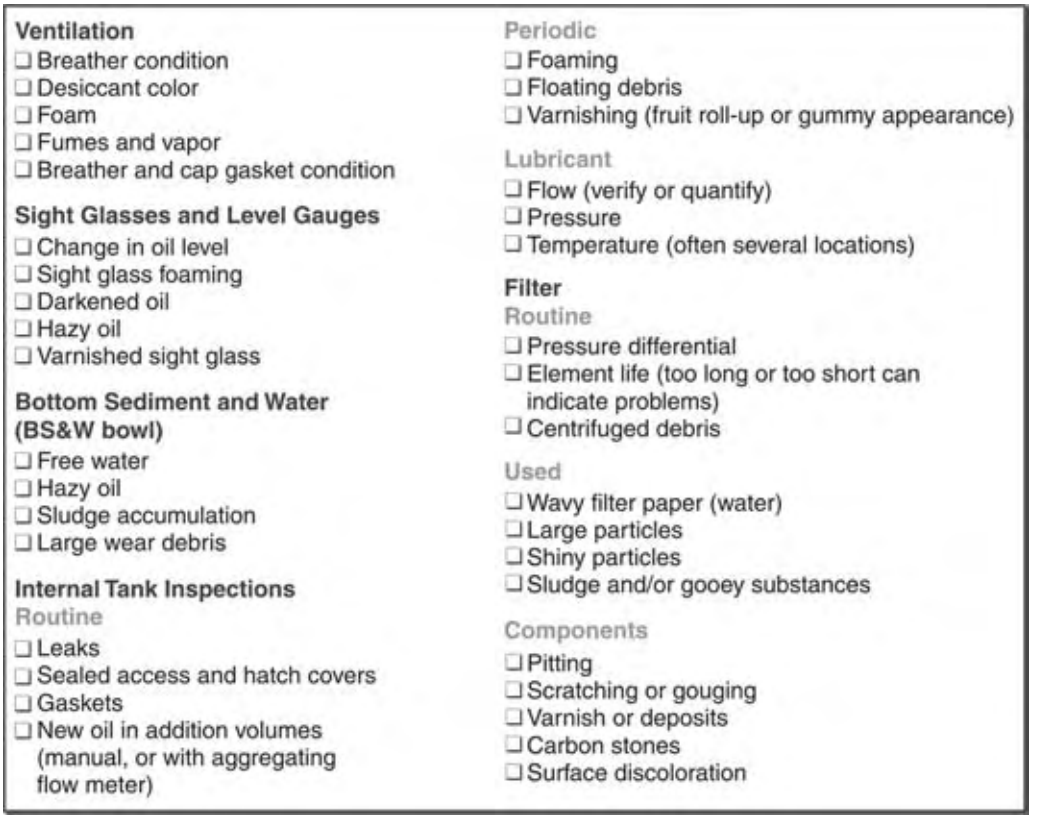

Fig. 6 Recommended inspection list. *(View this art in color at www.dekker.com.)*

container that gathers the experience and expertise of employees, outside consultants, vendors, and others into a single document. This convergence process also enables the team to align the procedure to the goals of the organization. Just enough ''best practice'' for one machine may be too much for another, depending upon the relative importance of the two machines to plant operations, even if they are identical in design.

Training: Lubrication procedures form the basis for training lube technicians. Basic training about lubrication, lubricants, oil analysis, etc. is designed to provide the foundation that enables the individual to think like a lube technician. Certification is another important part of the training process because it confirms that the individual possesses the skills to perform the job functions. This is called technology training. While it is important, technology training fails to convey specific task-based instructions for completing a lubrication-related work order. A set of procedures serves as a natural curriculum for task-based training. It also serves as the basis for evaluating an individual's ability to carry out the assigned tasks. Combining basic technology training and third-party certification with task-level training and skill verification creates a powerful combination and a valuable employee.

Elements of an Effective Lubrication Procedure

Emphasize Best Practice: As previously mentioned, procedures enable the incorporation of best practice. However, this is not automatic. A concerted effort must be made to build best practice into the procedure. Access the experience and knowledge of a maintenance team and bring in outside support as required to ensure that procedures are up-to-date and aligned with the business goals.

Communicate Clearly: Use clear, easy-to-understand language when creating procedures. Also, use digital photographs to reduce the procedure's dependence upon words. For intricate tasks, a digital video is an excellent way to communicate tasks that are difficult to describe orally. The best are procedures that include a top-view of the plant along with easy-to-spot landmarks that reveal the location of the machine. Getting to the right machine is the first step.

Electronic: Prepare lubrication procedures in an electronic form, preferably on a company-wide intranet, or onto an internet account for those who are moving toward web-based application support. When the procedures are electronic, they can be updated globally, attached to work orders, and linked to like

machines in a computerized maintenance management system system. Digital photographs and video images can be easily attached to a document. Documenting procedures electronically is more efficient and effective than the paper and three-ring binder method.

Continuous Improvement: Unfortunately, there is a downside to procedures. Without management, they can anchor the organization to the past, inhibiting the inclusion of new technology and best practices. Make sure the program includes a periodic review and improvement process to update and upgrade lubrication procedures. Keeping procedures in an electronic form simplifies continuous improvement because updates do not require tedious activities to physically replace pages in the lubrication manual. Changes can be documented and communicated in one memorandum, while updating the procedures themselves requires only the touch of a button.

There are a number of important areas that should be covered by lubrication procedures. These include the following:

- Cleaning and reconditioning of lubricant containers.
- Flushing machines and systems after overhaul and repair.
- Draining and refilling oil into a machine.
- Using a grease gun and other similar lubrication practices.
- Adding grease to single-point lubricators or centralized systems.
- Changing oil filters, separators, and breathers.
- Using a filter cart.
- Handling and disposing of waste oil/grease.

ACCESSORIZING EQUIPMENT FOR PROPER LUBRICATION

Many OEMs include only the minimum equipment for lubrication as a part of the original bill-of-material. Anything else is optional and therefore frequently left out. While these options add to the cost, many generate real value when selected. Following is a list of lubrication-related hardware and accessories that, where suitable for a particular machine and application, could and should be factory-installed. If not, they will need to be retrofitted onsite.[23,24]

Inspection

- Level gauges—located near fill ports and large enough to easily determine oil level.
- Expanded-metal guards on chains, couplings, belts, etc. Sheet-metal guards restrict easy inspection of lube points and moving seal parts.
- BS&W bowl—bottom sediment and water (BS&W) sight glasses enable quick inspection of low-lying contaminants and sludge.
- Mag plugs—magnetic drain plugs and other magnetic inspection devices enable wear metals to be examined and removed from lubricating oil.
- Large reservoirs and sumps should be equipped with inspection hatches and should have lips, gaskets, and compression clamps/bolts to control accidental dirt entry, ingression (dirt, wash-down sprays, etc.), and air movement.

Oil Sampling and Analysis

- Primary sampling ports/valves should be properly located and installed at the factory.
- Secondary sampling port/valves should be installed on various circulating systems.

Contamination Control

- All circulating systems should have quality beta-rated oil filters at a capture size and efficiency consistent with contamination control objectives.
- High-performance breathers should have capture size and efficiency consistent with contamination control objectives.
- Hydraulic cylinders should be equipped, where practical, with rod boots to control ingression.
- Reservoirs should have suitable baffling and be sized to enable contaminants to settle (dirt, water, sludge) and both air and gaseous contaminants to detrain.
- Dust protection covers should be installed where grease fittings are used.
- Off-line filters (kidney loop) should be installed on many bath/splash-lubricated machines.
- Headspace purge or other suitable headspace management equipment should be used with large reservoirs.

Instrumentation (Where Practical and Needed)

- Fluid pressure gauges.
- Flow meters.
- Temperature gauges.
- Free water alarm.
- Low oil-level alarms.
- Pressure differential gauges and filter bypass alarm.
- Air-intake vacuum gauges for diesel engines and breathers.

- Online oil properties' sensors: viscosity, ferrous density, particle count, moisture, etc.
- Headspace dew point meters.

Lubrication

- Optimum selection of lubricant delivery devices based on equipment performance needs drip, circulating, oil mist, splash oiled, constant-level oilers, single-point lubricator, grease fittings, centralized lube system, spray systems, etc.
- Optimum selection of seal type and quality for long-life service to control the ingress of contaminants and leakage.
- Use of temperature management systems, including heaters (start-up) and coolers as needed.
- Availability of grease purge ports where grease fittings are used.
- Proper selection of rolling-element bearing seals and shields.
- Proper use of lubricant return-line diffuser to control tank aeration.
- Installation of prelube system for engine cold-starts.
- Installation of power-flush quick- connects on tanks, reservoirs, and sumps.

LUBRICATION PROGRAM METRICS

Any pursuit intended to produce excellence needs a performance metric—machinery lubrication is no exception. If used properly, a performance metric works like a compass for the organization. It helps the users find their bearings and get back on track when performance is substandard. Once the organization performs on target, metrics help to keep it on track and facilitate continuous improvement. Likewise, it can serve as a common denominator for comparing plants within the organization, or even benchmarking entire industries. Performance metric also serves to push the team in the right direction. When the team is aware that something is being measured, trended, and managed, their behavior is affected.

Many organizations presently measure overall equipment effectiveness (OEE), which is the product of Availability $\times$ Quality rate $\times$ Yield.

Simply stated, OEE measures the plant's performance compared to the theoretical maximum production rate for the assets. It is a powerful metric that gives management an overall look at production effectiveness and eliminates the practice of hiding reliability shortcomings into scheduled downtime.

The metric overall lubrication effectiveness (OLE) (Fig. 7), employs a similar structure as the OEE, but focuses on variables that constitute effective machinery lubrication. The general equation for OLE is the product of the following three lubrication program-related factors:

- Percent compliance to scheduled lube PMs.
- Percent compliance to contamination control targets.
- Percent compliance to lubricant quality targets.

OLE measures an organization's performance in machinery lubrication, a critical input to machine reliability, and ultimately, profitability. Percent compliance to each of the target goals was selected because it is easy to calculate and understand. If OLE increases toward the target or holds steady above the target, it is heading in the right direction. If the OLE begins to trend downward, or holds steady below the target level, an intervention needs to occur in order to make corrective actions. The input variables are now discussed in more detail.

Calculating OLE

$$\mathrm{OLE} = \mathrm{PClpm} \times \mathrm{PCcct} \times \mathrm{PClqt}$$

where OLE, overall lubrication effectiveness; PClpm, percent conformance–lube PMs; PCcct, percent conformance–contamination control targets; and PClqt, percent conformance–lube quality targets.

Percent Compliance to Scheduled Lube PMs

Many lubrication tasks are scheduled activities related to performing inspections, sampling for oil analysis, regreasing, top-ups, and scheduled oil changes (where condition-based oil changes are not feasible). Several common problems exist with respect to completion of scheduled PMs. First, supervisors often pull designated technicians away from lube PMs to help with repair or to perform a number of other tasks within the plant. In some plants, lube technicians are called away from lubrication tasks 50% of the time or more. These PMs either pile up or get canceled, so they are not completed until the next time they come up on the schedule. Another problem, often referred to as ''pencil whipping,'' is the act of falsifying PM completion forms. This occurs when technicians have an overly heavy workload or they fail to see the relevance of a particular PM or group of PMs.

The keys to success in performing lubrication PMs include:

- Optimize PM tasks so that each one is relevant.
- Develop easy-to-follow written procedures for completing the tasks.

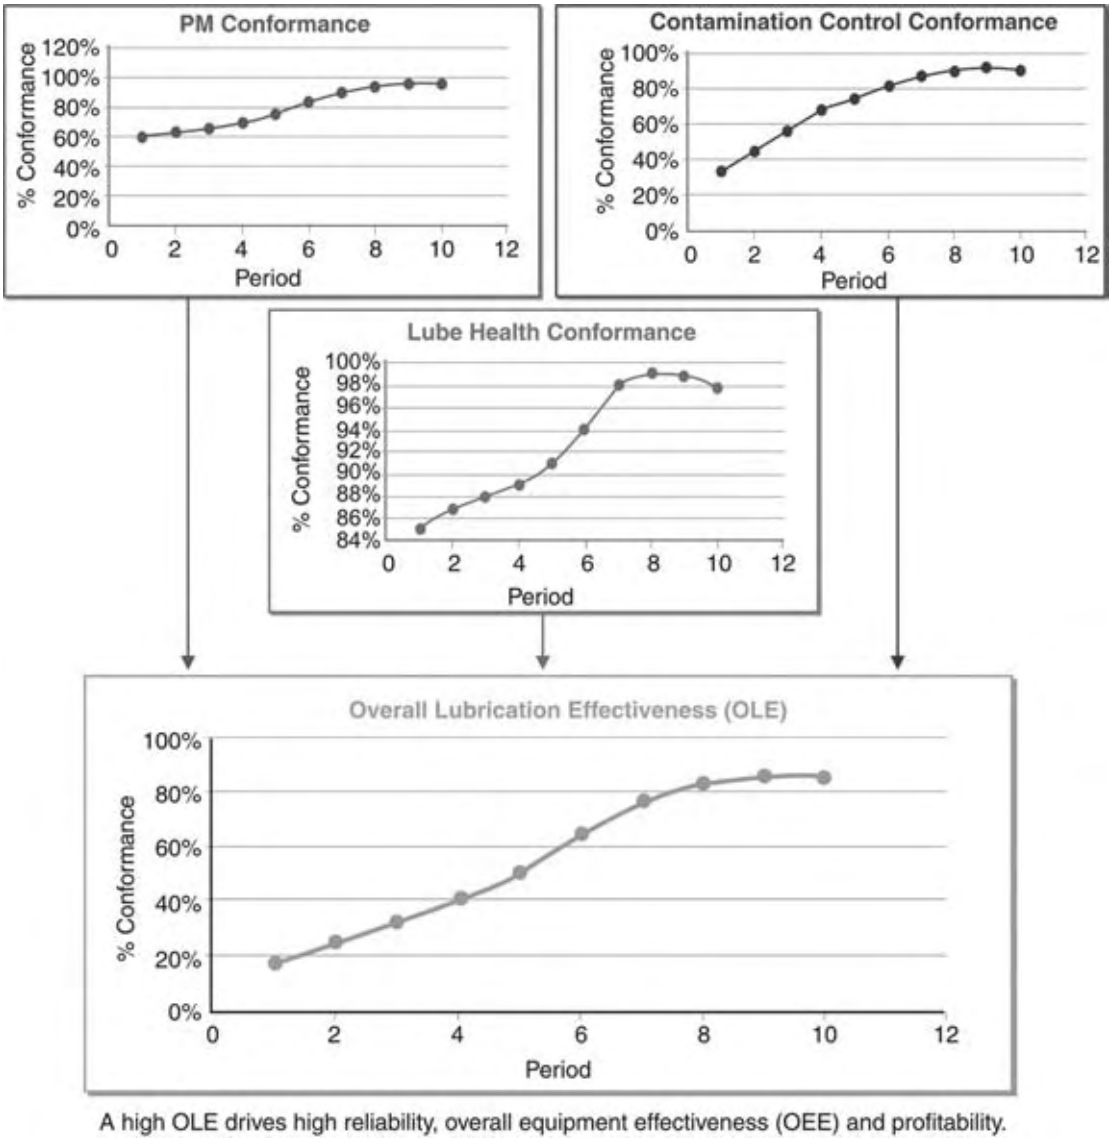

Fig. 7 Example overall lubrication effectiveness (OLE) performance metric. *(View this art in color at www.dekker.com.)*

- Train individuals to perform the tasks so they understand why those tasks are important.
- Periodically audit completion and quality.

Percent Compliance to Contamination Control Targets

The factor of percent compliance to contamination control targets aggregates the organization's performance in various aspects of contamination control. This includes new oil management and dispensing practices, filter selection and maintenance, breather selection and maintenance, seal selection and maintenance, proper combustion management, and other aspects of effective contamination control. If the machine is not in conformance, one or more of the above named (or other) sources of contamination requires attention.

Used oil analysis serves as the measurement apparatus for the contamination factor. Start by establishing meaningful target levels for each of the machines, taking into account mechanical sensitivity, application and/or environment severity and the machine's criticality to production, safety, environmental protection and/or other aspects of the mission. Compare the actual performance to targeted performance and report the percentage of the machines that comply with contamination targets (Fig. 8).

Percent Compliance to Lubricant Quality Targets

To operate reliably, the machine must contain the correct lubricant, the lubricant must be fit for service, and

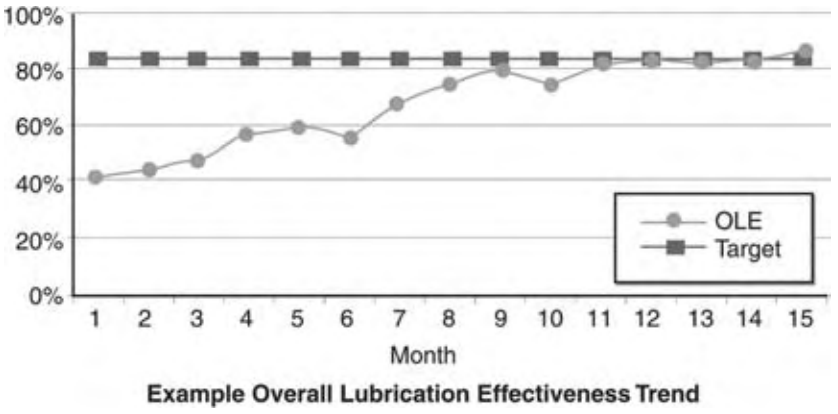

Fig. 8 Example overall lubrication effectiveness (OLE) trend. *(View this art in color at www.dekker.com.)*

it must be kept in the machine. Applying the incorrect lubricant or allowing the lubricant to become disabled due to chemical degradation and/or additive depletion can result in increased rates of mechanical wear and/or corrosion. Leakage of the lubricant can compromise the machine and create risk of injury and/or environmental mismanagement penalties.

The keys to success in ensuring lubricant quality are to select lubricants properly, store, and deliver them in a way that will minimize mixing and reduce chemical degradation, minimize aeration, run the machines as cool as the application will allow, and monitor regularly with oil analysis. Report the percentage of lubricants that conform to these lubricant quality targets.

OLE, like other global metrics, is designed to provide an overview for the management concerning how well the organization lubricates its equipment. The real work for lubrication and reliability engineers and technicians is in the factors themselves. As is the case with other global metrics, one can work to either improve the program, or work solely to improve the number. By including just a small percentage of the plant, excluding equipment that is hard to handle lubrication-wise, initiating flimsy contamination targets and lube quality alarms, arbitrarily cutting out PMs, or falsifying records can make the OLE look promising.

Trending an overall performance metric like the proposed OLE helps to drive improvement, keeps everyone focused, and serves as a rallying point to get and keep the team members working in the right direction and aligned to the goals of the organization.[25]

CONCLUSIONS

Modern lubrication programs in the chemical process industry are going through necessary transformations to modernize the selection and the use of lubricants to reduce operating costs and optimize machine reliability. The transformation has several unique elements, including:

Lubricant Selection: Lubricants are selected to best fit the changing demands from machinery and reliability expectations from users.

Application Methods: Applications methods of both oil and grease are changing to reduce labor content and improve the delivery to the needs of the machinery.

Contamination Control: Even the best lubricants and application methods can be severely compromised by invasion of harmful contaminants. Keeping contaminants in check using the proactive maintenance strategy is essential to effective lubrication.

Lubricant Sampling and Analysis: The routine analysis of lubricants is a vital condition-monitoring program element, providing information on the health of the lubricant, contaminant ingression, and machine condition.

PMs and Inspection Practices: Lubrication programs need to continually revisit scheduled PMs and inspection practices to rationalize their use for precision maintenance.

Lubrication Procedures and Documentation: Development of lubrication procedures consistent with industry best practices must include documentation and training.

Accessorizing Machinery for Precision Lubrication: Even the best lubrication procedures and PMs are of little value if the equipment is not properly equipped with hardware that enable their use.

Education and Skill Development: Today's lubrication technicians are knowledgeable workers and are well trained and possess skill competency certifications.

Program Metrics: OLE is an important program metric to trend continuous improvement and validate successes.

Mass Transfer Enhancement Because of Flow Instabilities

Vimal Kumar
K. D. P. Nigam
Department of Chemical Engineering, Indian Institute of Technology, New Delhi, India

INTRODUCTION

The transfer of mass within a fluid mixture or across a phase boundary is a process that plays a major role in various engineering and physiological applications. Typical operations where mass transfer is the dominant step are falling film evaporation and reaction, total and partial condensation, distillation and absorption in packed columns, liquid–liquid extraction, multiphase reactors, membrane separation, etc. The various mass transfer processes are classified according to equilibrium separation processes and rate-governed separation processes. Fig. 1 lists some of the prominent mass transfer operations showing the physical or chemical principle upon which the processes are based.

Several difficult but highly important approaches have come to the forefront in recent years to enhance the mass transfer operations, e.g., by increasing the surface area between the gas and the liquid, and/or by raising the intensity of mass transfer fluxes through increasing the intensity of turbulence. Nowadays, flow instabilities have been used to improve the mass transfer in chemical processes. In laminar flow regime, flow instability is often evidenced by the emergence of a structure that is periodic in space or time. More generally, it is associated with a loss of space–time symmetry by the initial flow considered. For instance, a small laminar stream of water from a faucet can give rise to regularly spaced drops because of an imbalance between gravity and surface tension.

Our main concern here is to present the mass transfer enhancement in several rate-controlled separation processes and how they are affected by the flow instabilities. These processes include membrane processes of reverse osmosis, ultra/microfiltration, gas permeation, and chromatography. In the following section, the different types of flow instabilities are classified and discussed. The axial dispersion in curved tubes is also discussed to understand the dispersion in the biological systems and radial mass transport in the chromatographic columns. Several experimental and theoretical studies have been reported on dispersion of solute in curved and coiled tubes under various laminar Newtonian and non-Newtonian flow conditions. The prior literature on dispersion in the laminar flow of Newtonian and non-Newtonian fluids through curved tubes has been compiled by Nigam and Saxena[1] and is analyzed in this entry. In addition, a new and more effective mass transfer device is also discussed based on the phenomenon of flow inversion. The effectiveness of the present device can be assessed by the fact that even at a Dean number of 3 a value of dispersion number as low as 0.0013 is obtained under the condition of significant molecular diffusion, and in the case of negligible molecular diffusion the value of dimensionless time at which the first element of tracer appears at the outlet is as high as 0.85. It is expected that this device can be used for chromatographic columns, cryogenic systems, and biochemical operations. The design also has potential as a membrane configuration for further improved operations.

TYPE OF FLOW INSTABILITIES

There are several direct and indirect approaches to enhance the mass transfer processes. In the membrane separation processes, concentration polarization and fouling are the two main limiting factors that affect the performance of any process. Therefore, for successful membrane process design, the flow configuration and module geometry must be considered along with membrane chemistry and structure. Fig. 2 shows a schematic analysis to overcome concentration polarization and fouling in membrane separation processes. A number of techniques have been used to achieve this goal by introducing various instabilities in the flow. Some of them are discussed here.

Roughness (placing protuberance or corrugation on the surface): These techniques are difficult to scale-up to intermediate or large size modules and are often limited by their high axial pressure drop. The approach, however, does demonstrate that shear stresses developed by flow instabilities enhance membrane permeation rates for difficult feeds.[2,3]

Pulsation: Superimposing an oscillating pressure gradient onto bulk axial flow in a tube produces a velocity profile with two equal maxima nearer the wall than the centerline. The net result of this is increase in the wall shear rate and the back migration of the solute in the bulk flow region, which results in improved performance.[4,5] Beside the improvement in performance,

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007850

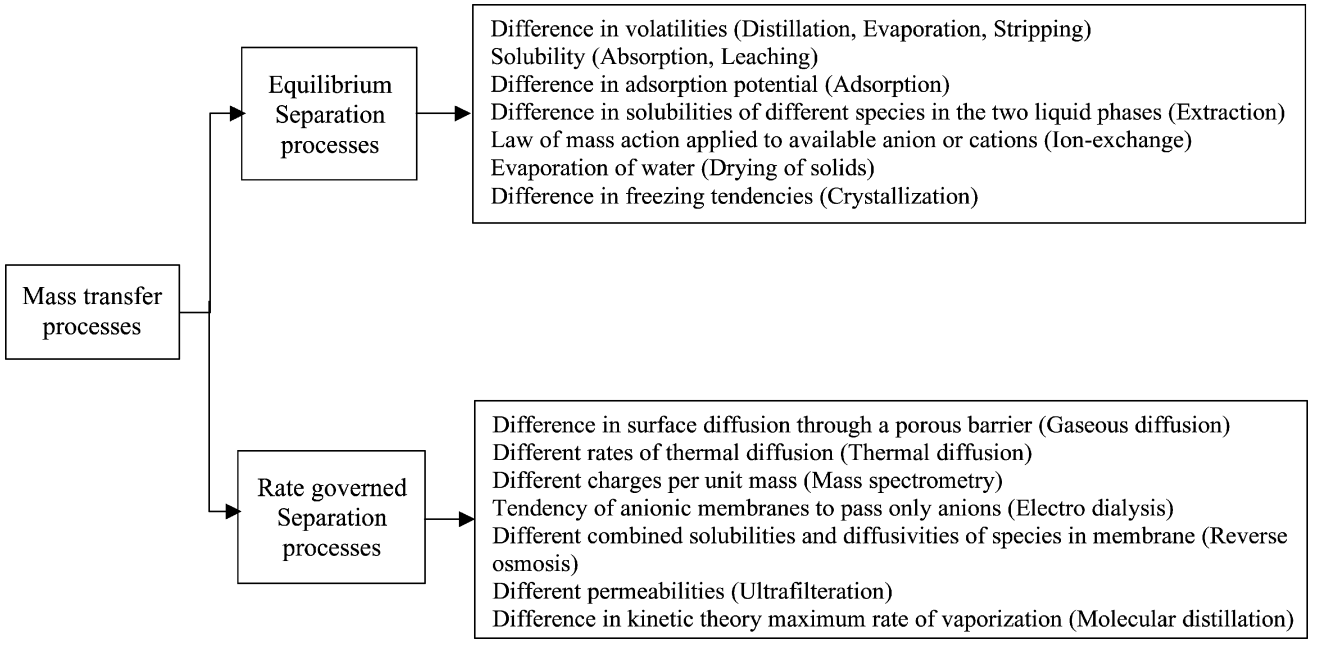

Fig. 1 Various mass transfer processes in the chemical industry.

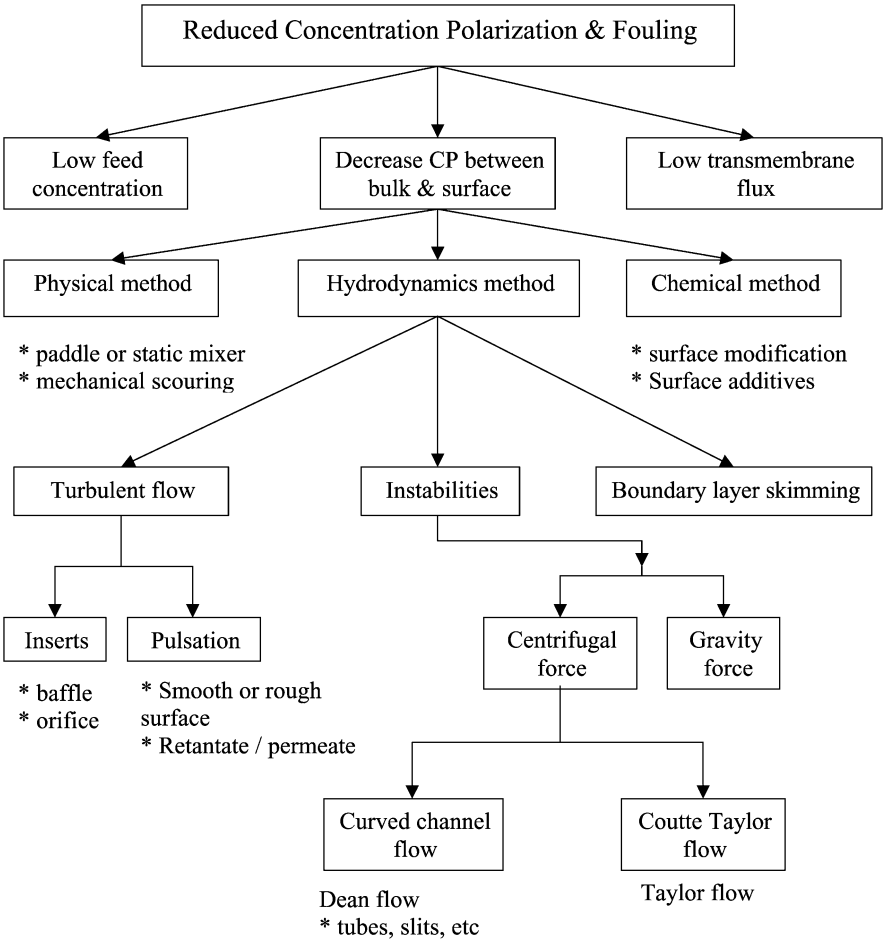

Fig. 2 Flow transfer instabilities in membrane separation processes. CP, concentration polarization.

pulsed axial flow decreases the penalty of high power consumption and loss in productivity. Detailed discussions on this aspect are given in Ref.[6].

Taylor Vortices: Taylor vorticesoccur in a rotating annular pipe and are very effective in reducing concentration polarization and particle deposition because of high shear rates. They are decoupled from the axial feed flow owing to the enhanced mass transfer between the boundary layer and the bulk phase.[7–12] The limitations are high-energy consumption, scale-up, and sealing problems.

Dean Vortices: When the fluid flows through a curved channel at Reynolds number above a critical value for incipient production of vortices, the flow changes from laminar to unstable laminar flow with counter rotating eddies or vortices.[13] These vortices are used to depolarize the solute buildup near the membrane–solution interface. These types of design are easy to scale-up and should not have exorbitant energy requirement. The only disadvantage of this type of equipment is the higher axial pressure drop as compared with conventional equipment.

Air Sparging: Gas sparging or injection of air bubbles has been effectively used to reduce concentration polarization and enhance mass transfer.[14–20] The secondary flows around bubbles promote mixing and reduce the thickness of the concentration polarization boundary layer. When the bubble diameter exceeds that of the membrane (tubular or hollow fiber), slugs are then formed; further increase in bubble diameter has no effect on flux improvement. Large slugs can displace most of the boundary layer and cause the pressure to pulsate. This results in enhancing the flux.

Backflushing Techniques: Periodic backflushing is widely used in membrane separation processes as a method to clean the membrane. By using a reverse transmembrane separation (TAMP) for very short periods of time, permeate is forced through the membrane in the reverse direction, and causes the filter cake or gel to expand, declog, and eventually be carried away. Periodic or intermittent backflushing is another form of instability that influences the concentration polarization boundary layer, particularly when high-frequency backflushing is used.[21,22] The efficiency of backflushing is dependent on optimizing the parameters (e.g., frequency, duration, pressure, single or multiple pulses, uniform or variable pressure, and duration) suitable for the specific application.

Further details of the mass transfer enhancement techniques in membrane separation processes are reported by Belfort[6] and Al-Bastaki and Abbas.[23] In this entry, the focus is on the flow instabilities produced by Dean vortices in curved and coiled tubes because of their advantages over the other techniques, viz., lower axial dispersion, better radial mixing, residence time distribution closer to plug flow, higher mass transfer, and critical Reynolds number for the transition from laminar to turbulent flow. Dean vortices arise from the centrifugal force and it may result in an enhanced wall shear stress. These vortices lower the concentration polarization, reduce the buildup of particle layers on the membrane, and improve the filtration performance.

BACKGROUND

The phenomenon of Dean vortices was first observed by Dean[13] in a curved tube. The fluid in the central part is driven toward the external wall by the centrifugal force, which gives rise to a secondary flow. This results in the inward movement of the fluid near the wall and the outward movement of the fluid near the center (Fig. 3A,B). Curved tubes may be classified as torus, bends, helical coils (with a constant curvature), and spirals (with a variable curvature). Fig. 4 shows the helical coiled, spiral, and bend tubes. The hydrodynamics in a coiled tube can be characterized by a dimensionless number named after Dean and is defined as:

$$N_{De} = N_{Re}\sqrt{\frac{d_i}{d_c}} \tag{1}$$

where N_{Re}—is the Reynolds number, d_i the internal diameter (m), and d_c—the coil diameter (m). In a helical tube, the so-called modified Dean number (N'_{De}) can be used to take into account the pitch effect, b:

$$N'_{De} = N_{Re}\sqrt{\frac{d_i}{d'_c}} \tag{2}$$

where d'_c denotes the effective coil diameter that varies as a function of the pitch of the coiled tube, i.e.,

$$d'_c = d_c\left[1 + \left(\frac{b}{\pi d_c}\right)^2\right] \tag{3}$$

The secondary flow in curved tube results in a pressure gradient between a maximum pressure at the outer wall and a minimum pressure at the inner wall. The frictional energy loss near the tube wall is increased, resulting in a higher-pressure drop as compared with that of a straight tube (Fig. 3C). The friction factor for laminar flow in the coiled tubes can be calculated from the correlation of Mishra and Gupta[24] giving the ratio of the friction factor in a coiled tube, f_c, to the friction factor in a straight tube, f:

$$\frac{f_c}{f} = [1 + 0.033(\log_{10} N_{De})^4] \tag{4}$$

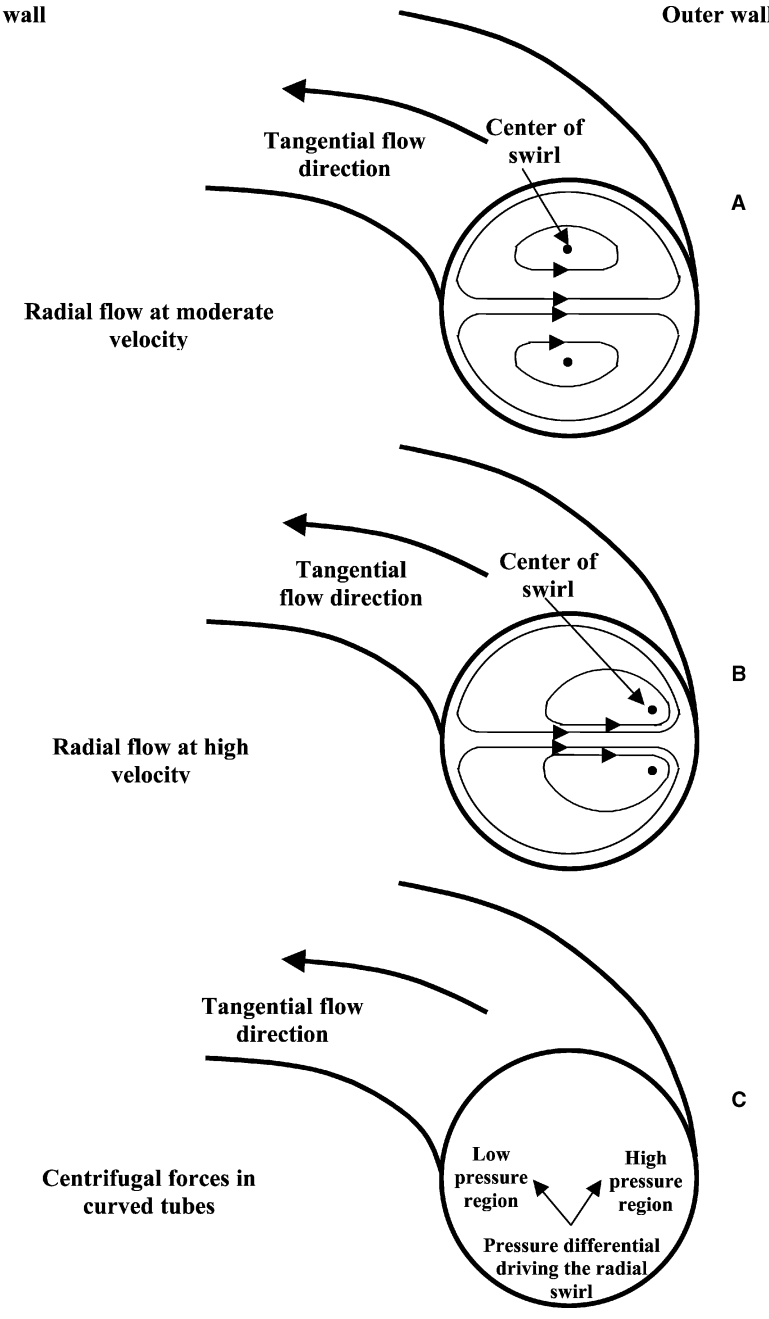

Fig. 3 Secondary flow in the cross-section of a curved tube: (A) radial flow at moderate velocity, (B) radial flow at high velocity, and (C) pressure gradient between a maximum pressure at the outer wall and a minimum pressure at the inner wall.

Experimental investigations showed that Eq. (4) is not only valid for helical tubes but also for sinusoidal curved tubes.

MASS TRANSFER IN MEMBRANES

In membrane separation processes, there is convective flow of the feed solution or suspension from the bulk toward the surface of the membrane, where separation and simultaneous slow diffusion of the rejected particles into the bulk occur because of a concentration difference. This slow back transport, coupled with membrane fouling, is a major limiting factor in the separation process. Over recent years, much attention has been devoted to the improvement of both the design and the operation of membrane separation modules. It has been reported that Dean vortices,[13] generated in curved geometries (which provide a high mixing potential by secondary flow) can be used to modify the hydrodynamics near the membrane surface.

The investigation of Dean vortices and their application to membrane separation processes has been the subject of several experimental and theoretical studies concerning the improvement of microfiltration (MF), ultrafiltration (UF), and nanofiltration (NF),

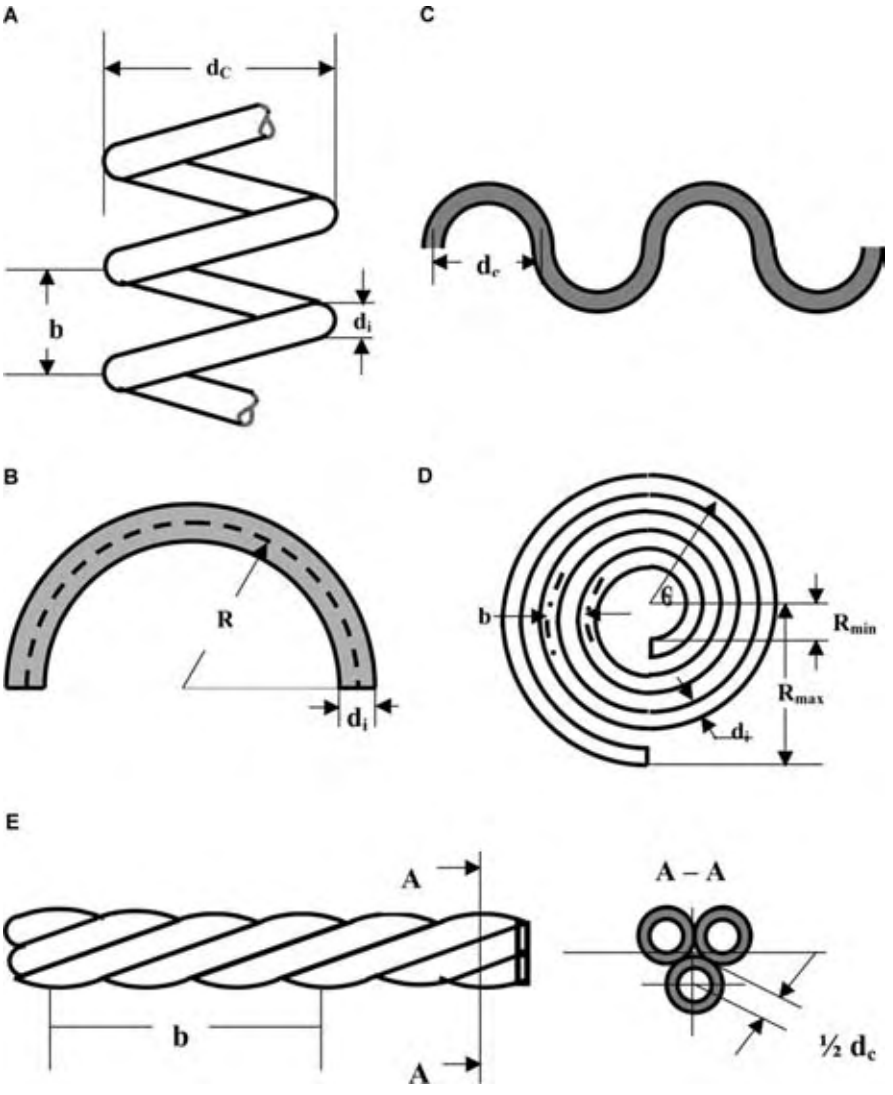

Fig. 4 Physical illustration of different types of curved tubes: (A) horizontal helical coil, (B) bend tube, (C) serpentine tube (meander-shaped tube), (D) spiral, where r is the tube radius, R the coiled tube curvature, b the coil pitch, and R_{min} and R_{max} are minimum and maximum radii of curvature of the beginning and end of the spiral, and (E) twisted tubes.

or pervaporation. Belfort and coworkers [25–27,31,38–40] experimentally and theoretically studied the Dean flow instabilities in curved channels to improve the performance of membrane processes for micro-, ultra- and nanofiltration in a helically coiled and curved slit membrane system because of Dean vortex flow. Moulin et al.[43] have shown an increased mass transfer coefficient for a helical hollow fiber module compared with a linear hollow fiber module and demonstrated the effectiveness of using Dean vortices for several applications, such as pervaporation and ultrafiltration of suspensions of yeast and bentonite.[51,52] Ophoff et al. proposed a design of helically twisted tubular membrane and reported significant flux improvement for the UF of a dextran solution.[41,42] Manno et al.[46] obtained up to 400% improvement of the limiting permeate flux for concentrated baker's yeast suspensions. Guigui et al.[47] experimentally demonstrated the efficiency of secondary flow for reducing membrane fouling in a coiled hollow fiber module. The shear stress is higher than in a straight module and is maximum near the external wall of the coiled tube. Gehlert et al.[48] used polysaccharide, protein, and yeast suspensions to compare UF and MF in the presence and absence of Dean vortices. In Fig. 5, a plot of enhancement in mass transfer vs. Reynolds number from different authors has been compiled.

Wille et al.[49] investigated the crossflow MF of polystyrene latex (0.005 wt.%) and baker's yeast suspension (0.3 wt.%) using tubular polypropylene membranes. Their investigation was focused on single straight and meander-shaped tubular membranes. Mallubhotla et al.[53,54] studied the helical nanofiltration (NF) modules and found improvement in the flux of aqueous solutions. Chung et al.[31] used a three-dimensional numerical model to quantify the concentration polarization for Dean vortex flow in a spiral reverse osmosis (RO) system. They showed that the presence of Dean vortices promotes mixing and inhibits the growth of the concentration polarization boundary layer. Kuakuvi et al.[58] employed a new

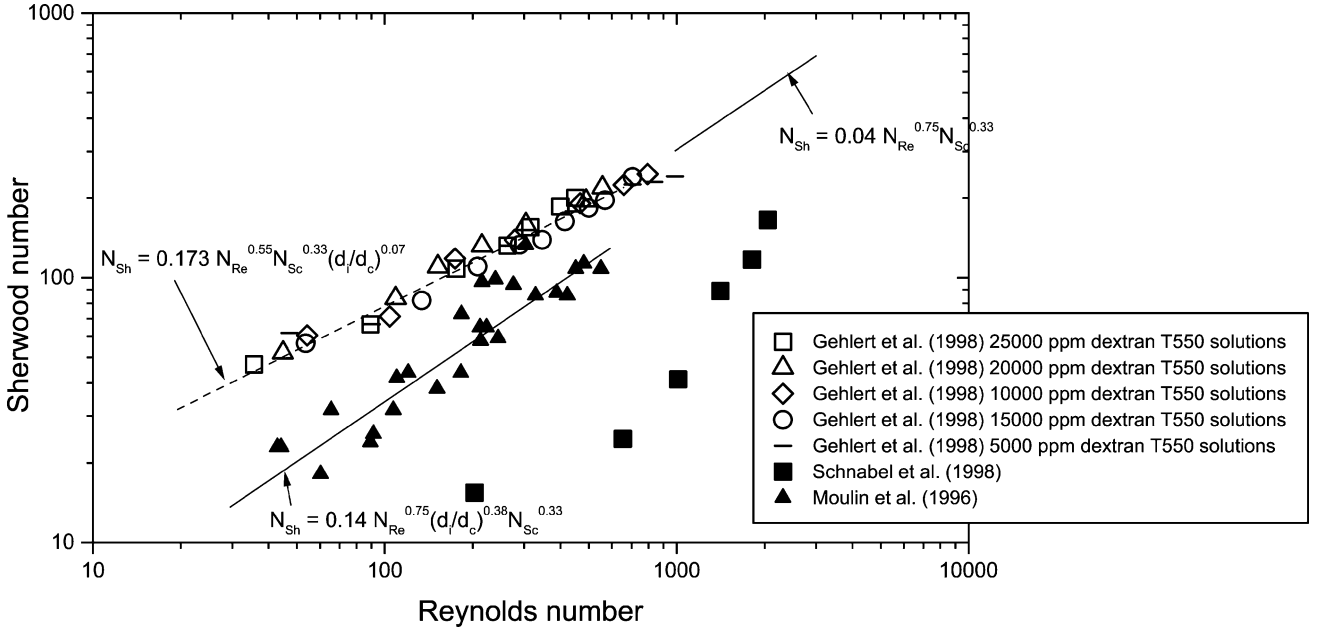

Fig. 5 Sherwood number vs. Reynolds number.

geometry, namely, woven hollow fiber UF membranes as a means of generating Dean vortices. They found that in the woven geometry, flux increases in a manner similar to the results observed for helical fibers but at lower energy consumption. Ghogomu et al.[59] experimentally compared the performance of several designs of curved membrane modules (straight, helically coiled, twisted and sinusoidal, or meander-shaped) with Dean vortices at steady state condition. They observed that the different curved geometry configurations gave the same limiting permeate flux at the same Dean number.

Al-akoum et al.[63]experimentally and theoretically reported the flux enhancement in three particular systems: shear-enhanced filtration with a vibrating membrane module, gas/liquid two-phase flows, and Dean vortices for yeast suspension system. They reported that the permeate flux was found to obey the empirical law: $J = K\tau_{wm}^{n}$ (where τ_{wm}^{n} is the mean wall shear stress, Pa) with $0.43 < n < 87$ and K depending on the membrane type and the yeast concentration for a particular system.

Several research groups [25–64] experimentally and theoretically reported the enhancement in mass transfer in membrane separation processes using Dean vortices, and their findings are summarized in Tables 1 and 2.

Helical Baffles and Stamps

A somewhat different methodology has also been used to enhance the mass transfer using Dean vortices to promote turbulence using helical baffles, and stamped and corrugated membranes. Gupta et al.[65] produced helical baffles by winding wires onto rod supports. These baffles were located axially inside a ceramic tubular membrane. They studied the separation of two different systems such as yeast suspensions and oil and water mixtures and observed up to 50% permeate flux enhancement as compared with linear modules at the same energy expenditure. Elmaleh and Ghaffor[66,67] used a UF membrane with helical baffles introduced in the filtration element and treated the suspensions of crude oil and biological cell. Significant flux improvements were reported. Broussous et al.[68] used a helical stamp (helical stamps are created on the internal surface of the ceramic macroporous support and shaped by a simple adaptation of the extrusion process) on the inside of a tubular ceramic MF membrane. They compared the performance of the proposed module with a smooth-surface membrane and reported that the permeate flux increased by a factor of 6. Scott and Lobato[69] studied the influence of crosscorrugated membranes and the orientation of flow to the angle of corrugation (90°, 45°, and 0°) on the mass transfer coefficients. They observed that the maximum improvement in mass transfer is reached when flow takes place at an angle of 90° to the corrugated membrane.

Energy Expenditure and Mass Transfer Enhancement

As the pressure drop is higher in coiled tube than in straight tube module, it is important to consider the performance of the coiled tube geometry in terms of

Table 1 Theoretical study for membrane separation processes in curved tubes

Author (Ref.)	Technique	Modules	Remarks
Brewster et al.[25]	Numerical solution (wide gap theory)	Spiral tube	Dean vortices in curved the tube were reported
Chung et al.[26]	Finite volume method and nuclear magnetic resonance flow imaging technique	Spiral tube	Velocity and pressure fields in the curved tube have been reported numerically, and it has been observed that Dean vortices can successfully depolarize solute buildup and fouling
Chung et al.[27]	Numerical solution	—	Flux improvement of 2–5 is obtained in the curved module over the straight module
Mallubhotla and Belfort[28]	MRI measurement and numerical technique	Helical coils	Velocity profiles and the dynamic behavior of Dean vortices in the curved tube flow were reported
Moulin et al.[29]	Finite volume method	Straight, torus, helical, and woven modules	Reported the influence of the geometrical parameter (d_s, d_i, b, N_{Re} and N_{De}) on the shear stress distribution and Dean vortices
Moll et al.[30]	Numerical solution and laser visualization	—	The numerical approach shows that the instantaneous velocity profile always exhibits a maximum value at the extrados of the coil, while in some cases, laser visualizations yield results that seem somewhat different and inconsistent
Chung et al.[31]	ADI scheme	Spiral tube	Dean vortex flow promotes rapid mixing and inhibits the growth of the solute concentration boundary layer

energy expenditure. Most of the studies reported so far are related to the constant energy dissipation in the straight and curved tube membranes. Moulin et al.[43] extended their work for the application in the gas–liquid membrane contactor for the case of water oxygenation. They reported that for a given energy dissipation, the permeate flux remains higher in the presence of secondary flows as shown in Fig. 6. Kuakuvi et al.[58] and Ghogomu et al.[59] presented an energy expenditure analysis in the curved membranes. According to their analyses, for a given energy consumption, the permeate flux is higher for a curved module than for a straight one. They have also reported a correlation for the energy consumption in curved tube modules:

$$\frac{W_S}{W_C} = \frac{\nu_S}{\nu_C} = 1 + 0.033[\log_{10}(gN_{Re})]^4 \quad (5)$$

Bubolz et al.[70] also reported a similar kind of analysis for laminar flow in coiled tubes.

AXIAL DISPERSION IN CURVED TUBES

Dispersion theory is concerned with the dispersal of a solute in a flowing liquid owing to the combined action of a nonuniform velocity profile and molecular diffusion. Numerous authors have discussed flow dispersion in a straight tube since the pioneering work of Taylor.[71] Additional complexities arise when flow instabilities are introduced using Dean vortices, where lateral mixing owing to molecular diffusion is augmented by the convective secondary motion. The dispersion in curved tubes is also of physiological interest because of the prevalence of the curved and bifurcational vessels in the circulatory and respiratory system.[72–74] Comprehensive reviews for the axial dispersion of Newtonian and non-Newtonian fluids in curved tube have been published.[75–99] Several experimental and theoretical studies have been reported on dispersion of the solute in curved tubes for Newtonian and non-Newtonian laminar flow conditions, and are listed in Tables 3 and 4. Fig. 7 shows the empirical correlation for dispersion in coiled tubes from various workers as a function of dimensionless number $N_{De}N_{Sc}^{1/2}$.

Axial Dispersion Owing to Tube Bending

It can be seen from Fig. 7 that in curved tubes, there is a drastic reduction in axial dispersion with an increase in Dean number. These studies reveal that very high Dean numbers are required to induce significant mixing in the cross-sectional plane. Saxena[100] proposed a simple and more effective alternative to helical coils. Helical coils are very efficient in inverting the flow

Table 2 Experimental study for membrane separation processes in curved tubes

Chung et al.[37,38]	Acrylic transparent sheet	Water doped with $CuSO_4$	Dean vortices can depolarize the solute buildup near the membrane surface
Chung et al.[39]	Curved slit channel with 180° curve section	DI water, monodispersed polystyrene latex particle and yeast suspension	Dean vortices depolarize the solute buildup near the membrane–solution interface
Mallubhotla et al.[40]	Polypropylene microfiltration membrane	Cerevisiae broth suspension	Flux improvement of 60% was reported in curved module over the straight module
Ophoff et al.[41,42]	Twisted tubular membranes	Dextran T70 solution	Flux increase of 40% with respect to straight tube membranes
Moulin et al.[43]	Coiled silicone tubular membranes	Oxygenation operation with water	Dean vortices give better performance in terms of oxygen transfer, and the improvement was 2–4 times higher than in linear membranes
Mallubhotla and Belfort[44]	Polysulfone, polypropylene MF membrane	DI water with salt	Improvements in permeate flux of up to 150%, 80%, and 100% for the helically coiled modules over the linear modules for MF, UF, and NF at $N_{De} = 292, 450$
Crowder and Gooding[45]	Silicon rubber hollow fiber	O_2 removal from water and pervaporation of trichloroethylene	Mass transfer coefficient values observed for O_2 transfer were at least 20% higher than those achieved with traditional spiral wound modules
Manno et al.[46]	Cellulose acetate hollow fiber	Baker's yeast suspensions	Secondary flow enhances membrane permeation by a factor of up to 5
Guigui et al.[47]	Coiled hollow fiber module	Bentonite and yeast suspension	Concentration polarization and fouling are reduced and the limiting flux is improved by up to 5 times
Gehlert et al.[48]	Polyether sulfone	Polysaccharides, proteins, and beer yeast suspensions	A new empirical correlation of UF in dextran solution is proposed
Wille et al.[49]	Polypropylene membranes	Polystyrene latex and baker's yeast suspension	The efficiency for the curved modules is three times higher than for straight modules

Mallubhotla et al.[50]	Polyamide, poly(ether sulfone) helical membrane	Glutamic acid, glutamine, and lysine	Flux and rejection were higher for the helical module than for the linear module in the range of $375 \leq N_{Re} \leq 500$
Schnabel et al.[51]	Polydimethylsiloxane hollow fiber membranes	*n*-Butanol–water and chloroform–water	Improvement factor increases with Reynolds number and liquid mass transfer is twice in helical modules than that in straight modules
Moulin et al.[52]	Cellulose acetate hollow fibers	Colloidal bentonite solution and dextran solution	Secondary flow reduces the fouling phenomenon and the permeate flux is twice in the coiled membranes than in the linear membranes
Luque et al.[55]	Helical and linear modules	Cell suspensions (yeast, *Escherichia coli*, and mammalian cell cultures)	Flux and capacity improvements of up to 3.2-fold (constant TMP operation) and 3.9-fold (constant flux operation) with the helical module over the linear module
Kluge et al.[56]	Helically wound hollow fibers	Polyethylene glycol solutions and silica suspensions	Flux improvements of up to 45% in helical modules over straight modules
Kluge et al.[57]	Helical and linear modules	Suspended yeast cells (MF) and the solution of BSA and beer yeast (DF)	The capacity of helical module was 19 times that of the straight modules, and the flux improvement was 18–43%
Kuakuvi et al.[58]	Cellulose acetate hollow fiber membrane	Dextran solution	For a given energy consumption, the limiting flux observed in the woven hollow fiber module was higher than that in the helical and straight modules.
Ghogumu et al.[59]	Cellulose acetate hollow	Bentonite (montmorillonite) particle fiber membrane	A new empirical correlation was proposed and for a given permeate flow rate, the energy consumption is lower for a curved module than for a straight one
Schutyser et al.[60]	Polyethersulfone helical and linear modules	rBDNF inclusion bodies from an *E. coli* cell suspension	Dean vortex improves the filtration performance. A highly concentrated solution is obtained, and it is highly energy saving
Schutyser and Belfort[61]	Polyethersulfone helical and linear modules	Tetradecyltrimethyl-ammonium bromide and sodium salicylate with silica suspension	Proposed a new empirical correlation and reported that the permeate flux decreased with increasing TTASal concentration and increasing Reynolds number
Kaur and Agrawal[62]	Cellulose acetate membrane	Lysozome	Dean vortices enhance the mass transfer coefficient and an empirical correlation is proposed
Liu et al.[64]	Polysulfone hollow fiber module	30% TBP (in kerosene) + phenol + water	Coiled fibers provide better mass transfer performance than the straight fibers, and the improvement factor is in the range of 2–4

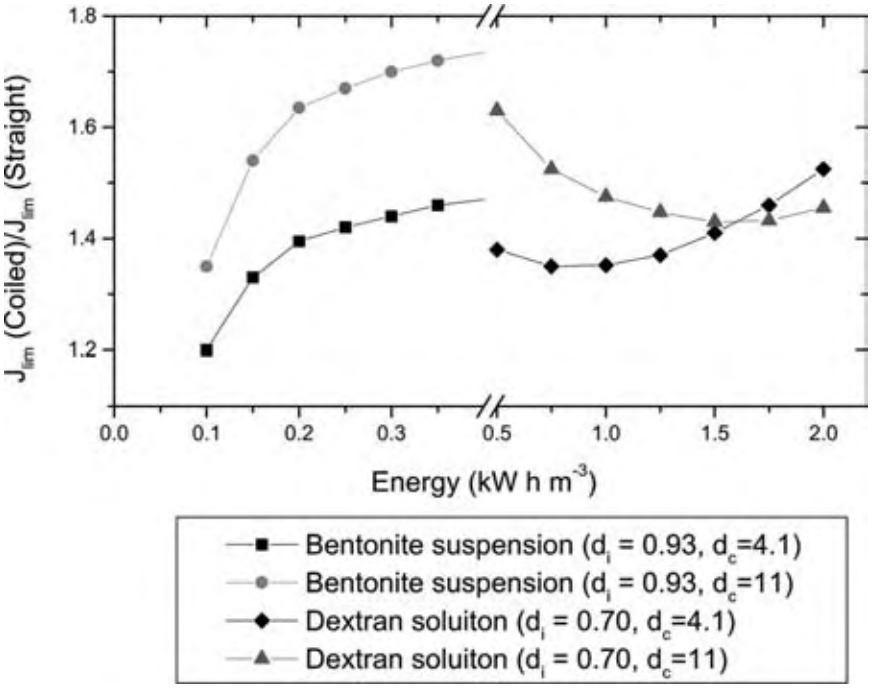

Fig. 6 Ratio of limiting permeate flux between a coiled and a straight module vs. energy consumption.[42] *(View this art in color at www.dekker.com.)*

and improving cross-sectional mixing in a coiled tube. Saxena[100] proposed that it is possible to obtain complete flow inversion by shifting the direction of centrifugal force. He conducted the residence time distribution experiments under the condition of significant molecular diffusion, using water as the flowing media. The Dean number was varied from 3 to 60. Taylor's dispersion model[101] was fitted to the experimentally obtained step input curve (F curve). Fig. 8 shows their best-fit computed values of dispersion number as a function of Dean number. It is interesting to mention that about a 20-fold reduction in dispersion number (D/uL, where D is diffusion coefficient, u the velocity in the tube, and L the length of tube) was obtained as compared with that of a helical coil in the new device.

AXIAL DISPERSION IN CHROMATOGRAPHIC COLUMNS

Ideally, a chromatographic column should yield the largest possible number of theoretical plates in the shortest possible time. While the use of microparticulate packings facilitates considerable increase in the efficiency, it has the disadvantages of poor reproducibility (owing to variations in mobile phase flow path length) and prohibitively high operating pressures. On the other hand, the use of open tubular columns is hindered by the relatively slow diffusion in liquids. Normally, radial mass transport is governed by molecular diffusion alone; in gas chromatography, where the diffusion coefficient is five times higher than in liquid chromatography, the radial diffusion is sufficiently fast to allow the use of capillary columns. In liquid chromatographic systems, however, undesirable band broadening occurs in columns with larger inner diameter. Such stringent inner diameter limitations result in detection and dead volume constraints.

Gidding[102] proposed a coupling concept analogy, in which the radial dispersion is represented by the combination of molecular diffusion and convection, thus providing a radial convection mechanism to facilitate the use of open tubular columns with larger internal diameters. Various techniques have been applied to enhance radial mass transport. Taylor[71] and Knox[103] worked in the turbulent regime while Desty and Douglas[104] utilized static mixers to enhance the radial mixing.

Effect of Dean Vortices

Hofmann and Halász[105] investigated the radial mixing without considering the axial dispersion in band broadening (band broadening is because of the multiple path of an analyte through the column packing, molecular diffusion, and effect of mass transfer between phases) in squeezed, twisted, and coiled tubes. Tijssen[106,107] predicted the heavy equivalent theoretical plate (HETP) in a chromatographic column using Dean's profile, based on dye tracer experiments in a transparent tube. He derived a correction factor to the Taylor dispersion model[71] using an analogy based

Table 3 Theoretical studies for the axial dispersion in curved tubes

Author (Ref.)	Technique	Parameters range	Remarks
Erdogan and Chatwin[75]	Perturbation analysis	$N_{De} \leq 17$	Followed Dean's solution; dispersion is reduced by curvature only if $N_{Sc} > 0.124$
Nunge et al.[76]	Perturbation analysis	$N_{De} \leq 17$	Followed Topakoglu's[77] solution; at low N_{Re} coiling enhances axial dispersion for liquids and at high values of N_{Re} coiling results in a reduced axial dispersion
Janssen[78]	Numerical integration	$N_{De}^2 N_{Sc} < 5000$	Introduced a new parameter $N_{De}^2 N_{Sc}$. For $N_{De}^2 N_{Sc} < 100$ no significant reduction, when compared with straight tube, was reported, while for $100 < N_{De}^2 N_{Sc} < 5000$ the ratio decreased more than threefold
Johnson and Kamm[79]	Monte Carlo and spectral model	$1 < N_{De}^2 N_{Sc} < 10^5$	Results were qualitatively similar to those of Ref.[77], the effective diffusion in coiled tubes fell to about 0.2 of its value in straight tube
Daskapoulos and Lenhoff[80]	Method of moments		Their results were very similar to those of Refs.[77,78] except for the fact that the results were applicable to higher values of Dean number
Eckman and Grotberg[81]	Perturbation technique	$N_{Sc} \approx 1$	An abrupt increase in transport rate was observed for the ratio of stroke length to tube diameter
Pedley and Kamm[82]	Asymptotic analysis and numerical solutions	$N_{Sc} \approx 1$	Effect of oscillatory flow on axial dispersion was reported; when the secondary flow time equals the oscillation period, a resonance is formed that gives rise to a prominent maximum in the transport rate
Sharp et al.[83]	Monte Carlo and spectral model	$0.01 < N_{De} < 1000$; $0 < \alpha < 100$; $N_{Sc} = 0.68, 10{,}000$	Effect of oscillatory flow on axial dispersion was reported; secondary flow decreases axial transport by a factor of 5 for low values of $\alpha^2 N_{Sc}$
Agarwal et al.[84]	Perturbation method	$0.2 < n < 1.5$; $1 < N_{De}^2 N_{Sc} < 700$; $\lambda = 30, 100$	Axial dispersion decreases with increase in the value of $N_{Re} N_{Sc}$ for a given coil and power law fluid, while it increases with increase in curvature ratio for a given $N_{Re} N_{Sc}$ and power law fluid
Agarwal and Jayaraman[85]	Spectral method with finite difference method	$100 < N_{De}^2 N_{Sc} < 10^4$	For the range of $N_{De}^2 N_{Sc}$ from 100 to 10^4 the axial dispersion in a circular curved tube is markedly less than that in a straight tube

Table 4 Experimental studies for the axial dispersion in curved tubes

Author (Ref.)	System (fluid)	Parameters range	Correlation proposed	Remarks
Koutsky and Adler[86]	Water–electrolyte	$300 < N_{Re} < 40{,}000$	$\log_{10}\left[N_{Di}\left(\frac{L}{D}\right)^{0.702}\left(\frac{R}{R_C}\right)^{-2.26}\right] = mZ + n$ where m, Z, and n are functions of ellipticity, curvature, and Reynolds number, respectively	For $N_{Re} < 300$, axial dispersion in helical coils was found to be of the same order as that in straight tube, and for equal power consumption helical coils facilitate less axial dispersion than do straight tubes
Van Andel et al.[87]	Air–butane, water–electrolyte	$100 < N_{Re} < 2000$; $\lambda = 30, 50$	—	For liquids, the Peclet number has no definite trends with the operating parameters, but for gases the axial dispersion approaches ideal plug flow
Trivedi and Vasudeva[88]	29% DEG solution in water	$10 < N_{Re} < 1600$; $1.5 \times 10^3 < N_{Sc} < 8.7 \times 10^3$; $10 < \lambda < 280$	—	1.5- to 500-fold reduction in values of K_c depending upon the values of N_{Re} and λ
Nigam and Vasudeva[89]	Water	$0.5 < N_{Re} < 10$; $10 < \lambda < 785$	—	For a nearly 80-fold variation in curvature ratio, the effect of coiling on K_c was negligible if $N_{De} < 0.15$
Mouljin et al.[90]	He–N_2, Kr–N_2, N_2–He, Pr–He, Fr–He	$1 < N_{Re} < 800$; $0.23 < N_{Sc} < 3.02$; $9 < \lambda < 47$	—	At low velocities, coiled tubes and straight tubes show identical dispersion behavior, and the Taylor–Aris model is applied up to $N_{De}N_{Sc}^{1/2} \approx 10$
Shetty and Vasudeva[91]	DEG solution	$7000 < N_{Sc}N_{De}^{1/2} < 55{,}600$; $10.3 < \lambda < 785$	$\frac{D_C - D_M}{D_S - D_M} = 1$ for $N_{De}N_{Sc}^{1/2} \le 7$; $\frac{D_C - D_M}{D_S - D_M} = 1.52 - 0.275 \ln(N_{De}N_{Sc})$ for $N_{De}N_{Sc}^{1/2} > 7$	Proposed an empirical correlation

Van Den Berg and Deelder[92]	Nitrobenzene–*iso*-octane, benzene–chloroform, benzene–hexane	$10 < N_{De}N_{Sc}{}^{1/2} < 200$	$\kappa = 1$ for $N_{De}N_{Sc}^{1/2} \leq 10$; $\kappa = 5.6\ (N_{De}N_{Sc}^{1/2})^{0.68}$ for $10 < N_{De}N_{Sc}^{1/2} < 200$	For increasing values of $N_{De}N_{Sc}{}^{1/2}$, the axial dispersion in the helical coils decreases as compared with that in straight tube
Saxena and Nigam[93]	Sodium carboxy methyl cellulose (CMC)	$N_{Re} < 140$; $0.6 < n < 1.0$; $10 < \lambda < 220$	—	Axial dispersion decreases with increase in the value of $N_{Re}N_{Sc}$, while it increases with increase in curvature ratio for flow of non-Newtonian fluids
Iyer and Vasudeva[96]	—	$N_{De}N_{Sc}^{1/2} \sim 7000$	$\frac{D_C - D_M}{D_S - D_M} = 1$ for $N_{De}N_{Sc}^{1/2} \leq 7$; $\frac{D_C - D_M}{D_S - D_M} = 1.65 - 0.863 \log(N_{De}N_{Sc}^{1/2})$ for $N_{De}N_{Sc}^{1/2} > 7$	Correlation is valid for higher values of $N_{De}N_{Sc}^{1/2}$
Deelder et al.[97]	Nitrobenzene–*iso*-octane, benzene–chloroform, benzene–hexane	$N_{De}N_{Sc}^{1/2} < 200$	$\kappa = 1$ for $N_{De}N_{Sc}^{1/2} \leq 12.5$; $\kappa = 1.52 - 0.275 \ln (N_{De}N_{Sc}^{1/2})$ for $12.5 < N_{De}N_{Sc}^{1/2} < 200$	Proposed an empirical correlation
Singh and Singh[98]	H_2–A, air–A, O_2–A, air–H_2	$10 < N_{Re} < 100$; $0.176 < N_{Sc} < 1.359$; $26.6 < \lambda < 98$	—	For $N_{De}N_{Sc}^{1/2} < 10$, the effect of coiling on axial dispersion is not significant
Kauffman and Kissinger[99]	Buffer solution of sodium phosphate monobasic	$N_{De}N_{Sc}^{1/2} > 4$	$\kappa = 1$ for $N_{De}N_{Sc}^{1/2} < 4$; $\kappa = 1.27 - 0.517l, \log(N_{De}N_{Sc}^{1/2}) + 0.0759 \log(N_{De}N_{Sc}^{1/2})^2$ for $N_{De}N_{Sc}^{1/2} > 4$	Serpentine geometry enhances the radial mixing better than the helically coiled reactors even at low flow rates

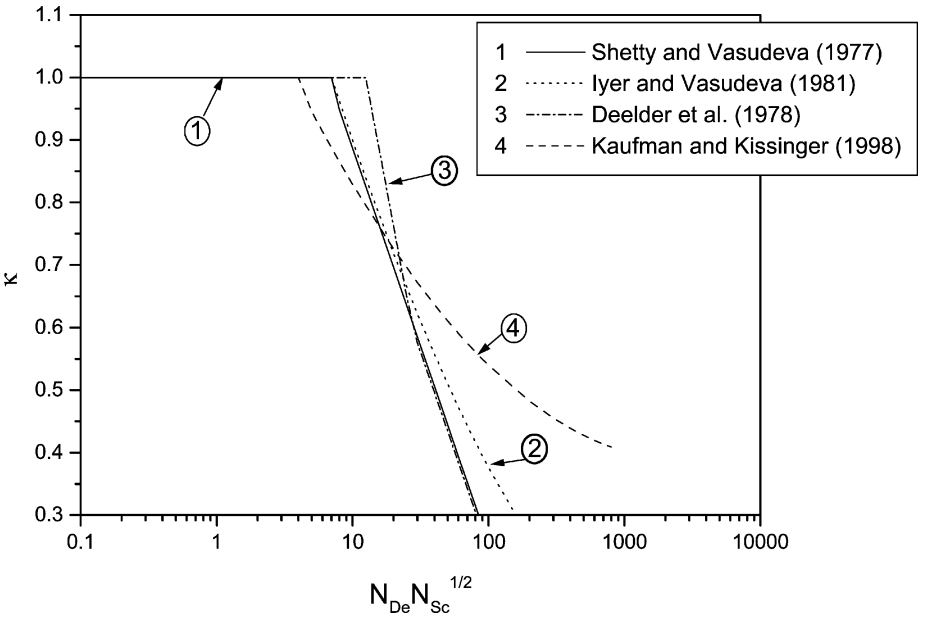

Fig. 7 Comparison of various axial dispersion correlations ($\kappa = D_c/D_s$, ratio of dispersion in coiled tube to the straight tube).

on heat transfer. Katz and Scott used serpentine tubes (Fig. 4C) as low dispersion connectors.[108] Tubes stitched through steel mesh framework and knitted onto themselves were used for postcolumn reactors.[110] According to Kauffman and Kissinger,[109] there is no distinct advantage in terms of band spreading between any of the serpentine geometries and the smallest diameter helical coil. However, using these geometries reduced the band spreading by up to 44% when compared with a linear tube of the same length.

Grochowicz et al.[110] modeled the secondary flow in serpentine and coiled tubes as the measure of the radial mixing using computational fluid dynamics techniques. They showed that flow characteristics in serpentine tubes result in considerably less band broadening per unit length than in linear tubes of the same inner

diameter. They[111] further reported the feasibility of rapid chromatographic separations in open tubular serpentine columns of 100–250 mm ID. They compared the serpentine and helical tubes from the point of view of band broadening. The use of comparatively large column diameters is permissible for the enhancement of native diffusion mass transfer with a secondary mechanism of radial mixing. The new device that has been proposed here (Fig. 9) can also be used as a chromatographic column because of its compactness, narrower RTD, and less axial dispersion as compared with the conventional, helical chromatographic columns.

CONCLUSIONS

Several novel techniques for mass transfer enhancement reported in the literature have been discussed in detail. The present study is focused on the mass transfer enhancement in the rate-controlled separation processes using flow instabilities. There are a large number of examples about the success of flow instabilities produced by Dean vortices in improving the performance by increasing flux and reducing fouling in membrane separation processes. Several curved modules (helically, coiled, twisted, spirally wound, and sinusoidal modules) with Dean vortices have been described, and their performances are analyzed in comparison with conventional linear modules. It has been reported that, for a given energy consumption, the permeate flux is higher for a curved module than for a straight one. Besides this, the influence of secondary flow on the extent of dispersion in curved and coiled tubes helps to enhance mass transfer. It has been reported that Dean vortices markedly reduced axial dispersion and, for equal power consumption, helical coils facilitate less axial dispersion than straight tubes. In the chromatographic systems undesirable band broadening occurs in columns, which results in detection and dead volume constraints. This can be avoided by using helical and serpentine columns. It has been observed that flow characteristics in serpentine tubes result in considerably less band broadening than in linear tubes of the same inner diameter. A further development in modeling of membrane filtration processes will provide a better understanding of the flow and mass transfer in curved membrane.

A new type of flow reactor is also presented, which has narrower RTD and higher heat and mass transfer as compared with the conventional reactors. The proposed reactor has a 20-fold reduction in axial

dispersion as compared with the helical coils. The ease of fabrication, compactness, and the lower axial dispersion found establish their superiority over other mechanical devices known in literature for inducing mixing in a cross-sectional plane. Because of the above advantages, the proposed device, which is based on the principle of flow inversion, will have a higher mass transfer coefficient and can be used in membrane separation (to improve permeate flux at low-energy consumption) and as a chromatographic column.

INTRODUCTION

Industrial scientists face the challenge of developing advanced materials by manipulating the relation between the chemical structure and the desired performance. Predicting the final performance property requires an integrated approach among the various length- and time scales of material behavior. Materials modeling must then answer questions at all these length scales integrating methods as shown schematically in Fig. 1. It must answer questions about bulk properties of a material and its behavior under external environments—thermal, mechanical, and electromagnetic. In designing a material with given bulk properties, one must understand how molecules or clusters of molecules can be engineered to attain these bulk properties. Thus, ab initio methods as well as atomistic and mesoscale methods become significant. This entry acts as a primer on various kinds of modeling techniques and points to references where any of these methods can be further explored.

CONTINUUM MODELS

Finite Element and Finite Difference

The behavior of materials is governed by the physical processes that act on those materials. Mathematical models of these physical processes are based on partial differential equations (PDEs). Most of the time, only materials undergoing simple processes can be treated with direct analytic solutions. Numerical methods then become the only alternative available for the solution of detailed and realistic models. Material developers call upon numerical methods to solve a PDE or a combination of PDEs on discrete set of points of the solution domain called ''discretization.'' Here, the solution domain is divided into subdomains having the discretization points as vertice; the distance between two adjacent vertices is the ''mesh size.'' Time is also subdivided into discrete intervals; ''timestep'' is the interval between two consecutive times at which the solution is obtained. The PDE is then approximated, or discretized, to obtain a system of algebraic equations, where the unknowns are the solution values at the discretization points. This system of algebraic equations can then be solved on a computer by ''direct'' or ''iterative'' techniques. The approximate solution of the original PDE has an error called ''discretization error.''

The finite difference approach is a widely used discretization technique because of its simplicity. Finite difference approximations of derivatives are obtained by using truncated Taylor series. The following Taylor expansions can be used:

$$u(x + \Delta x) = u(x) + \Delta x \frac{\partial u}{\partial x} + \frac{\Delta x^2}{2} \frac{\partial^2 u}{\partial x^2} + \frac{\Delta x^3}{6} \frac{\partial^3 u}{\partial x^3} + O(\Delta x^4) \quad (1)$$

$$u(x - \Delta x) = u(x) - \Delta x \frac{\partial u}{\partial x} + \frac{\Delta x^2}{2} \frac{\partial^2 u}{\partial x^2} - \frac{\Delta x^3}{6} \frac{\partial^3 u}{\partial x^3} + O(\Delta x^4) \quad (2)$$

The first order derivative is given by the following finite difference approximations: from Eq. (1): forward difference

$$\frac{\partial u}{\partial x} = \frac{u(x + \Delta x) - u(x)}{\Delta x} + O(\Delta x) \quad (3)$$

from Eq. (2): backward difference

$$\frac{\partial u}{\partial x} = \frac{u(x) - u(x - \Delta x)}{\Delta x} + O(\Delta x) \quad (4)$$

By subtracting Eq. (1) from Eq. (2): centered difference

$$\frac{\partial u}{\partial x} = \frac{u(x + \Delta x) - u(x - \Delta x)}{2\Delta x} + O(\Delta x^2) \quad (5)$$

An approximation for the second order derivative is obtained by adding Eq. (1) to Eq. (2):

$$\frac{\partial^2 u}{\partial x^2} = \frac{u(x + \Delta x) - 2u(x) + u(x - \Delta x)}{\Delta x^2} + O(\Delta x^2) \quad (6)$$

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120023856

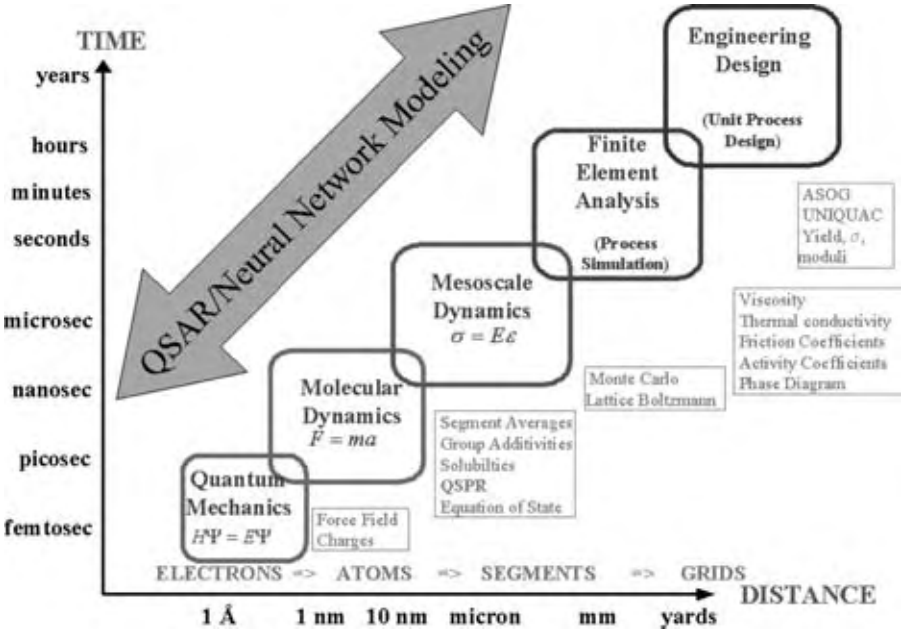

Fig. 1 Schematic of multiscale modeling approaches. *(View this art in color at www.dekker.com.)*

The terms $O(\Delta x)$ and $O(\Delta x^2)$ are the truncation errors. If a better approximation is needed, one could either reduce the size of the mesh or add more information by including higher order neighbors.

Finite element methods (FEM) are used to simulate physical systems governed by ordinary and partial differential equations. The basic concept is the separation of a complex materials system into simpler, disjoint entities called finite elements. A good analogy to illustrate this comes from structural mechanics where the mechanical response of an element is characterized by degrees of freedom. A set of node points (or simply nodes) represent values of the unknown functions for degrees of freedom. The element response is described by algebraic equations. The total response of the original system is approximated by that of the discrete model constructed by assembling all the elements. This separation process intuitively occurs when materials scientists or engineers analyze systems. Mathematically, FEM obtain numerical approximations to differential equations in a domain Ω, and this domain is replaced by the union of disjoint subdomains E, called finite elements. The unknown functions are locally approximated over each element by an interpolation expression (called shape functions) written in terms of values taken by the functions (and their derivatives in some cases) at a set of nodes located on the element boundaries. The union of the shape functions over adjacent elements forms an approximation, which is inserted into the governing equations to determine the unknown values by the Galerkin, least-squares, or Ritz methods.

USES OF FEM MODELS

Materials design via virtual prototyping is being increasingly incorporated into the product development process because of their criticality in minimizing costs and improving time-to-market. By including the effects of multiple physics when they are coupled together, FEM allow the researcher to address real-world structural, thermal, electromagnetic, and fluid-flow behaviors of 3-D product designs.

FEM have provided a wide range of solutions in many industries. For example, automotive engineers evaluate and optimize many performance and reliability aspects of their designs in sheet metal forming, gasket analysis, seal integrity, noise and vibration, crash simulations, etc. Aerospace/defense engineers routinely perform static, dynamic, and coupled acoustic–structural analysis of aircraft frames; simulations of space structures (solar sails, space radar, and antennas); wing panel buckling and crack propagation in the fuselage; bird strike simulations; the effects of underwater explosions on ships and submarines; structural analysis of submarine frames; and simulation of nozzles, piezoelectric motors, self-lubricating hinges, and various bearings. Consumer/electronics engineers utilize FEM to simulate the design, manufacturing, and performance of different types of consumer and electronic products and associated packaging including: drop testing of consumer electronics and fluid-filled containers; the manufacturing of new materials, such as paper and film; design and validation of acoustic properties of audio equipment; thermomechanical simulation of electronic products; thermal analysis of chip packaging; and the

design of consumer appliances such as washers and dryers. Manufacturing engineers design their equipment (pumps, motors, and compressors); perform fatigue analysis of power generation equipment, such as boilers, turbines, and heat exchangers; dynamic analysis of piping systems under various loads, such as thermal, pressure, seismic, etc. Biomedical engineers engage FEM in the design of mechanical connectors commonly used in all types of medical devices, simultaneously enhancing proprietary issues and regulatory approvals. They commonly use FEM to estimate the wear of materials used in dental implants, and hip, knee, and other prosthetic implants. In the rubber industry, developers seek the use of FEM to design bushings, seals, vibration damping systems, tire–road interactions, and tire wear.

SYSTEMS MODELING

Materials in the macroscopic sense follow laws of continuum models in which the nanoscale phenomenon is accounted for by statistical averages. Continuum models and analysis separate materials into solids (structures) and fluids. Computational solid mechanics and structural mechanics emphasize the analysis of solid materials and its structural design. Computational fluid mechanics treats material behaviors that involve the equilibrium and motion of liquid and gases. A relative new area, called multiphysics, includes materials systems that contain interacting fluids and structures such as phase changes (solidification, melting), or interaction of control, mechanical and electromagnetic (MEMS, sensors, etc.).

A more general concept is systems. Systems identify material objects that combine to perform a distinguishable or desired function. Examples of systems are airplanes, buildings, engines, electronic chips, trees, cats, human organs and cells, etc. There are no simple differential equations that can capture the diversity and the complexity of systems. It is important then to divide and conquer and finish with abstraction from these parts. Nowadays, materials designers define the system with the required functionality and separate it into subsystems, with each subsystem having its own design requirements. These subsystems can be subdivided again until components are specified. Components are sufficiently simple in geometry, connectivity, and raw materials so that they can be reasonably described by continuum mathematical models. For example, in the FEM, components are the finite elements and are obtained from FEM libraries based on mathematical models. The system model is then obtained (abstraction) by reversing the process, from component equations to subsystem equations, and from those equations to the complete system. In mechanical design, the system assembly process is governed by the classical principles of Newtonian mechanics. In molecular design, the system assembly process involves a more complex multiscale approach. In complex materials design, the processing parameters/environment play a key role in determining the final properties of the materials, and hence need to be part of the ''assembly process'' to properly describe the final system. When designing materials systems, one needs to address the issue of system optimization and realize that combinations of optimized subsystems do not necessarily yield an optimized system. One needs to involve the use of multidisciplinary optimization for a truly optimized system. Here, trade-offs are necessary as subsystems and the system do not share the same optimal point. Great advances in multidisciplinary optimization and computational power are enabling greater system optimization in which multidisciplinary teams work together rather than adopt a piecemeal approach of subsystem optimization.

ELECTRONIC AND ATOMISTIC MODELING

Macroscale models cannot answer questions regarding interaction between molecules, rates of change in these interactions, and the structures that evolve—questions that are important in catalysis, separation processes and media, surface engineering, electronics processing, among others. Models at the atomistic scale capture phenomena relevant to these questions. Significant advances have been made at the other extreme of the length- and time-scale spectrum for the development of methods that can accurately describe electronic structures of materials, specific interactions between atoms, as well as mobility of these atoms to engineer new materials.

Ab Initio Methods

Models that attempt to predict the behavior of materials using first principles quantum theory fall within this regime. These methods are applied to the development of ''traditional'' materials such as steels, refractory materials, ceramics, etc. as well as new materials such as those for microelectronics industries, catalysts of various kinds,[1,2] materials for fuel cell applications, to name a few. Some examples of such properties are electronic properties of solids such as conductivity, absorption spectra, etc.,[3] reactivity of molecules,[4] selective binding of molecules to specific sites on surfaces, catalytic reaction pathways, and active sites on molecules.

To gain insights into the above-mentioned problems, one needs to solve Schrodinger's equation:

$$H\Psi(\{\vec{r}\},\{\vec{R}\}) = E\Psi(\{\vec{r}\},\{\vec{R}\}) \quad (7)$$

$$H = T_{\text{electron}} + T_{\text{nuclei}} + U_{\text{electron-electron}} + U_{\text{electron-nuclei}} + U_{\text{nuclei-nuclei}} \quad (8)$$

where H is the Hamiltonian of the system, E the energy, Ψ the wave function (which is a function of electronic coordinates $\{\vec{r}\}$ and nuclear coordinates $\{\vec{R}\}$), T_{electron} the operator for kinetic energy of the electrons, T_{nuclei} for kinetic energy of the nuclei, $U_{\text{electron-electron}}$ for interaction between the electrons, $U_{\text{electron-nuclei}}$ for interaction between the nuclei and the electrons, and $U_{\text{nuclei-nuclei}}$ for interaction between the nuclei.

This equation has $3N(Z + 1)$ degrees of freedom, where N is the number of atoms and Z is the atomic number of the atoms. Apart from a few simple cases, an exact solution of this problem is far beyond the currently available computational power. A number of approximations have to be made to solve this many-body equation. The first and foremost is the Born–Oppenheimer approximation.[5] This is based on the fact that there is a huge difference in the mass of the electrons and the nuclei. It assumes that the motion of the electrons is determined by the instantaneous positions of the nuclei, and that of the nuclei by the average position of the electrons. The nuclear degrees of freedom thus only enter Schrodinger's equations as parameters. Density functional theory[6] is used to reduce the many-electron-problem to a series of coupled single particle equations. The central theorem for this theory implies that the charge density of the system uniquely determines the Hamiltonian of the system. Thus, all quantities that can be deduced a priori when the Hamiltonian is fixed can be written as functionals of the charge density. This theory (for which Walter Kohn got the Nobel Prize in 1998) is formally exact, but in practice some approximation has to be made for the exchange-correlation functional.[7] Besides this, often one also uses the pseudopotential approximation;[8] as only the valence electrons count in any chemical reaction, only they are considered explicitly. This approximation treats the remaining ''core'' electrons via an effective potential called pseudopotential. With these approximations one is left to solve:

$$\left(\frac{-\nabla^2}{2} + V_{\text{effective}}\right)\phi_i = \varepsilon_i\phi_i \quad (9)$$

where

$$V_{\text{effective}} = V_{\text{hartree}}[\rho] + V_{\text{ion}} + V_{\text{exchange-correlation}}[\rho] \quad (10)$$

$V_{\text{hartree}}[\rho]$ is the coulombic interaction between the electrons, V_{ion} the interaction between the nuclei and the electrons (either as a pseudopotential or just $1/r$ potential), and $V_{\text{exchange-correlation}}[\rho]$ the exchange-correlation potential from density functional theory. The charge density is given as

$$\rho(r) = \sum_{i=1,\text{occupied}} \phi_i^*\phi_i \quad (11)$$

The above three equations are solved self-consistently[9] to give a charge density and potential. Properties are then calculated based on this charge density and potential. This formalism based on density functional theory has become a very popular tool for investigating properties of materials.

Molecular Mechanics

It is not always necessary to detail the electronic behavior of materials; an accurate understanding of the atomic interactions is often sufficient to describe the phenomenon of interest with reasonable accuracy. In contrast to ab initio methods, molecular mechanics is used to compute molecular properties, which do not depend on electronic effects. These include geometry, rotational barriers, vibrational spectra, heats of formation, and the relative stability of conformers. As the calculations are fast and efficient, molecular mechanics can be used to examine systems containing thousands of atoms. However, unlike ab initio methods, molecular mechanics relies on experimentally derived parameters so that calculations on new molecular structures may be misleading.

The idea of building models to represent molecular structure is a fundamental tool that is used to understand chemistry and the structures that atoms adopt as they are found in molecules. In the not too distant past, molecular modeling was accomplished using plastic balls and straws. Watson and Crick discovered the structure of DNA using this type of model[10] in 1953. These plastic models were truly atomistic in nature in that they treat each atom as a discrete entity, with complex arrangement of electrons treated explicitly.

Today, computational techniques are used to model the conformational behavior and energetic properties of molecules. Molecular mechanics (MM) is a mathematical formalism, which uses a classical, physical

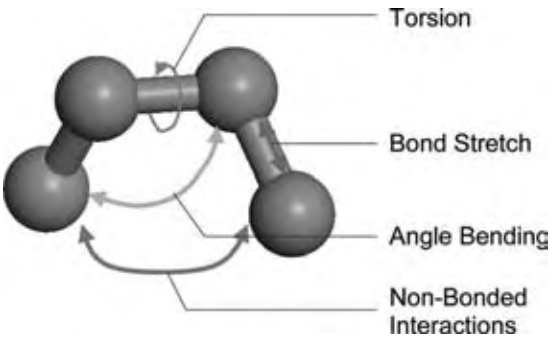

Fig. 2 The mechanical molecular model considers atoms as spheres and bonds as springs. The mathematics of spring deformation can be used to describe the ability of bonds to stretch, bend, and twist. *(View this art in color at www.dekker.com.)*

description of the molecule to calculate the energy of that particular conformation:

$$\text{energy} = f(\text{nuclear positions}) \tag{12}$$

Based on our history of physical and chemical experiences, we can think of molecules as mechanical assemblies made up of simple elements like balls (atoms), rods (bonds), and flexible joints (bond angles and torsional angles) —see Fig. 2. Eq. (12) can then be expressed as

$$\text{energy} = E_{\text{stretching}} + E_{\text{bending}} + E_{\text{torsion}} + E_{\text{nonbonded interactions}} \tag{13}$$

Eq. (13) makes the distinction between bonded (interactions between atoms that are connected by no more than three bonds) and nonbonded (interactions between atoms that are not connected to each other at all) interactions . The nonbonded energy accounts for repulsion, van der Waals attraction, and electrostatic interactions. van der Waals attraction occurs at short range and rapidly dies off as the interacting atoms move apart by a few angstroms. Repulsion occurs when the distance between interacting atoms becomes even slightly less than the sum of their contact radii.

The electrostatic interaction is modeled using a coulombic potential. The electrostatic energy is a function of the charge on the nonbonded atoms, their interatomic distance, and a molecular dielectric expression that accounts for the attenuation of electrostatic interaction by the environment (e.g., a solvent or the molecule itself).

The simplest calculation in molecular mechanics is the calculation of the potential energy of the system, which is performed by summing the numerous energy terms for the given conformation of the system using the given set of potential energy functions and parameters:

$$E_{\text{potential}} = \sum E_{\text{stretching}} + \sum E_{\text{bending}} + \sum E_{\text{torsion}} + \sum E_{\text{nonbonded interactions}} \tag{14}$$

Typically though, MM calculations are used to find the minimum energy conformations for a given molecule. There are numerous energy techniques used to find the minimum energy, from simple grid searching to more complex methods such as ''steepest descent,'' ''conjugate gradient,'' and ''Newton–Raphson.'' These methods tend to find the local minimum and not the global minimum, as the algorithms do not ''climb over'' energy barriers. To optimize the minimization procedure, it is usually best to combine several algorithms in a minimization scheme.

Some common applications of energy minimization in macromolecular systems are relieving strain in experimentally obtained structures, refinement of molecular models, or in search protocols aimed at finding the global energy minimum of the system.

Molecular Dynamics

All chemical process involves the motion of atoms within a molecule. Molecular dynamics (MD), in the broadest sense, is concerned with molecules in motion. It combines the energy calculations from molecular mechanics with equations of motion. Generally, an appropriate starting structure is selected (normally an energy minimized structure). Each atom in the system is then assigned a random velocity that is consistent with the Maxwell–Boltzmann distribution for the temperature of interest. The MM formalism is used to calculate the forces on all the atoms. Once the atom positions are known, the forces, velocities at time t, and the position of the atoms at some new time $t + \delta t$ can be predicted. More details about the method can be found in Ref.[11].

Molecular dynamics simulations have been used in a variety of ways. They can be used to compute mechanical moduli by studying the response of a model of the bulk polymer to a constant stress or strain, and to study the diffusion of molecules in membranes and polymers.[12] There are numerous biomolecular applications. Structural, dynamic, and thermodynamic data from molecular dynamics have provided insights into the structure–function relationships, binding affinities, mobility, and stability of proteins, nucleic acids, and other macromolecules that cannot be obtained from static models.

Monte Carlo Simulations

Often we are only interested in the equilibrium structure of a set of molecules. When the system is at high densities or includes a large number of conformations, other methods become computationally unfeasible, and one often uses Monte Carlo (MC) techniques. Monte Carlo methods use random number generators to integrate systems with very high degrees of freedom.[13] These integrals are then used in theories of statistical mechanics to evaluate thermodynamic properties of materials.[14]

Any macroscale thermodynamic state can be represented by a very large number of consistent microstates. The thermodynamic properties of the material are a result of contributions from these various microstates. Monte Carlo simulations ensure that these microstates are efficiently accounted for. Those that contribute significantly to the thermodynamic state are given greater importance through importance sampling algorithms.[13] Monte Carlo simulations further ensure that less accessible states are also accounted for[15] through various biasing methods.

STATISTICAL CORRELATIONS

While first principles modeling methods are most sought after—as they help one understand the mechanisms behind a phenomenon and hence engineer the phenomenon—it is not always possible owing to the complexity of certain systems or processes. In such situations, neural network models are often used to help understand the system or to optimize the system without necessarily understanding it completely.

Quantitative Structure–Property and Structure–Activity Relationships (QSPR/QSAR)

The idea that the behavior and properties of a molecule are concealed in the fundamental structural formulae has been around for a long time. Modern physical chemistry has become increasingly orientated toward understanding how these properties can be decoded from the structure. Ideally, all properties of a chemical compound would be calculated from first principles. This is, however, unlikely in the foreseeable future because of a number of reasons, including the lack of sufficient theory and limits of available computational power. An alternative approach to finding qualitative mathematical relationships between the intrinsic molecular structure and observable properties of a chemical compound will be extremely valuable to both industrial and academic chemists.

The concept of QSAR/QSPR is to transform searches for compounds with desired properties using chemical intuition and experience into a mathematically quantified and computerized form. Available programs enable scientists to easily generate and present molecular data including geometries, energies, and associated properties (electronic, spectroscopic, and bulk). The usual paradigm for displaying and manipulating these data is a table in which compounds are defined by individual rows, and molecular properties (or descriptors) are defined by the associated columns. A QSAR/QSPR attempts to find consistent relationships between the variations in the values of molecular properties and the biological activity or material property for a series of compounds so that these ''rules'' can be used to evaluate new chemical entities. A QSAR generally takes the form of a linear equation:

$$\text{Activity/property} = \text{Const.} + (C_1 \times P_1) + (C_2 \times P_2) + (C_3 \times P_3) + \cdots \quad (15)$$

where P_1 to P_n are descriptors computed for each molecule, and the coefficients C_1 to C_n are fitted so as to give the best correlation to the activity or property of interest.

Once a correlation between structure and activity/property is found, any number of compounds, including those not yet synthesized, can be readily screened on the computer to select structures with the properties desired. The most promising compounds may then be selected for synthesis and evaluation in the laboratory. In the pharmaceutical[16] and environmental areas,[17] QSPR has been applied to predict properties like the efficacy of drugs (with different substitutions) or behaviors like the accumulation of pollutants in fish, despite the fact that the exact mechanisms are unknown. The QSAR/QSPR approach conserves resources and accelerates the process of development of new molecules for use as drugs, materials, additives, or for any other purpose.

It is not easy to find successful structure–activity/property correlations, but the rapid growth of publications dealing with QSAR/QSPR studies clearly demonstrates the progress in this area. To obtain a significant correlation, it is crucial that appropriate descriptors be employed, whether they are theoretical, empirical, or derived from readily available experimental characteristics of the structures. Many descriptors reflect simple molecular properties and thus can provide insight into the physicochemical nature of the activity/property under consideration.

The QSPR/QSAR methods have many direct benefits like property prediction, target molecular design, and structural refinement, and indirectly it can help to

elucidate not-so-obvious physics, unknown mechanisms, or molecular behaviors.[18]

Neural Networks

Artificial neural network (ANN) is an information-processing paradigm inspired by the way the densely interconnected, parallel structure of the mammalian brain processes information. The processing ability of the network is stored in the interunit connection strengths, or "weights," obtained by a process of adaptation to, or "learning" from, a set of training patterns.[19] Neural networks can be used in the same general applications as QSPR/QSAR. While there is software available for generating a neural network, it is still very much an art to understand the model outputs, especially when trying to elucidate mechanistic information.

NANOSCALE AND MESOSCALE MODELING

Modeling at the continuum scale is well understood, and the accuracy, precision, and robustness of results using continuum methods have been analyzed. Modeling at the atomistic scale has also begun to be accepted as part of routine research protocol. Results from such methods are now accepted with a reasonable understanding of their accuracy and robustness. The weak link in the modeling spectrum is the area of mesoscopic and nanoscopic modeling. This is the scale where one cannot use continuum scale assumptions and yet the system one deals with is often larger than a few molecules, thus precluding atomistic modeling. How do we study systems that are made of clusters of thousands of molecules that interact in specific ways? How do we take results from atomistic simulations and correlate them to parameters we need for continuum studies?

Nanoscale is broadly defined as phenomena that occur in the range of 10–100 nm. Modeling nanoscale phenomena in industrial materials design becomes increasingly significant, as nanoscale engineering of materials becomes critical in developing superior materials. This includes engineering of molecular clusters or of functionalized nanoparticles, crystals, and liquid crystalline structures (such as clathrates and micelles) that are used as templates for porous membranes;[20] materials with specific enzymatic or catalytic properties;[21] control of flow behavior; nanocontainers with controlled release,[22] or materials with specific thermal, electromagnetic,[23] or mechanical properties.[24] As a significant fraction of these materials is designed by self-assembly of atoms or molecules to form nanosized clusters, modeling becomes a critical tool in engineering such materials. Modeling is also used to understand conditions or optimize processes to functionalize or engineer aspects of these structures—such as size of cluster, surface properties, or charges. Fig. 3 shows some examples of nanoscale clusters.

From a modeling perspective, there are a number of aspects to be addressed. Modeling helps to translate macroscopic observations based on nano- or mesoscale phenomena. Judicious use of simulations helps understand why certain behavior is seen—critical knowledge for engineering such behavior. For example, how can one predict the behavior of silicon nanoparticles whose surfaces have been modified with specific functional groups when they are in a polymer matrix[25]—or alternatively, how can one engineer the surfaces of nanoparticles so that polymer-particle composites may manifest a certain set of desired properties. Similarly, what kind of structures do micelles made up of specific amphiphiles form and how do they behave at different concentrations—or alternatively, what additives and amphiphiles could one use to engineer certain rheological properties in fluids, engineer specific surface properties, or design specific micellar structures,[26] how do molecules cluster in various environments,[27] and how does that affect their thermodynamic properties and their mobility. Another area with significant modeling effort is vis-à-vis biomolecules.[28] Simulations have been used to understand binding mechanisms of biomolecules on surfaces[29] and with each other, enzymatic pathways, mobility of molecules, design of encapsulants, etc.—all with the aim of engineering drugs for specific action as well as methods of targeted delivery. Nano- and mesoscale models can be used not only to look at the equilibrium behavior of materials but also to study mobility of particles and rupture behavior of adhesives—essentially nonequilibrium phenomena—as well.

Modeling mesosystems is difficult as the phenomenon of interest is neither atomistic, so that solutions can be grasped by understanding the behavior of a few atoms and computers are still not fast enough to deal with thousands of molecules rigorously, nor is it macroscopic so that continuum properties of the material can be assumed without losing events occurring in the smaller scale regime. Modeling phenomena that span different orders of length- and time scale require the use of multiscale models (schematic in Fig. 1).[30] Two kinds of multiscale methods—hierarchical and handshake—have provided feasible solutions to real problems.

Approximating a number of polymer molecules or solvent molecules as single beads with tunable interactions is an example of hierarchical models.[31] These models use information lumped from a smaller size scale or shorter time scales to predict phenomena at the scale of simulation and/or predict parameters or observations at larger scales. The parameters of the bead, in this case, are obtained from atomistic or quantum calculations on the molecules. The beads and

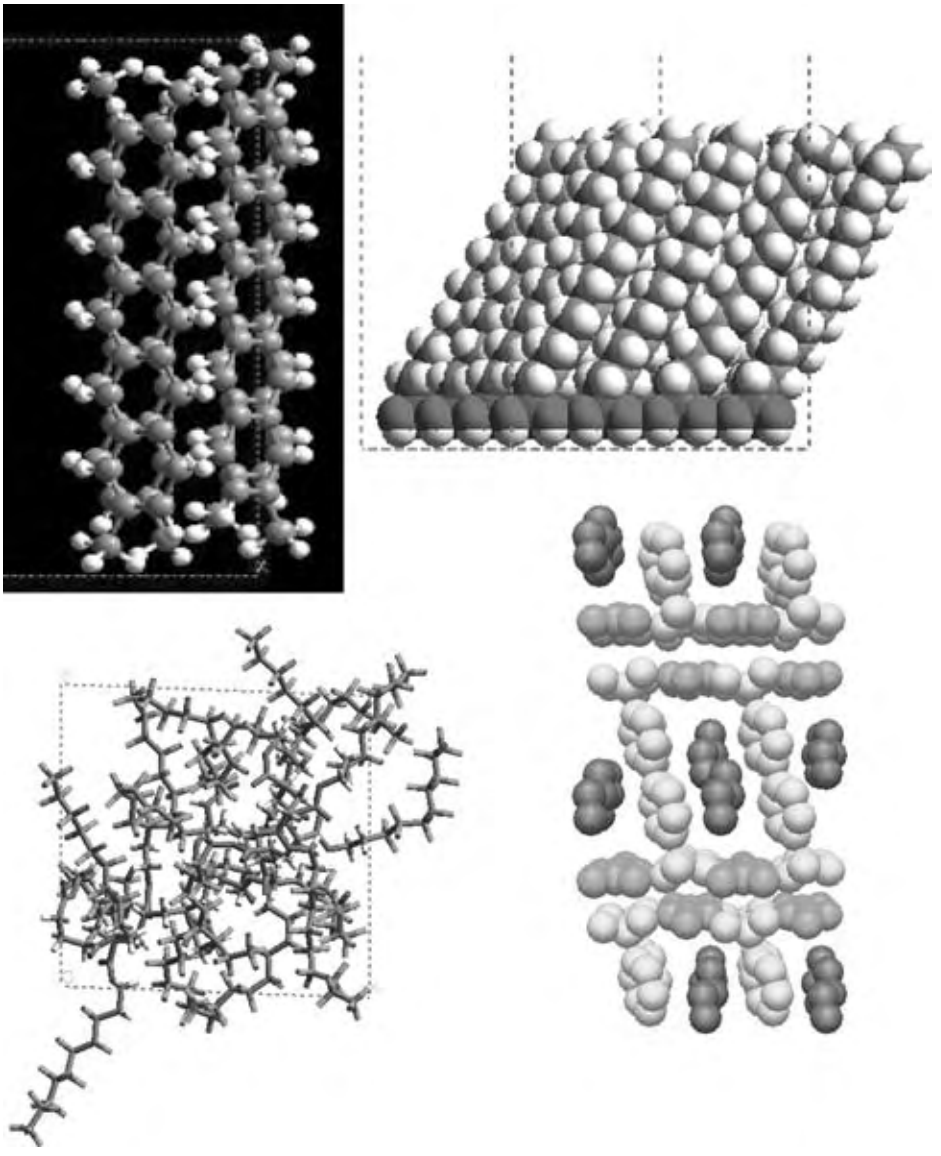

Fig. 3 Examples of nanoscale clusters whose properties may be controlled to engineer materials with specific thermal, mechanical, or electromagnetic properties. *(View this art in color at www.dekker.com.)*

chains, in turn, are used to predict viscosity and material properties, which can then be used in flow models or structure/stress models to predict macroscopic behavior of the material. Such methods are used to study equilibrium structure of polymers[32] and composites as well as nonequilibrium processes such as relaxation and/or fracture.[33] More complex versions of this algorithm have also been used in the study of nanoparticle interactions with polymers as well as a variety of solvents.[34]

Lattice models consist of spanning the system of interest by meshes or nodes. Molecules that are moving or reacting are lumped into coarser particles, and the nodes or the meshes keep a track of the extent of mobility or reaction. Examples include curing of polymers, diffusion in porous structures, and stress calculations in materials.

Handshake methods describe the problem by identifying one area where continuum assumptions hold while focusing on atomistic or mesoscale models to solve another aspect in a way that these two regions influence each other. Dynamic fracture is a very good example.[35] Energy from large-scale elastic fields is concentrated on the angstrom scale of the electrons that participate in atomic bonding. A simulation of this phenomenon requires an accurate description of atoms bonding at the crack tip, while at the same time including a proper description for very large volumes of strained material, with the resolution varying with distance from the crack tip. Far away, it is adequate to use the equations of motion for a macroscopic-averaged continuum field. This spatial decomposition makes it possible to combine different simulation methods describing the different physical regions into

a single, powerful simulation tool. Another example is the use of a handshake model to predict micelle free-energies: an analytical solution suffices in the continuum assumption of the hydrocarbon core, while molecular simulations are required to understand the head groups and their interactions with the solvent.[36]

Alternatively, different molecular models may be used in different regions. The combination of quantum mechanics (QM) (close to the docking site) and molecular mechanics (MM) (in the rest of the protein) methods allows one to predict the behavior of molecules docking on proteins. Particular attention must also be paid to an accurate joining of the two regimes at the boundary region.

Today, a significant fraction of related literature is on model systems, which explains trends and behavior of ''ball-spring models'' but is of little use in predicting the behavior of systems with specific chemistry. While there is a growing effort to solve real systems of industrial importance, this certainly is the area of weakness in the modeling toolbox today.

CONCLUSIONS

With the advent of powerful computational tools and algorithms, applications of modeling have become widespread. Modeling now not only offers a better understanding of materials phenomenon, but also has become a predictive tool useful in materials design. In this entry, we have described some modeling techniques that are useful for modeling phenomenon at various length- and time scales. These techniques allow industrial scientists to model real-world applications (and not just model systems). These techniques—at atomistic, mesoscale, and macroscale—when used either alone or in conjunction with one another, provide scientists with powerful tools to investigate properties of materials.

INTRODUCTION

Phosphors are materials doped with impurities that give off cold light when excited. This fluorescence is caused by the ions in the lattice structure emitting a photon to de-excite, vs. nonluminescent phonon processes. Light emitted from a phosphor is not caused by thermal effects, and as such, is considered cold. Fluorescent materials are used in a variety of applications including television screens, lighting, photocopy lamps, scintillators, as x-ray conversion screens, and sensor technology. The materials used for these sensors are typically inorganics doped with impurities that provide characteristic fluorescence and are commonly referred to as phosphors. Sensor technologies based on these materials use characteristics of the light emission to determine various parameters, such as temperature, impact/pressure, and radiation dose. In the following sections, the fundamental principles of each of the three sensor types will be discussed and applications described.

TEMPERATURE EFFECTS

Phosphor-based temperature sensors are adaptable to the needs for a wide variety of situations and are based on fluorescence material properties. The thermal dependence of fluorescence may be exploited to provide a noncontact, emissivity-independent optical alternative to other more conventional techniques, such as those employing pyrometry, thermocouples, or thermistors. In fact, there are certain situations where fluorescence-based thermometry is the only useful approach, such as in devices like turbines or engines.

Background

Phosphors have many emission characteristics that can be temperature dependent. These characteristics include emission intensity, absorption wavelength shift, emission wavelength shift, and emission lifetime.

The emission spectra of a phosphor can have multiple distinct wavelength peaks. As stated earlier, the emission level of these peaks can change with temperature. For instance, Fig. 1 shows the emission spectra of $La_2O_2S:Eu$.[1,2] Each emission line is characterized by a wavelength for which the intensity is a maximum. Its value may change slightly with temperature, and this is termed a line shift. An emission line has a finite width called the line width, which is often referred to as the spectral width at half the maximum line intensity. Line width and line shift, which change as a function of temperature, are generally small and not often used in fluorescence thermometry. This spectrum at 36°C shows that the relative intensities of the lines near 465 and 512 nm are less than those at 4°C, and thus are temperature dependent. In fact, typically certain lines in these phosphors get weaker, i.e., become less bright, as the temperature of the material is increased. The intensity ratio of distinct emission peaks can also be used as a temperature sensor and has been suggested as a method to make two-dimensional measurements.

An absorption spectrum is obtained by measuring the amount of light transmitted through a specimen as a function of wavelength, whereas an excitation spectrum is determined by monitoring the intensity of an emission line while the excitation wavelength is varied. The absorption spectra of many phosphors consist of a relatively broad band at the blue or ultraviolet end of the spectrum, along with sharper absorption features in the visible and near infrared. The sharper features are often due to atomic transitions of the dopant atom and, as noted above, exhibit some temperature sensitivity. As the broad absorption band results from direct interaction with the host, it may show more temperature dependence. This characteristic can be utilized in two ways. First, using a set excitation wavelength no measurements can be made below the temperature where the excitation spectrum matches

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120041071

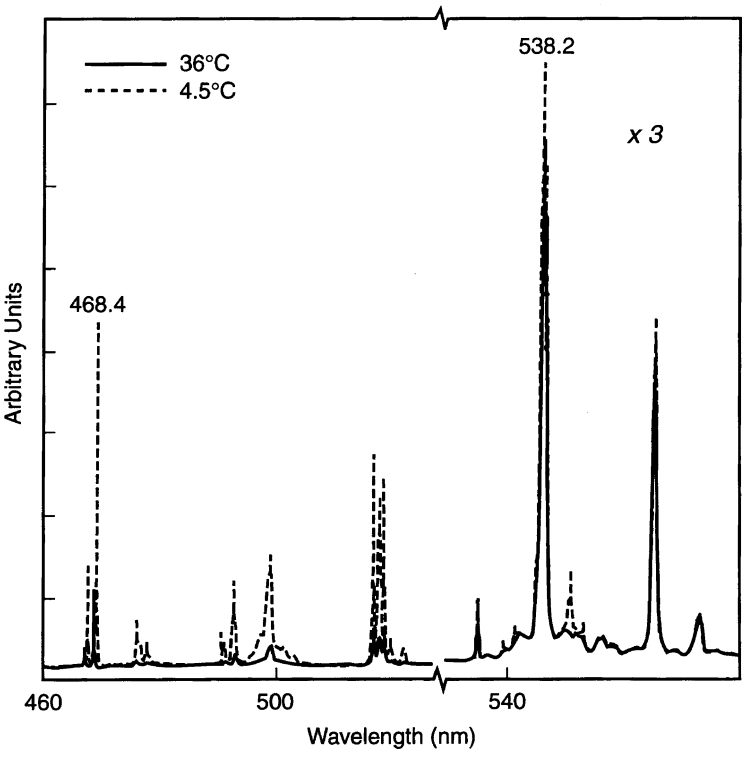

Fig. 1 Emission spectra for $La_2O_2S:Eu$ at two temperatures.

the excitation light. Second, this can be used as an indication of substrate heating. If the substrate is coated with a phosphor that is not excited at room temperature, as the light emission begins and gains intensity it becomes an indication of the substrate heating.

The emission lifetime is often used to determine surface temperature with the advantage that the technique is insensitive to blackbody background. This technique requires excitation by a pulsed source, the persistence of the resulting fluorescence can be observed providing that the length of the source pulse is much shorter than the persistence time of the phosphor's fluorescence. For certain phosphors, the prompt fluorescence decay time (τ) varies as a function of temperature and is defined by:

$$I = I_0 \exp\left\{-\frac{t}{\tau}\right\} \quad (1)$$

where I = fluorescence light intensity (arbitrary units), I_0 = initial fluorescence light intensity (arbitrary units), t = time from cessation of excitation source (sec), and τ = prompt fluorescence decay time (sec).

The time needed to reduce the light intensity to e^{-1} (36.8%) of its original value is defined as the prompt fluorescence decay time (τ). By measuring the decay time as a function of temperature, the phosphor can be calibrated.[1,2]

Calibration

A typical phosphor-based optical thermometry system will consist of at least the following components: 1) a source of excitation energy; 2) a means to deliver the energy to the target (typically beam-steering elements or a fiber-optic bundle if the energy is in the optical spectrum); 3) a fluorescing medium that is bonded to the target and illuminated by the incident flux; 4) an optical system to collect and transport the fluorescence that is subsequently generated; 5) a detector or an array of detectors to monitor the fluorescence signal; and 6) a data acquisition and analysis system that yields the target's temperature. Fig. 2 shows an elementary example of this arrangement. The particular system depicted here was designed to demonstrate the feasibility of making remote, noncontact measurements of the temperatures and strains in high-voltage devices in electrical substations in the Tennessee Valley authority's power grid.

By gradually raising the temperature of a phosphor sample and measuring the emission lifetime at selected temperatures, a calibration can be made. Once the lifetime values have been recorded over the expected temperature range, data are fit to produce a mathematical expression for the temperature as a function of the lifetime. Having calibrated the phosphor over the temperature range of interest, a small surface deposit of phosphor is excited with a pulsed laser and the fluorescent decay is measured (typically in less than 1 msec) to

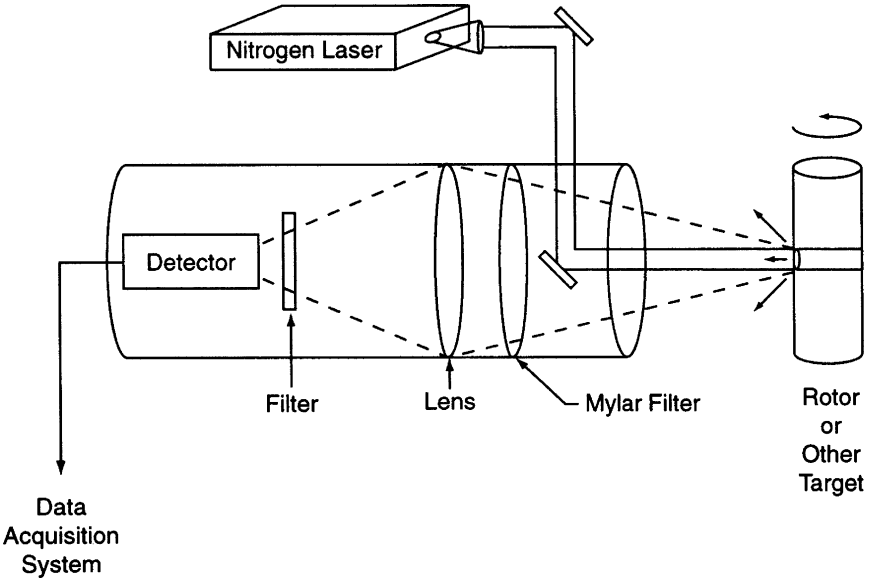

Fig. 2 Typical example of phosphor-based optical thermometry system.

calculate the temperature of the substrate. This technique has been evaluated for temperature ranging from cryogenic to upward of 2000 K. Fig. 3 shows the calibration curves for a variety of different phosphors.

Applications

Phosphor thermometry has been used in a variety of applications from aerospace to manufacturing. The technique becomes indispensable in situations that have large blackbody background, such as combustion, and when the surface is in motion, such as in jet turbines. The technique is also very useful when the surface emissivity varies with time. This technique can also be expanded to include measurements of heat flux by applying phosphor to two sides of an opaque insulator material.

Gas turbines

Previous successful applications led to efforts aimed at measuring the temperatures of surfaces and structures inside turbine engines, particularly those of the rotating blades and the stationary vanes. The history of that research is documented in a series of papers, as shown in Refs.[1,2] Several other groups have independently applied phosphor thermometry to turbomachinery, and in what follows we provide a synopsis of the work done in this field.

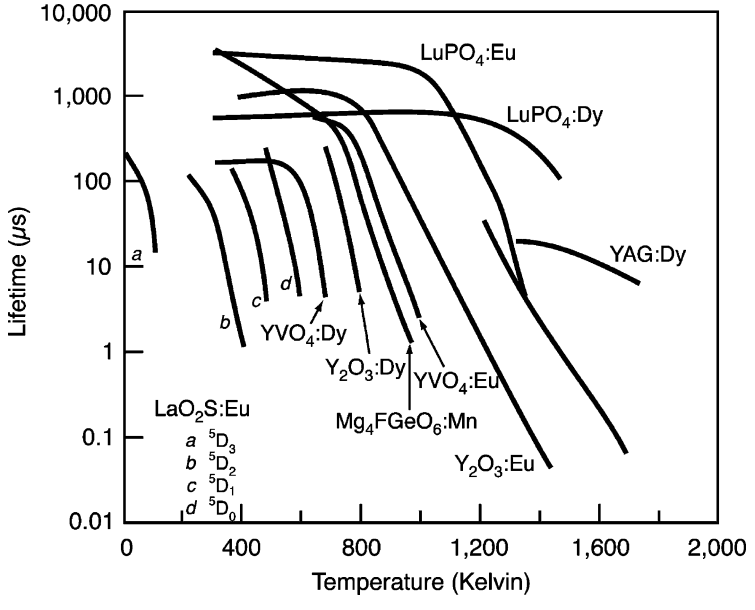

Fig. 3 Example calibration curves for a variety of phosphors. (From Refs.[1,2].)

One of the original intents of the Oak Ridge National Laboratory (ORNL) phosphor thermometry program was to provide a means of sensing the temperatures of objects within the combustion–flame environment. The first experimental tests of the technique were carried out inside a high-altitude simulation wind tunnel at the Arnold engineering development center (AEDC).[3] In them, the exhaust from the aft end of a Pratt & Whitney (PW) F100 engine impinged on a variable area extractor (VAE), a cone-shaped center body that aids in pressure recovery and the pumping process. Measurements were made of the VAE surface temperature, both with and without an afterburner plume intervening between the surface and detection optics. The VAE was water-cooled, consequently, its temperature was rather low, typically 150°C. The laser-induced fluorescence signals from the phosphor targets bonded on the VAE surface were successfully captured through the optical background created by the plume. This is shown in Fig. 4, which is a print made from a 16 mm film of the afterburner and the VAE. The white spot is the phosphor luminescence. The resulting data made it possible to track the temperature change of the VAE during the course of afterburner ignition transients.

Subsequent engine experiments were performed at a burner–rig installation. The usual arrangement involves mounting several blades on a mechanical carousel, which is then rotated at relatively low speeds through a jet flame. Phosphor thermometry tests by Tobin et al. in one such installation demonstrated the workability of the technique up to 1100°C.[4,5] Other studies have been carried out in spin pits, where the higher rotational speeds and the intermediate range temperatures encountered in operating turbine engines can be simulated without the exhaust flame present.

A number of in situ experiments have also been carried out, including measurements made on the first-stage stator vanes inside a PW 2037 engine on the vanes of a turbine disk running near full speed (14,600 rpm) in an advanced turbine–engine gas generator system, on the components of a PW joint technology developmental engine, and inside an experimental turbine engine at Virginia Polytechnic Institute and State University.[5–7] Collectively, these tests have demonstrated that phosphors based on materials such as yttrium oxide, yttrium vanadate, and yttrium aluminum garnet (YAG) can survive for extended periods even when bonded in place in the first stage of a turbine, where the blades are adjacent to the burner. Useful optical signals were obtained at temperatures well in excess of 1000°C. Separate calibration studies showed that the fluorescence decay parameters of some of the phosphors were still readily measurable at 1200°C.[8] The preferred design of the optical probe now consists of a two-fiber configuration with internal optical elements that are coated to minimize stray reflections, laser-induced damage to the input fiber, and the optical background due to blackbody radiation. On a related note, studies of the heat transfer through combustion engine components have also been undertaken with thermographic (temperature sensing) phosphors.[9]

Several others have also explored turbine engine and other aerospace applications of phosphor thermometry. For instance, Alaruri et al. exposed samples of Y_2O_3 : Eu to the combustion flows in a burner rig.[10] The gas velocities in the rig ranged from 245 to 407 m/sec at roughly atmospheric pressure. Data were taken over the range from 400°C to 1000°C with the overall accuracy of the measurements estimated to be ±3%. They noted that the phosphor's fluorescence

Fig. 4 Phosphor thermometry measured in an exhaust plume of jet engine afterburner.

was easily distinguishable from the luminescence because of the fuel pulses.

Phillips and Tilstra describe a thermographic phosphor temperature sensor based on the decay-time approach and designed using a 200 μm optical fiber to convey the fluorescence signals.[11] It has been tested over the range of 75–350°C, at altitude simulations of up to 21.3 km (70,000 ft), and under accelerative loadings equivalent to 20 g over the range of 5–2000 Hz. It can be used for measuring engine inlet total temperature, fuselage total temperature, and engine inlet immersion temperature, all without being subject to the effects of electromagnetic interference. Simons, McClean, and Stevens describe calibrations of additional phosphor materials of use for moderately high temperature measurements.[12]

Galvanneal steel

Galvanneal steel is an important material widely used in the production of automobiles. The accurate determination of temperature of galvanneal sheet during manufacture is a critical problem, which has recently been addressed with fluorescence thermometry.[13] In the galvanneal process, steel strip is dipped into a zinc bath. After exiting the bath, the sheet, with its molten-zinc coated surface, passes through an annealing furnace that promotes the diffusion of iron into the zinc coating. During this stage process, up to four metallurgical phases, or layers, are formed, each containing increasing amounts of zinc toward the surface. To control the final microstructure that determines the end product quality, precise control over the time–temperature relationship is crucial. The constantly changing emissivity of the strip surface and the strip motion rule out most optical pyrometers and thermocouples as practical measurement options. In addition, several parameters will vary during production, such as sheet thickness, sheet speed (which is up to 900 ft/min), and power to the induction furnaces. All of these affect the steel surface temperature and, so, must be controlled in real time to achieve a high-quality end product. Precision thermometry can provide for enhanced product quality, less product variability, and reduced process spoilage.

Clearly, the problem of surface emissivity is circumvented by fluorescence thermometry. A phosphor-deposition device applies the phosphor, under command from a control computer. As seen in Fig. 5, this deposition takes place several feet underneath the

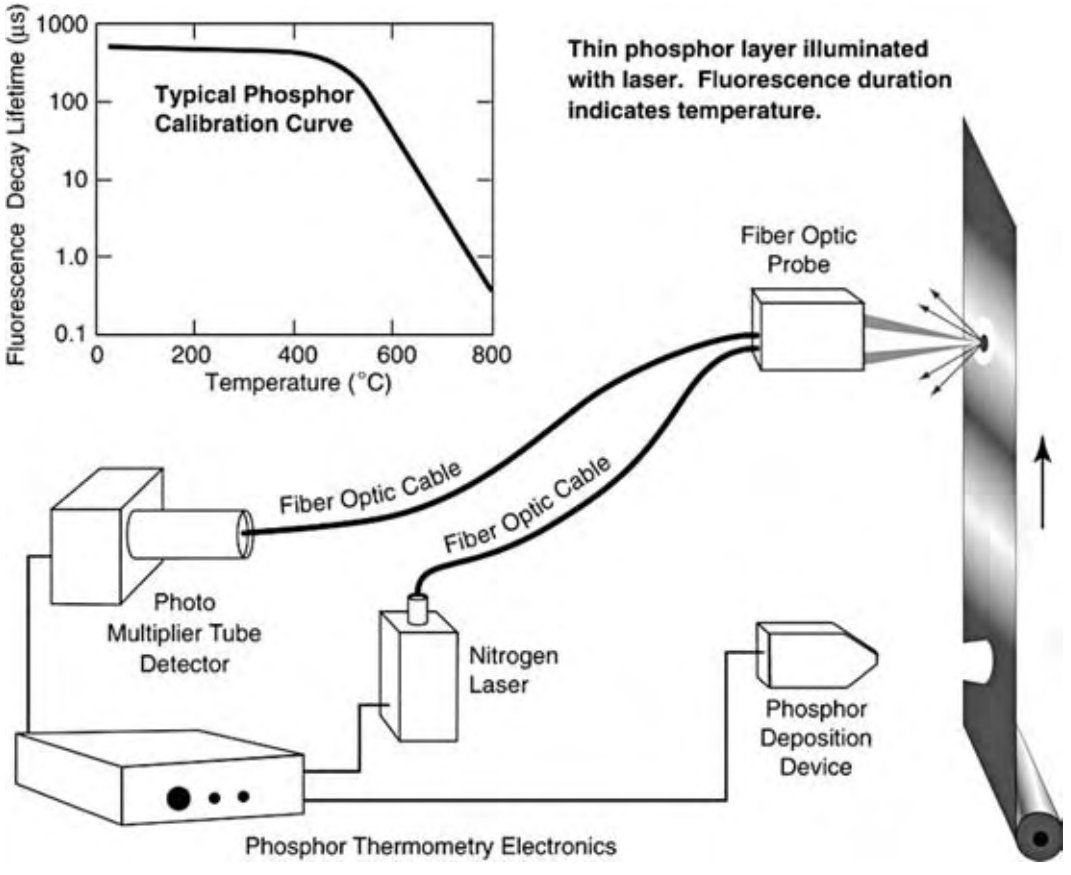

Fig. 5 Configuration of phosphor thermometry system for galvaneal steel.

temperature measurement equipment. This allows time for the thin phosphor layer to reach thermal equilibrium with the galvanneal surface. A laser with an optical fiber illuminates the phosphor. A given phosphor stripe is targeted several times by the laser so that the desired number of waveforms can be accumulated and averaged for good statistical sampling. Another optical fiber conveys the fluorescence photons to a remotely located photomultiplier tube (PMT) detector, which converts this optical signal to its electrical analog. The data analysis system is built around a personal computer (PC) using commercial software as well as hardware and software designed at ORNL. A custom interface board in the PC performs timing, control, and signal conditioning functions. The decay constant of the averaged signal is calculated and compared to an onboard calibration equation that determines the temperature reading. The most recent temperature is displayed on the computer screen. If the system is unable to obtain a stable measurement, no update occurs and the process is repeated. It should be pointed out that the introduction of microgram quantities of the phosphor material has been shown to have no detrimental impact on product quality.

An example of results, taken over a 100 min period, from a galvaneal line at National Steel is shown in Fig. 6. The temperature ranged between 460°C and 470°C. The apparatus can be used in other line-based industrial processes. For example, it was used at Bethlehem Steel for a much lower temperature. Different phosphor materials may be used depending on the temperature range of interest. This system received an R&D 100 Award for 1999.

In conclusion, the apparatus should be readily adaptable to other steel industry applications, such as slab heating, melt thermometry, roller thermometry, surfaces in reheat ovens, and galvalume processing. To extend the technology to these uses, issues like optical access, mechanical fixturing, phosphor adhesion, compatibility, and temperature range need to be addressed.

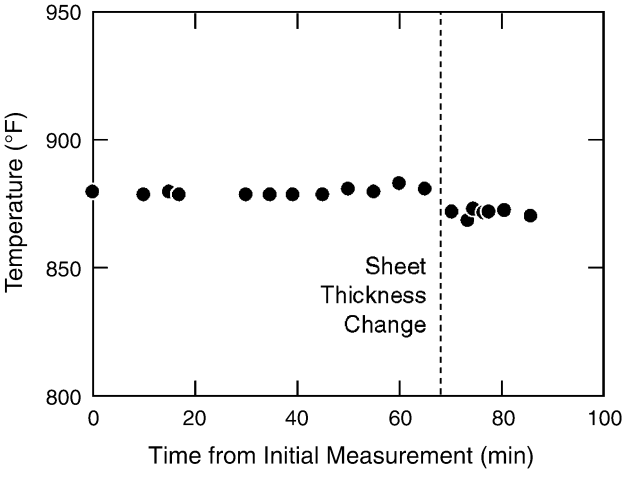

Fig. 6 Typical temperature data from galvaneal steel thermometry measurement.

Heat Flux

The determination of the heat flux through a surface is important in a variety of scientific and engineering applications. Noel, Turley, and Tobin, and Turley et al. pursued development of several thermal phosphor-based heat flux gauges.[14,15] A standard expression relates the heat flux, q, to the insulator thickness, d, thermal conductivity, k, and temperature difference, ΔT, across an insulating barrier:

$$q = \frac{k\Delta T}{d} \tag{2}$$

As originally conceived, a phosphor-based heat flux gauge would consist of a sandwich of two different types of phosphors separated by a UV-transparent insulator. The first realization of such a device incorporated $Gd_2O_2S:Tb$, in which the ratio of the D3 state at 415 nm to the D4 state at 490 nm served to provide the temperature of the top surface. The bottom surface was made of $La_2O_2S:Eu$, and its temperature was derived from the ratio of the emission of the D2 band at 511 nm to that of the D0 band at 614 nm. A demonstration arrangement, utilizing a hot-air stream, applied heat to one such gauge bonded to a water-cooled aluminum container. Levels of heat flux up to $40\,kW/m^2$ were measured in this way.

A second gauge consisted of an array of discrete circular and triangular spots of phosphor. This made it possible to obtain a two-dimensional determination of a heat flux through the surface of interest. Also, only one phosphor is required when, for instance, one-half of a semicircle of it is deposited on the top of the insulator with the matching half bonded onto the bottom. Fig. 7B is a close-up photograph of a fluorescing heat-flux gauge with matching triangular phosphor layers. Fig. 7A depicts the gauge attached to a turbine blade. Fig. 8 shows the experimental arrangement for this type of heat-flux gauge.

Baumann has also made heat flux measurements using thermographic phosphors.[16] Wind tunnel models made of three different materials (steel, Macor™ glass ceramic, and Norcoat™ 4000 silicone elastomer), all of which had thin coatings of $Y_2O_2S:Eu$ (0.15%) applied, were monitored during blow-down tests in a hypersonic flow facility. The response time of the measurement system was typically less than 200 msec, and the values of the heat flux measurements obtained with

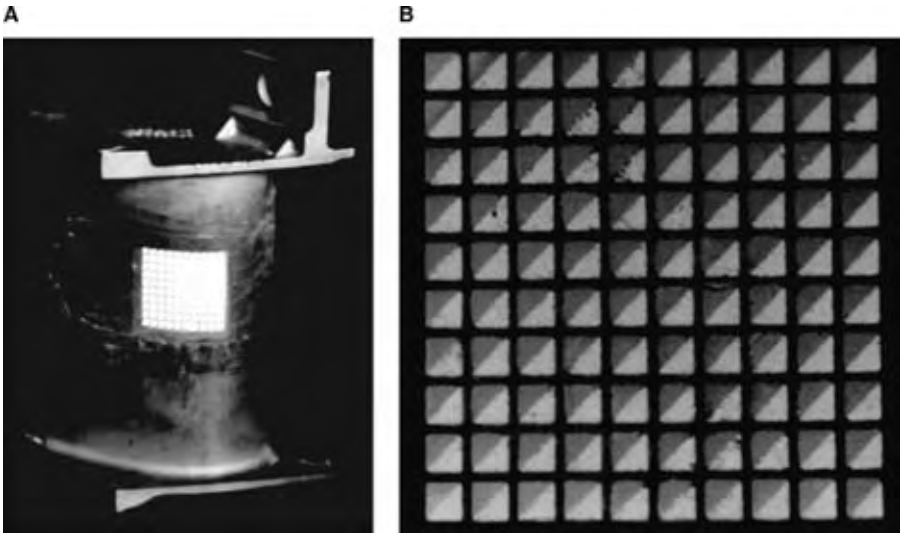

Fig. 7 (A) Phosphor-based heat flux gauge on turbine blade and (B) fluorescing gauge with matching triangular phosphor layers.

his technique compared well with the standard spot-gauge methods.

As a practical point, we note that the oxysulfide-based phosphors begin to degrade chemically in air near 450°C. However, other phosphors may be used for this application at higher temperatures. Another limiting factor encountered at high temperatures is the difficulty in finding a suitable insulator. To circumvent this, Noel has developed a theory and a resulting design that eliminates the need for an intervening insulator in the gauge.[17] As a related matter, we note that a detailed calculation of the heat flow through a thin

film heated by a laser has been carried out by Abraham and Halley.[18]

IMPACT EFFECTS

Triboluminescence (TL) is light produced while striking or rubbing two pieces of a material together. Sir Francis Bacon first studied it 400 yr ago and it is basically defined as the light from friction, as the term comes from the Greek tribein, meaning "to rub," and the Latin prefix lumin, meaning "light."[19,20]

Most crystals will emit light when fractured. Because most inorganic phosphors have a crystalline structure, they should emit TL. One phosphor, namely, zinc sulfide doped with manganese (ZnS : Mn), has often been noted for its TL. To develop an effective phosphor-based sensor, the relationship between TL intensity and impact velocity for ZnS : Mn or any other material must be quantified.

A specially designed drop tower for evaluating powder samples was constructed and is shown in Fig. 9.[21] It was made from 0.75 in. (19 mm) medium density fiberboard, 0.25 in. (6 mm) Plexiglas plate, and a common 1.25 in. (32 mm) piece of PVC pipe. The pipe has holes drilled in measured increments. These holes are used to place a pin that holds a 1.25 in. (32 mm) diameter steel ball (0.13 kg) bearing in place, and serves as the release mechanism.

The sample powder is placed on the Plexiglas plate as shown in Fig. 9B. The material is arranged so that it is aligned about the center of the tube. After several drop tests, the Plexiglas begins to show pits from the impact of the drop mass. These pits are used to align the sample so that the majority of the material is in the impact zone.

The ZnS : Mn powder can be widely displaced by the impact. After each test, the drop tube is removed, the drop mass is cleaned, and the powder is redistributed near the center of the target area. This redistribution is accomplished by placing a small piece of PVC in the tower base and moving the powder into an even layer. After each test, a small amount of the powder is removed when the ball bearing is cleaned. Apparently, this change in sample mass does not appear to affect the intensity or repeatability of the measurements.

To monitor TL intensity, a PMT was placed approximately 0.75 in. (9 mm) under the Plexiglas plate

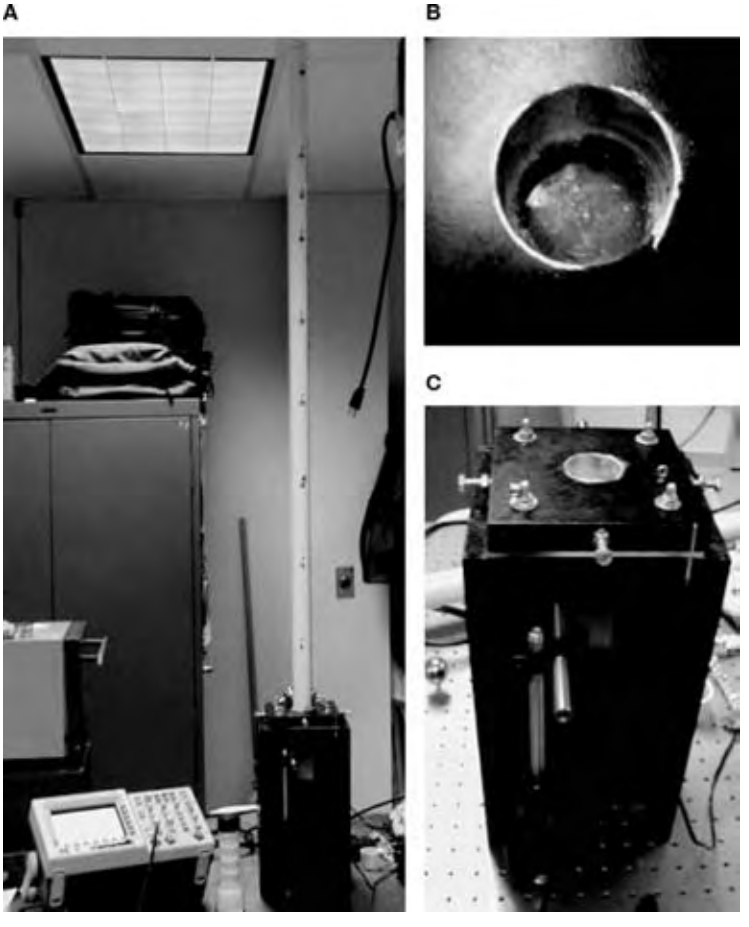

Fig. 9 Experimental arrangement for the drop tower: (A) drop tower with oscilloscope, (B) sample tray formed by tube support and Plexiglas bottom, and (C) drop tower base showing the mounting of the PMT.

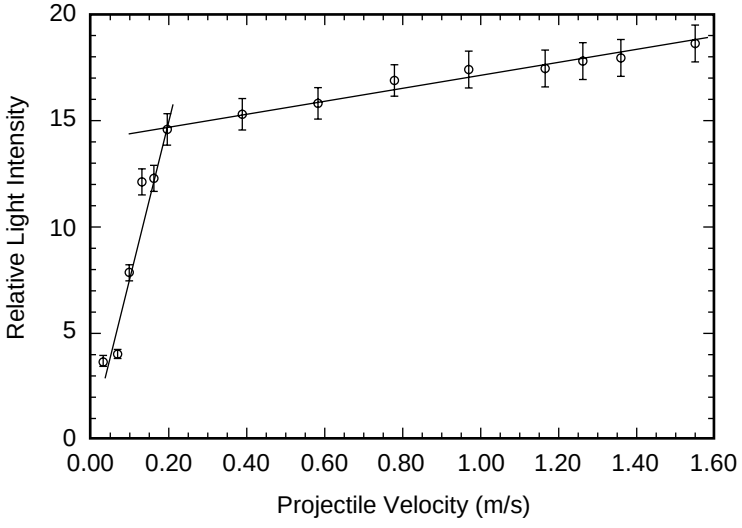

Fig. 10 Plot of the PMT output potential from ZnS : Mn and impact velocity.

as shown in Fig. 9C. To reduce effects because of stray light, a 589 nm filter is positioned in front of the PMT. Remember the maximum emission from ZnS : Mn is about 585 nm. The TDS 3052 oscilloscope captures the luminescence data in single sequence mode. The room light was turned off to further reduce background light noise in the PMT. The gain on the PMT was adjusted using a screw potentiometer until it was about half the total range.

Fig. 10 shows the variation in light emission characterized by the output potential from the PMT (V) vs. the drop velocity (m/sec). The impact velocity is defined based on Newton's equations for a free-falling object. These equations assume that air resistance is negligible and the ball does not make contact with the sides of the drop tube. The approximate measurement uncertainty is about ±5%, as shown by the error bars plotted in Fig. 10.[21]

The intensity of the triboluminesent response appears to be a function of impact velocity with two regions of interest as shown in Fig. 10. This is totally consistent with other measurements completed by the authors. The first region is in the threshold velocity ranges below 2 m/sec. The production of TL light appears to have a threshold at about 0.8 m/sec. Above the threshold, the projectile has sufficient velocity (or energy) to break ZnS : Mn crystals and to produce TL light. The TL luminescence increases rapidly until about 2 m/sec. The second region starts at about 2 m/sec and appears to be more like a saturation state, where the slope is much shallower and would indicate less sensitivity to impact velocity. Understanding these relationships will be very beneficial in the design of smart materials to detect damage caused by the impact of foreign objects. Once an impact is detected, the severity can be determined without the need for immediate inspection. These impact data could also be saved in a database and used to determine maintenance and inspection procedures. It was found that the reduction in TL material encountered in testing does not affect the repeatability of the measurements.

IONIZING RADIATION EFFECTS

For more than a century, phosphors that emit visible light when exposed to ionizing radiation have been used for a variety of scientific and engineering purposes. These materials exhibit a large fluorescence efficiency that makes them an effective accelerator beam detector or positioning system. Any phosphor used for this purpose will be exposed to large doses of beam radiation. This candidate material must be able to withstand such doses with a minimal reduction of fluorescence.

Half-Brightness Dose

The expression half-brightness dose ($N_{1/2}$) was coined as a consistent figure of merit to evaluate the effectiveness of a material in emitting fluorescence as a function of exposure. The $N_{1/2}$ was defined as the amount of exposure needed to reduce the fluorescence efficiency to one-half of its original value.

Birks and Black showed experimentally that the fluorescence efficiency of anthracene bombarded by alphas varies with total dose as

$$\frac{I}{I_0} = \frac{1}{1 + (N/N_{1/2})} \tag{3}$$

where I, I_0, N, and $N_{1/2}$ represent the fluorescence intensity, initial fluorescence intensity, total incident

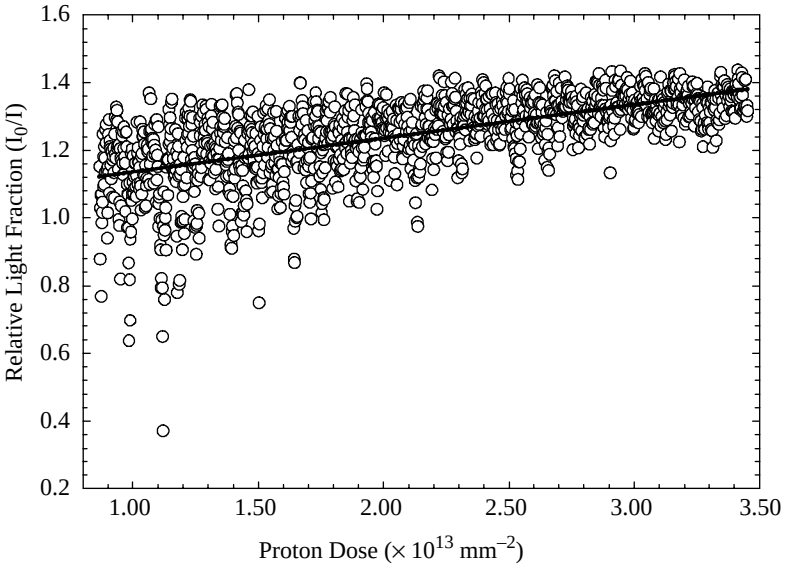

Fig. 11 Birks and Black plot for ZnS : Mn paint sample.

particle fluence, and the half-brightness dose, respectively.[22] The units of I and I_0 are related to the number of fluorescence photons interacting with the detector. When plotting the reciprocal of the light ratio (I_0/I) vs. proton dose, the resulting curve is linear with the slope equal to the inverse of $N_{1/2}$. The corresponding curve intercept was unity. Fig. 11 shows the relative light fraction as a function of proton dose for a ZnS : Mn paint sample. The line is determined by a linear, least-squares fit. Despite the low beam current, some charging/discharging of the sample was observed. The scattering of data points at low dose is probably due to this. As dose increases, the data are less scattered, suggesting that the protons were no longer building up on the surface. This could be the result of thinning of the layer due to beam sputtering or, more likely, a decrease in the proton cross section of the paint due to damage.

Schulman observed a similar effect to Eq. (3) when organic anthracene was exposed to γ-irradiation.[23] Black observed no efficiency degradation when the phosphor was exposed to 40 keV electrons, as they only cause ionization damage with no atomic displacements.[24] Northrop and Simpson found the fluorescence efficiency deteriorated in a similar fashion as was measured in previous measurements for organic phosphors.[25] Broser and Kallmann developed a similar relationship to Eq. (3) for inorganic phosphors irradiated using α-particles.[26] These results indicate that radiation produced quenching centers that compete with emission centers for absorbed energy.

3 MeV measurements

In the last decade, the authors have measured $N_{1/2}$ for several single-crystal and polycrystalline paint forms

Table 1 Selected 3 MeV proton $N_{1/2}$ data for several phosphor materials and forms

for selected yttrium, gadolinium, and terbium phosphors prepared at ambient temperature. Table 1 shows the resulting $N_{1/2}$ values vary between $0.12 \times 10^{14}\,\text{mm}^{-2}$ and $4.03 \times 10^{14}\,\text{mm}^{-2}$.[21,27–30] These phosphors were excited using a 3 MeV proton beam from a small electrostatic accelerator.

The polycrystalline samples consisted of a paint containing approximately 70% poly(phenyl methyl) siloxane (PPMS) and 30% phosphor powder. This formulation was found to give the toughest and the most wear-resistant paint. The grain size for the powdered polycrystalline phosphors was measured to be less than 10 μm. Small phosphor crystal slices were mounted directly to the sample holder for measurement. Proton beam current was kept low to minimize electrical discharge during each irradiation sequence.

45 MeV measurements

The measured 45 MeV half-brightness dose for several fluor materials can be found in Table 2.[8] Note that the right column in both the ambient temperature and 150°C data sections of Table 1 are labeled ''Ratio (45/3).'' These columns contain entries for the half-brightness dose measured at 45°MeV divided by the equivalent value at 3 MeV. For example, the proton $N_{1/2}$ for YAG : Ce was measured to be 2.2 times larger at 45 MeV than it was at 3 MeV for the ambient temperature samples. The same ratio for the 150°C data indicates that YAG : Ce takes 12.2 times more proton irradiation to drop the light intensity to half of its original value. The half-brightness dose values for the ambient temperature samples were 2.2 to 7.3 times

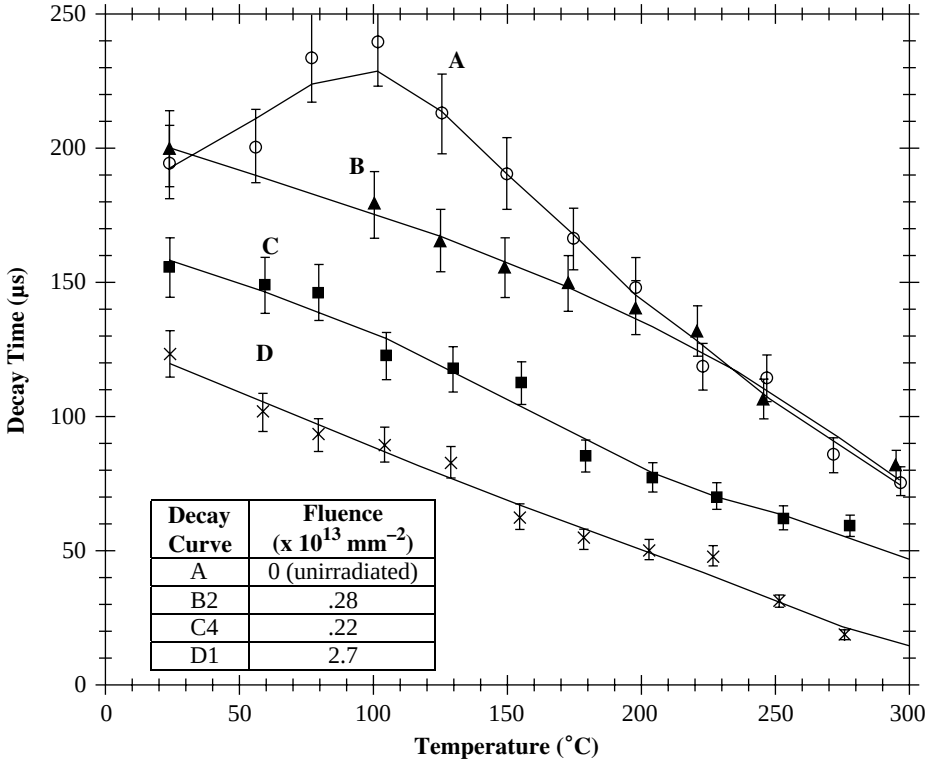

Fig. 12 Comparison of temperature-dependent decay times measured at the listed selection of 3 MeV proton fluences.

larger at 45 MeV than equivalent measurements at 3 MeV. The average ambient temperature ratio was approximately 5.2 for the set of four common fluors. The equivalent $N_{1/2}$ ratio at 150°C was 4.0–83.7 times larger at 45 MeV than the corresponding 3 MeV data. The average $N_{1/2}$ ratio at 150°C was 30 for the tested materials. The relationship between the half-brightness dose and the energy is unique at both ambient temperature and 150°C.

The proton interaction cross section is inversely proportional to energy, which causes the measured differences in half-brightness dose. Although fewer particles interact with the fluor at 45 MeV, each of the individual particles that do interact cause proportionally more damage to the scintillator than 3 MeV protons. A good analogy to this process is the use of a rifle bullet to knock down bowling pins. The probability that a rifle bullet (analogous to a 45 MeV proton) can hit a wooden pin is smaller than equivalent chance that a bowling ball (analogous to a 3 MeV proton) could do the same thing. Although the rifle bullet has a smaller interaction probability (cross section), the damage it causes when it hits a pin is much more extensive.

Fluorescence Decay Time

A plot of the temperature-dependent fluorescence decay time as a function of 3 MeV proton fluence is shown in Fig. 12.[31] The error bars shown in Fig. 12 for the measured decay times were calculated using standard uncertainty propagation techniques. Results indicate that a 3 MeV proton fluence as small as $2.28 \times 10^{13} \text{mm}^{-2}$ statistically reduces the ZnS : Mn decay time for measurement temperatures of less than 200°C. The unirradiated and $2.28 \times 10^{13} \text{mm}^{-2}$ decay time curves appear to be statistically identical after this temperature. A 3 MeV proton fluence of $2.28 \times 10^{13} \text{mm}^{-2}$ corresponds to one quarter of the half-brightness dose for ZnS : Mn.

Fig. 12 also shows that 3 MeV proton fluences greater than of $2.28 \times 10^{13} \text{mm}^{-2}$ uniformly reduce the ZnS : Mn decay time over all tested temperatures. It appears that reductions in temperature dependent decay time appear to be proportional to fluences larger than $2.28 \times 10^{13} \text{mm}^{-2}$. It is possible that radiation-induced dislocations in ZnS : Mn and the formation of sooty carbon in the polymer binder could account for these effects.

CONCLUSIONS

Fluorescent materials have been used in a wide variety of applications from lighting to x-ray detection. It has been well established that the light emission from many fluorescent materials are temperature dependent. This temperature dependence allows for the creation of noncontact and remote sensors that can be insensitive to blackbody backgrounds and radiofrequency interference. By observing the intensity of the light emitted after the material is struck, TL can be used to develop an impact sensor. Preliminary data indicate that there is a relationship between the light intensity and the impact energy for ZnS : Mn. Finally, it has been shown that the intensity of a fluorescent material is degraded by the bombardment of radiation. This degradation follows a linear pattern and has the potential to be used as an indicator of the total applied dose or fluence.

ACKNOWLEDGMENTS

We acknowledge the efforts of the many graduate and undergraduate students from the University of Virginia, University of Tennessee, Tennessee Technological University, University of Louisiana at Lafayette, and various other colleges and universities who have done much to establish the scientific and engineering foundations of phosphor measurement techniques over the past decade. We also thank the large number of colleagues at the Oak Ridge National Laboratory, the Los Alamos National Laboratory, Wright-Patterson Air Force Base, the University of Virginia, the University of Tennessee, EG&G Energy Measurements, Inc., and the International Bureau of Weights and Measures for their participation in this work. We give special thanks to Mr. W.A. (Bill) Stange of Wright Laboratory for his continued support of much of the effort described above for well over a decade. His influence has made possible the development of the method for important aerospace and turbine engine applications. Finally, we thank the workers at the Science and Engineering Library of the University of Virginia (Physics Branch Librarian Mr. James Shea in particular) and those at the Oak Ridge National Laboratory Library (Mr. Jon Arrowood in particular) for much valuable assistance in obtaining the various references cited here. The Oak Ridge National Laboratory is operated by UT-Battelle, LLC for the U.S. Department of Energy.

Membrane Reactors

Ivo F. J. Vankelecom
Centre for Surface Chemistry and Catalysis, Department of Interphase Chemistry, Faculty of Agricultural and Applied Biological Sciences, Katholieke Universiteit Leuven, Leuven, Belgium

INTRODUCTION

Although there is no commonly accepted definition of a membrane reactor (MR), the term is usually applied to operations where the unique abilities of membranes to organize, compartmentalize, and/or separate are exploited to perform a (bio)chemical conversion under conditions that are not feasible in the absence of a membrane. In every MR, the membrane separation and the (bio)catalytic conversion are thus combined in such a way that the synergies in the integrated setup entail enhanced processing and improved economics in terms of separation, selectivity, or yield, compared to a traditional configuration with reactor and separation separated in time and space. When the membrane itself carries the catalytic functions, it is mostly referred to as a ''reactive membrane.''

The combination of (bio)catalysis and membrane technology into an MR is truly multidisciplinary, involving aspects of material sciences, chemistry, biology, and biochemical engineering.

BASIC TERMINOLOGY OF MEMBRANE TECHNOLOGY

A membrane is defined as a semipermeable barrier between two phases that can either be liquid or gaseous.[1] Components permeate from one side of the membrane to the other under the influence of a driving force, being a gradient in concentration (or rather activity), (partial vapor) pressure, temperature, or electrical potential. Depending on this driving force, membrane processes can be further classified. Dialysis is the only concentration driven membrane process, while the pressure driven processes are subdivided into microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reversed osmosis (RO), with the latter two often referred to together as hyperfiltration. The line between these nomenclatures is sometimes blurred, but generally pressure differences of 0.1–2 bar, 1–10 bar, 10–35 bar, and 15–100 bar refer to MF, UF, NF, and RO, respectively. The applied pressure increases as the membrane pore size decreases to end up as dense membranes for the finest separations. Pervaporation (PV) is the only partial pressure driven membrane process and the only one involving a phase transition at the membrane, through either a dense membrane or one with very small pores. Gas separations can be achieved using either dense or porous membranes, while electrodialysis is the only process involving an electrical potential, hence necessitating conductive membranes. Membrane distillation is nothing but a distillation taking place with a porous membrane separating the liquid and the vapor phases.

The membrane is characterized by a selectivity and a flux or permeance (flux divided by the thickness of the active layer of the membrane) or permeability (permeance divided by driving force). When used in an actual process, membranes are mounted in modules with a certain geometry: flat sheet membranes are turned into spiral wound or plate and frame modules, whereas cylindrical membranes with decreasing diameter are called tubular, capillary, or hollow fiber (Fig. 1). The use of inorganic membranes in the form of multihole elements or monoliths is becoming increasingly popular. The materials used to prepare membranes are very diverse, either organic or inorganic in origin, or a combination of both in hybrid membranes. The latter are also often referred to as composite, mixed matrix, or organo-mineral membranes. In general, inorganic membranes are chemically and thermally more stable, which can be beneficial during membrane cleaning procedures, but they are more difficult to prepare on a large scale and more expensive. They have a very high tensile modulus, but can be very brittle. In a module, the maximum possible membrane area per module volume is always lower than for polymeric membranes.

GENERAL ADVANTAGES AND DISADVANTAGES OF MRs

The general advantages of MRs clearly show how they fit in the scope of developing sustainable processes:[2,3]

- An integrated process involves a more compact process with lower investment costs and with substantial potential savings in processing costs, hence improving the overall economics.

- Energy consumption can be saved, e.g., by less pumping.
- The removal of a product from a reaction mixture can shift the chemical equilibrium of the reaction and thus generate increased product yields or lead to similar yields, which are obtained at lower temperatures. The latter has the extra advantage of decreasing the extent of deleterious side reactions, such as coke formation.
- The continuous removal of product can decrease possible side reactions or product inhibition, thus increasing overall reaction rates.
- By selectively removing an intermediate product in consecutive reactions, enhanced selectivities for that intermediate can be realized.
- The downstream processing of the products can be substantially facilitated when removed from the reaction mixture by means of a membrane.
- The contact between two reactants can be mediated and controlled by a semipermeable membrane. In the field of selective oxidations, for instance, the oxygen feeding can thus be better controlled, or two hazardous reactants, like H_2 and O_2, can be reacted safely. Whereas the addition of gases to the reactor is often useful to give an extra stirring to the liquid mixture in the reactor, permeation through a dense, highly permeable membrane is sometimes preferred to integrate bubble-free aeration.
- When the membrane is placed as a contactor between two phases, solvents can be excluded and thus render the process environmentally and technically more attractive.
- Membrane separations often have the advantage of operating at much lower temperatures, especially when compared with, e.g., distillation, thus providing a solution for the limited thermal stability of either (bio)catalyst or product. Furthermore, membrane separations are not restricted to volatile components.
- Under specific conditions, the heat dissipated in an exothermic reaction can be used in an endothermic reaction taking place at the other side of the membrane, like, e.g., in hydrogenation/dehydrogenation.
- Coupling of sequential multistep reactions is possible.

In spite of these advantages, the combination and integration of two processes generally adds considerably to the technical complexity of the process, rendering modeling and prediction more difficult. Furthermore, MRs generally require more research, mainly related to optimization and design of a suitable reactor. Other possible drawbacks are the sealing of the reactor chambers, the manufacturing cost of the membrane and mainly the module, as well as the insufficient durability of the membranes and their fouling.

HIGH-TEMPERATURE CATALYTIC MRs

Most nonbiological MRs in the literature have been applied at high temperatures, with hydrogenations and dehydrogenations by far the most studied.[4–12] The reason was the existence of the remarkable Pd or Pd-alloy membranes showing an almost perfect hydrogen selectivity. In spite of all efforts, no industrial up-scaling has been realized yet, because of some important drawbacks. The cost of the membranes is very high, their commercial availability restricted, and their lifetime limited. Long-term operations may lead to surface inhomogeneity and competitive adsorption may lead to poisoning (e.g., with sulfides) or fouling (e.g., with carbon deposits). The intrinsically low permeability of such dense metal films is in fact the basic problem. To obtain sufficiently high permeabilities, their application is restricted to high temperatures. A reduction in membrane thickness is another possibility, but it creates an increased risk of defects. High-temperature applications entail difficulties when combining materials with different thermal expansion coefficients, leading to delamination of the membrane top layer from the support and bad sealing. Whereas Pd based membranes are strictly limited to H_2 permeations, highly selective membranes also exist for O_2 permeation based on Ag membranes or mixed inorganic oxides. They basically suffer from the same disadvantages as the Pd-membranes and even require temperatures above 500°C to show sufficient permeabilities. Nevertheless, because several important refinery and chemical feedstock reactions are excellent candidates to use MRs, many investigations have been performed already in this field of high-temperature applications.

Dehydrogenation Reactions

One of the most obvious choices for the application of MRs is the dehydrogenation of light alkanes to alkenes. Being endothermic, the reaction is performed at high temperatures. By removing selectively the hydrogen formed via a membrane, the equilibrium of these reactions can be driven to completion. At the same time, pure hydrogen is obtained at the permeate side, which is useful as a feed in other processes. In the pioneering studies by Gryaznov and coworkers, Pd or Pd-alloy dense membranes were used. Inorganic porous membranes have later been studied as alternatives, as well as zeolite and carbon molecular sieve membranes or proton-conducting solid state membranes.

Other dehydrogenations often investigated are the conversion of ethylbenzene to styrene, and cyclohexane to benzene, the latter being operated at such a low temperature that even polymer based membranes can become applicable. Also dehydrogenation of functionalized organics has been reported, as well as the nonoxidative coupling of methane to C_2-products. Fig. 2 illustrates how hydrogen removal through a selective Ag doped Pd-membrane increases the methylcyclohexane conversion to toluene and allows reaction at a lower temperature.

Hydrogenation Reactions

In liquid phase reactions, the use of hydrogen selective membranes as contactors between the gas and liquid phase to deliver the reactant at a controlled rate helps to avoid hot spots in the reactor or undesirable side reactions. Most interesting is the coupling of two reactions over one membrane with a dehydrogenation reaction at one side and a hydrogenation reaction at the other, with both hydrogen and energy flowing from one reactor to the other. Most importantly, hydrogen emerges at the other side of, e.g., a Pd-membrane in a highly reactive atomic form. Also, for this class of reactions, porous membranes and proton-conducting solid oxides have been tested. In the former case, the membrane can also function as a host for the catalyst, thus leading to a three-phase MR (gas–liquid–solid catalyst). Often studied reactions are the conversion of α-methyl styrene to cumene, cinnamaldehyde to

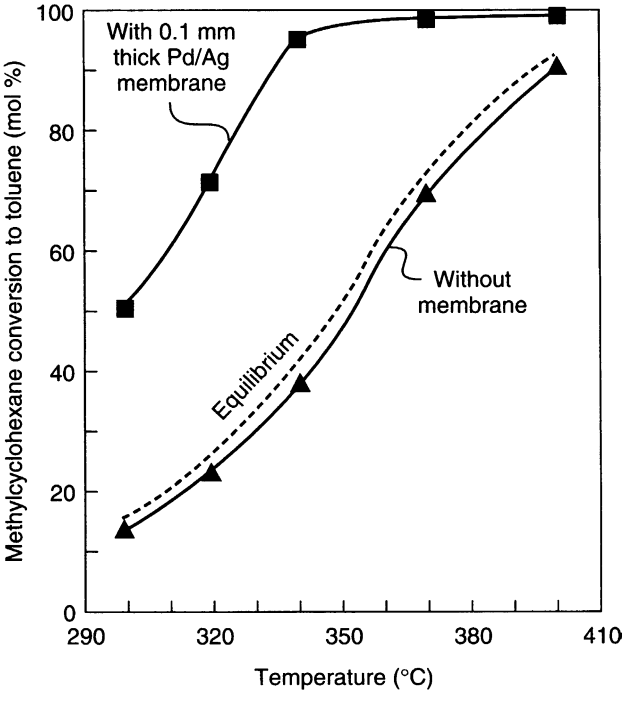

Fig. 2 Influence of temperature on the methylcyclohexane conversion to toluene in a membrane and a nonmembrane reactor. (From Ref.[8].)

hydrocinnamyl alcohol, and the hydrogenation of sunflower seed oil.

Selective Oxidations

The major advantage of using membranes in selective oxidations consists of the independent control of the concentration levels of each reactant in the reaction zone as oxygen and hydrocarbon (HC) can be fed in a controlled way from different sides of the membrane. In addition, the physical barrier between both reagents enhances safety aspects of the process. On the other hand, diminished reaction rates might appear because of the lowered oxygen partial pressure. The O_2/HC molar ratio might change along the length of the reactor owing to the depletion of a reagent during reaction. An elegant solution for the latter might be a ''chemical valve'' O_2 selective membrane showing an increased (HC + O_2) flux with decreasing O_2 concentration.[13]

Both dense and porous membranes, such as zeolite or alumina based membranes impregnated with catalytic species, have been applied. The dense membranes are mostly Ag or Ag-alloy membranes, solid oxides (Bi_2O_3, Mg stabilized zirconia, etc.), perovskites, and their oxygen deficient analogs brownmillerites. Brownmillerites and perovskites have increased thermal stability and better electronic conductivity. They refer to a general group of oxides with ABO_3 or $A_2B_2O_5$ structure, respectively.

Ion-conducting membranes could find application in two major industrial processes: the production of synthesis gas (syngas) by partial oxidation of methane and the oxidative coupling of methane to produce ethylene (Fig. 3). In the former, oxygen ions diffuse through the membrane to react with methane to form CO and H_2, a gas mixture that can be used for the formation of a variety of petrochemicals. In the latter, methane is converted to ethylene and hydrogen, permeating through the membrane to react with air oxygen to produce water. This second reaction produces the energy necessary to heat the process. Such reactions could allow the exploitation of natural gas fields for which utilization is currently not profitable because they are too far from the end users. The technical challenges on the membrane level are substantial: low-cost, defect-free anisotropic membranes operating at 800–1000°C without being poisoned or fouled.

Many other partial oxidations have been studied: methane conversion to methanol and formaldehyde,

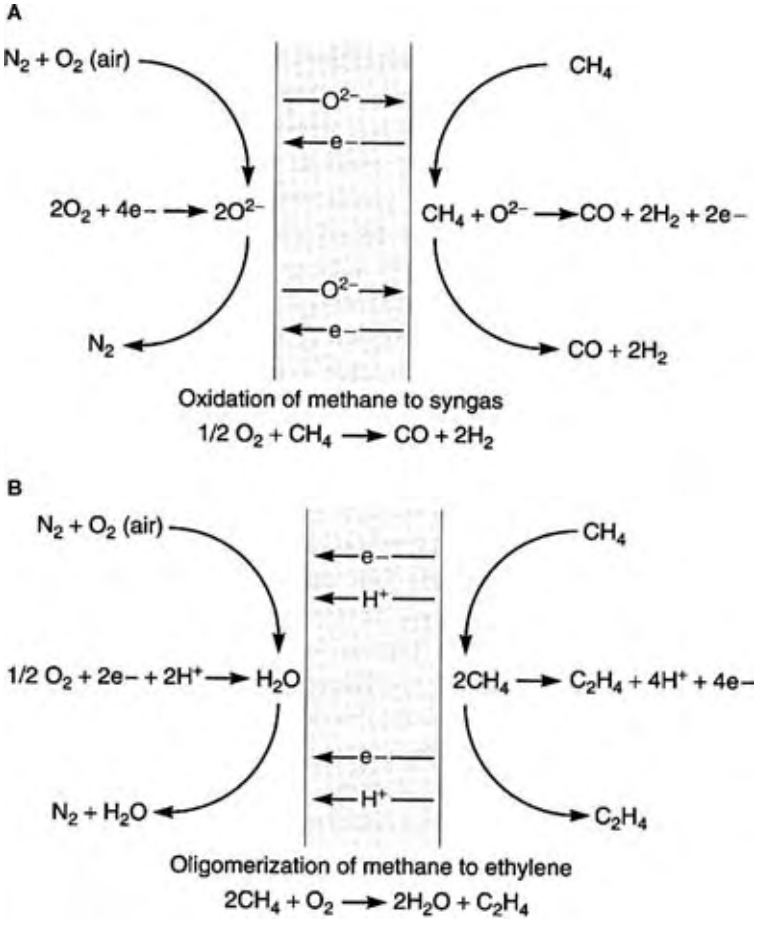

Fig. 3 A membrane reactor with ion-conducting membranes for the production of syngas (A) and ethylene (B). (From Ref.[8].)

benzyl alcohols to the corresponding aldehydes, ethane and propane to the respective oxides, butane to maleic anhydride, ethylene to acetaldehyde, propane to acrolein, oxidative dehydrogenation of alkanes and ethylbenzene, oxidative dimerization of propylene to benzene and hexadiene or of isobutene to branched octenes, oxidative dehydrogenation of methanol to CO_2 and H_2, and oxidative dehydrogenations of C_2–C_4 to their respective alkenes.

Other Reactions

Other major applications could lie in the water gas shift reaction, one of the oldest catalytic reactions to produce H_2, e.g., for the production of NH_3.

$$CO + H_2O = CO_2 + H_2$$

In this reaction, it would be extremely interesting to remove the CO_2 via selective membranes, but it is a challenge to find membranes stable at the harsh reaction conditions. Another important reaction with MR potential is the Fisher–Tropsch reaction to form higher alkanes:

$$CO + (1 - x)H_2 = CH_{2x} + H_2O$$

This reaction is exothermic, but for kinetic reasons it is most favorably performed at temperatures up to 700 K. The removal of water by, e.g., hydrophilic zeolite membranes would shift the reaction toward completion and reduce catalyst deactivation.

The decomposition of H_2S, NO, and NH_3; the breakdown of pollutants and volatile organics to CO_2 and H_2O; photocatalytic reactions involving TiO_2 as both catalyst and membrane; methanol reforming for the production of H_2, as well as direct H_2O decomposition for mobile fuel cell applications; CO_2 hydrogenation to produce methanol or CH_4 and H_2O; metathesis reactions of propene to ethylene and 2-butene; and the isomerization of *cis*-2-butene to *trans*-2-butene have all been reported.

LOW-TEMPERATURE CATALYTIC MRs[2]

In addition to the above-mentioned general advantages of combining reactions with membrane separations, the use of polymeric membranes in MRs entails some important extra possibilities, especially as reactive membranes (Fig. 4).[2] With a heterogeneous catalyst incorporated in a polymer matrix, a well-chosen polymeric environment can regulate the selective sorption of reagents and products with a beneficial effect on catalyst performance. In the case of an embedded homogeneous catalyst, the incorporation is a way to heterogenize and disperse the catalyst at the same time. Also, the coincorporation of additives in the membrane matrix can further increase the performance of such a heterogenized catalyst and substantially facilitate the downstream processing. Considering the high price of many homogeneous catalysts—especially the chiral transition metal complexes (TMCs)—the possibility of recycling them presents an important challenge, whereas good dispersions can generate higher stabilities and activities.

In selecting the most appropriate membrane, a much wider choice is available for polymeric than for either metallic or ceramic membranes. Polydimethylsiloxane (PDMS) is by far the most commonly used, thanks to its high permeability and stability. Polyvinylalcohol (PVA) and Nafion have also been described, especially for the more hydrophilic substrates. Operation of a polymer based MR at relatively

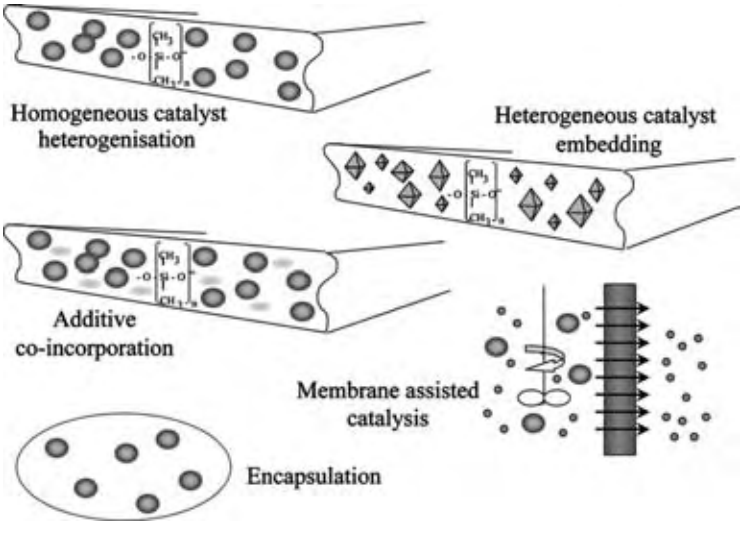

Fig. 4 Overview of the main applications of polymers in membrane reactors. *(View this art in color at www.dekker.com.)*

low temperatures is associated with less stringent demands for the materials in the module construction, thus leaving a wider choice to select the most optimal materials.

Encapsulation

Encapsulation refers to the confinement of a liquid solution within small capsules enclosed by a polymer or a surfactant. A potentially high interfacial area is thus created and the recovery of the catalyst is facilitated. The selective sorption through the membrane can further increase catalytic performances. Scaling-up is easy, but capsules should be as small as possible to prevent extra resistance to mass transfer in the non-agitated encapsulated volume. A problem associated with such capsules is the fact that there is no way to provide a fresh solution to the inner portion of the capsule or to continuously remove product from that phase. The capsules have to be either leached or broken at the end.

Phase transfer catalysts have been grafted onto the surface of porous capsules to facilitate product purification after reaction, and many types of immobilized cells, mycelia, enzymes, and catalysts have been encapsulated in polymers such as PDMS, PVA, or cellulose. In the specific case of PVA, they are named ''Lentikats,'' as commercialized by Genialab and used for nitrate and nitrite reduction and in the synthesis of fine chemicals. These beads show minimized diffusion limitations caused by the swelling of the polymeric environment under the reaction conditions. To avoid catalyst leaching, enlargement can be realized by linking them to, e.g., chitosan.

Incorporation of Heterogeneous Catalysts

Heterogeneous catalysts have been embedded in a membrane to improve their selectivity or activity thanks to a changed sorption in the catalyst, or to enable different reactor setups.[2] Activity can increase drastically when solvents become redundant with two immiscible reagent phases coming in contact via a membrane containing the embedded catalyst. It makes the system more environment friendly and facilitates product purification. The concept is claimed to be applicable to any catalytic reaction involving immiscible reagent phases, provided an appropriate choice is made of polymer type with respect to selective sorption and diffusion of reagents and products. Several oxidations, hydrogenations, isomerizations, dehydrations, esterifications, and epoxidations have been done this way already. The oxidation of propylene with hydrogen peroxide was described in a gas/liquid MR. Thanks to its transparent nature, PDMS has also been used in selective photo-oxidations. For photomineralization of organics in wastewaters or of volatile organics from air, acrylate based membranes were used containing a photocatalyst, mostly TiO_2, with a possible sensitizer. The systems were developed up to a preindustrial scale.

One of the most successful industrial applications of polymeric catalytic membranes is the Remedia Catalytic Filter System to destroy toxic gaseous dioxins and furans from stationary industrial combustion sources by converting them into water, CO_2, and HCl. The system consists of an expanded polytetrafluoroethylene (PTFE) microporous membrane, needle-punched into a scrim with a catalytically active PTFE felt. The catalyst is a V_2O_5 on a TiO_2 support. The microporous membrane captures the dust but allows gases to pass to the catalyst where they are converted at temperatures as high as 260°C.

Heterogenization of Homogeneous Catalysts

A whole set of TMCs, both chiral and achiral, have been already embedded for different hydrogenation, oxidation, and epoxidation reactions.[2] A specific and important problem occurring in liquid phase reactions with such membrane-occluded homogeneous catalysts is leaching of the complex and/or the coincorporated additive from the membrane. While the absence of strong interaction forces between the TMCs and the polymer is one of the strong points of this heterogenization with respect to catalyst reactivity, it renders them at the same time susceptible to leaching. This can be reduced or prevented by using solvents in which the complex does not dissolve, by establishing a chemical bond between the complex and the polymer, by enlarging the catalyst, or by selecting more appropriate reaction conditions, e.g., solvents that combine moderate membrane swelling with low solubility of the complex. On the other hand, adaptations on the level of the polymeric matrix can also restrict leaching: increasing the degree of cross-linking, decreasing the polymer chain length, or blending with other polymers to change the affinity.

TiO_2, Fe_2O_3, or Fe^{3+} have been embedded in Nafion, poly(ethylene) based polymers, and alginates for the photo-Fenton process to abate nonbiodegradable azo-dyes and in the selective oxidation of light alkanes. Similar or even higher activities were found owing to high polymer transparency, absence of aggregate formation, and a much better dispersion of the catalyst in the polymer.

On the basis of the metallic Pd-membranes, several authors incorporated Pd in polymeric membranes to create a higher active surface area with a smaller

amount of Pd. A variety of Pd-precursors and membrane polymers have been used to hydrogenate edible oils, isoprene, 1-octene, cyclopentadiene, propyne, propylene, ethylene, propadiene, and butadiene, and even in the controlled synthesis of hydrogen peroxide directly from molecular hydrogen and oxygen outside the explosion range.

Cation exchange membranes (CEMs) have been used as acid catalysts in the esterification of oleic acid with methanol. The reaction mixture was circulated between two CEMs. At the other side, these CEMs were in contact with a catalyzing acid, diluted in methanol. The proton thus appeared at the surface of the membrane, and was directed to the reaction mixture, while the anion associated with these protons remained at the other side preventing the proton from leaving the membrane.

Membrane-Assisted Catalysis

The key success factor of this concept is the choice of an appropriate membrane that allows the full retention of the catalyst and the complete passage of the products.[2] The aim is to achieve a high total turnover number, an easy recovery of the catalyst, or to operate in continuous or semibatch (also called ''repetitive batch'') modes. In contrast to a fixed bed reactor, membrane assisted catalysis has the advantage that fresh catalyst can be supplemented easily even in a continuous process. Because of the recovery of the catalyst, working at high catalyst concentrations becomes much more economical and competing noncatalyzed reactions can be controlled more easily. In a continuous mode especially, the educt concentration is kept low. Because the remaining free ligands are washed out during the initial phase of the membrane assisted process, the catalyst purification prior to the reaction can be shortened.

Mainly PV aided conversions have been studied and more in particular esterifications, a typical example of an equilibrium limited reaction with industrial relevance and well-known reaction mechanisms.[14,15] This hybrid process has already made it to several industrial applications. The thermodynamic equilibrium in such a reaction can be easily shifted and obtained in a shorter reaction time by removing one of the products. Pervaporation is especially interesting because it is not limited by relative volatility or azeotropes and energy consumption is generally low, because only the fraction that permeates undergoes the liquid/vapor phase change. It can also be operated at lower temperatures, which can better match the optimal conditions for reaction.

Because of the commercial availability of excellent permselective PVA, silica, or zeolitic membranes, it is especially the removal of water that became state-of-the-art technology over the past 15 yr. Modeling is important for these processes because, e.g., membrane permeability may change with temperature and composition of the mixture. A correct membrane surface area/volume ratio (A/V) is important because too low an A/V creates too slow a removal of the targeted compound, while too many reagents are removed with too high an A/V.

Apart from esterifications, dehydrations, condensations, oxidations, Diels–Alder alkylation, and hydrogenations also have been coupled to PV. In the production of alkyl coating resins at temperatures as high as 150–300°C, the use of microporous silica PV-membranes has been successfully investigated. A mixture of acids, acid anhydrides, and alcohols reacts to form a resin and water. In a kilogram-scale unit, energy savings turned out to be 40% and reactor efficiency increased by 30%.

When the membranes are too plasticized by the direct contact with the reaction mixture, vapor permeation can be a viable option. Gas separation has been described to enhance the conversion of the acid-catalyzed, equilibrium limited methyl-*tert*-butyl ether decomposition by the removal of methanol.

When rather small catalysts, like TMCs, have to be retained in pressure driven membrane processes, three approaches are possible: the catalyst can be enlarged to form dendrimers or hyperbranched polymers; it can be covalently bound to soluble polymers or insoluble supports; or membranes with a lower molecular weight cutoff (MWCO) can be selected, possibly at the expense of poor membrane flow.[16] A decrease in the MWCO of the membranes can be achieved by selecting tighter membranes or by changing the reaction conditions that influence this MWCO. Catalyst attachment or enlargement is often an elaborate task, creating structures that are nonuniform and uncontrolled. Mass transfer owing to hindered diffusion can lead to low catalytic activity. Another approach to enlarge TMCs is to add micelle forming amphiphiles to capture the catalyst. Emulsions can be easily retained by an appropriate UF membrane, often referred to as ''micellar enhanced UF.''

Whereas the pore-flow mechanism describes transport through porous UF, NF and RO membranes show a transient structure between porous and nonporous, with probably also sorption–diffusion as part of the transport mechanism. Nanofiltration is a relatively new membrane process with a nominal MWCO in the range of 200–1000 Da. Its application in water treatment has been growing rapidly, but the nonaqueous application is still an emerging field. All efforts to enlarge catalysts become superfluous when the membranes are capable of retaining off-the-shelf TMCs.

Aqueous NF played a crucial role in a continuous process that combines wet air oxidation, membrane separation, and biological treatment for the treatment of PEG containing wastewaters. In a first brief wet oxidation pretreatment, the polymers were degraded to a lower MW to increase the rate of the subsequent biodegradation of the permeate. The polymeric NF membrane proved resistant to the oxidative conditions created by excess oxidant still present in the oxidized process streams, even at 130°C. The integrated process thus showed a much higher treatment efficiency than any of the single optimized processes.

The idea of separating homogeneous TMCs with solvent-resistant NF(SRNF) membranes has only emerged over the last decade with the advent of commercial SRNF membranes. A nondestructive, energy efficient separation and concentration of reusable catalysts from reaction products can thus be realized. The SRNF-coupled catalysis can be run continuously, or alternatively in a semibatch operation mode to lower reactor occupancy or when reaction conditions are too harsh to be membrane compatible. Precipitating by-products could be simply removed from the reactor after filtration before refilling it.

For all catalysts (Jacobsen catalyst, Pd-BINAP, Wilkinson catalyst, Ru-BINAP, Rh-DUPHOS, phase-transfer catalysts) and solvents described, compatible commercial SRNF membranes were found that combined reasonable solvent fluxes with high catalyst rejection. However, some problems on the membrane level still need to be solved. Some membranes, marketed as SRNF membranes, swell to such an extent in certain solvents that they act like UF membranes with drastically increased MWCO. Fig. 5 shows the important consequences of tiny differences in rejections after many replacements of the reaction volume. Flux decline during operation can sometimes be observed owing to concentration polarization, increasing osmotic pressure, and membrane compaction. For some reactions, the membrane MWCO-curve is not steep enough or the cutoff is not low enough. Also, stability under certain ''aggressive conditions'' of solvent, temperature, pressure, and reagents can still be problematic. The very recent introduction of high-throughput membrane testing and the directed synthesis of membranes for a given purpose involving combinatorial synthesis techniques will undoubtedly further broaden the scope of available SRNF membranes and thus of catalytic applications.[17]

Also, dialysis was reported to remove TMCs from reaction mixtures. No mechanical pressure is needed here, clearly facilitating the mechanical and safety requirements. The first proof of concept was given with Ru-BINAP confined in a PDMS-''envelop'' simply submerged in the reactor. In a catalytic transfer hydrogenation, the PDMS-membrane retained the catalyst

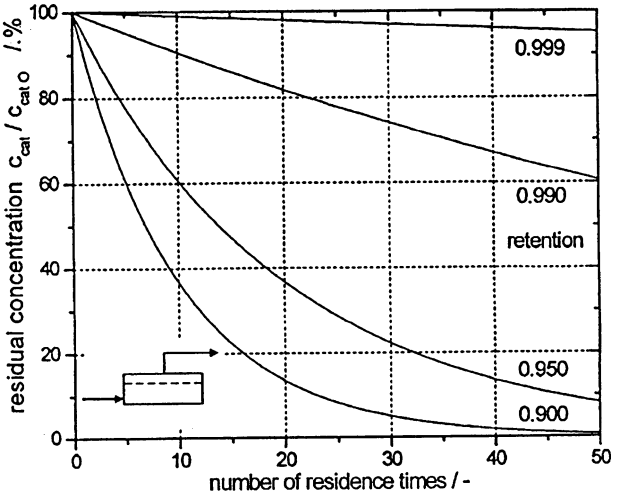

Fig. 5 Residual catalyst concentration as a function of the number of residence times. (From Brinkmann, N., Giebel, D., Lohmer, G.; Reetz, M.T.; Kragl, U. Allylic substitution with dendritic palladium catalysts in a continuously operating membrane reactor. J. Catal. **1999**, *183*, 163.)

insufficiently from the IPA-solution. Instead of enlarging the catalyst, the membrane composition and the composition of the solvent mixture were changed to improve the catalyst retention. Just like in SRNF, the use of solvents that induce strong swelling of the membranes makes laborious catalyst enlargement compulsory, as reported in SN_2 substitution reactions and Kharash addition.

MEMBRANE BIOREACTORS

Many industrial processes exist already in the production of biochemicals or for environmental applications.[18,19] One of the main reasons for this success is that the temperatures in these processes seldom exceed 60°C, thus enabling the use of inexpensive commercial polymeric membranes. Microfiltration and UF units are already proven and profitable technologies and well accepted by industry. Moreover, the fine chemical and biochemical MBR production leads to high value-added products, making the economics more favorable. The biocatalysts can be either enzymes or whole cells. The products range from food, liquid fuels (e.g., ethanol), and plant metabolites to more complex fine chemicals, such as pharmaceutical products or fragrances. Biological reactions typically generate a complex product mixture with some of these products often inhibitory or even toxic for the biocatalyst. Their continuous removal via a membrane separation process thus prolongs the biocatalyst's lifetime and increases the product turnover rate. But most often, the membrane's major role is in separating in situ the valuable

products from the unreacted raw materials and the often expensive biocatalysts, thus allowing continuous operation. Additionally, they increase the cellular concentration in the reactor, hence raising productivity and reactor throughput. The membrane offers the possibility of independently adjusting the residence times in the reactor of products, reactants, and biocatalysts to improve operational flexibility and provide effective process control, e.g., by controlled delivery of one of the reagents like in the bubble-free aeration. The membrane can act as the host for the biocatalyst when immobilized in the membrane pores.

In spite of the clear advantages, membrane-coupled processes often turn out to be still more expensive, because of the costs of membrane and all additional hardware associated with a membrane operation. Membrane separations tend to become more favorable for processes where the selectivity is more important than the conversion, because it replaces other purification steps that might lower such selectivities, like in the production of the chiral diltiazem intermediate. Membrane fouling, mass transfer limitations, biocatalyst activity loss, and biocatalyst denaturation are other potential disadvantages related to it.

Enzyme Membrane Bioreactors

The gap between enzyme catalysis and nonbiological catalysis will probably narrow in the future as adapted enzymes can work in organic solvents and catalysts that mimic enzymes are showing up. Biocatalysts are becoming commercially available to a greater extent, but often remain expensive. Enzymatic reactions are generally faster, but enzymes might need regular replacement because of denaturation. Recent efforts to increase the stability of enzymes were directed to either genetic manipulation or immobilization on a soluble polymer, on the membrane surface, or in the membrane pores. The amount of immobilized enzyme can be critical as blocking of the active site, multiple point attachment, or protein denaturation can occur above a certain loading. Furthermore, immobilization is often elaborate and may lead to only low immobilization yields and diffusional constraints in the supports.[8,20–22] Enzyme based MBRs (eMBRs) find application in the enzymatic hydrolysis of macromolecules, such as proteins, polysaccharides (cellulose, starch, etc.) or oligosaccharides (maltose, saccharose, lactose, etc.), and in the recycling of cofactors, such as NADH. An important application is the fruit juice clarification where the applied pectinases and cellulases are recovered via membrane filtration. Lipid hydrolyses or transesterifications catalyzed by lipases or phospholipases are complex micellar solutions of reactants and products. Enzyme based MBRs can be used here to selectively produce di- or monoglycerides by maintaining the system working at steady state at the desired conversion. Examples of polysaccharide production are also known, e.g., the synthesis of inulin from sucrose using a membrane immobilized fructosyltransferase.

A number of chiral drugs are currently being produced by means of eMBRs at scales up to 75 tons/yr. An optically active diltiazem intermediate is produced using an immobilized lipase. Also, for the production of naproxen from its ethyl ester, a lipase is immobilized in the wall of a membrane. The racemic ester is dissolved in methyl isobutyl ketone flowing through the shell side of the fiber, which is in contact with a buffered aqueous solution at the lumen side. The hydrolyzed substrate is transferred to the aqueous phase. The remaining enantiomer in the shell side is then racemized in a separate reactor and recirculated to the eMBR to achieve an almost 100% conversion.

An attractive MR concept is called ''cascade MR.'' Two reactions of which the optimal reaction conditions are significantly different can be carried out in series. Two different lyases have thus been used for the production of l-alanine from fumaric acid in two consecutive reactions. A UF membrane had to be used to retain both enzymes in their appropriate reactors. Each reactor could then be operated at the most optimal conditions of pH and temperature. In another example, GDP-mannose was prepared by linking two reactors through a UF membrane. The overall enzymatic consumption in the two-step eMR cascade was only 15% of that in the batch reactor and 45% of that in a single eMR.

Whole-Cell Membrane Bioreactors

Most of the work in this field involving plant or mammalian cells, bacteria, or yeast has been devoted to environmental applications treating wastewaters and to fermentation processes producing biochemicals.

With the earliest developments already in the 1960s, MBRs are state of the art in environmental applications and have been applied already worldwide in water treatment. They offer an important advantage compared to traditional physicochemical approaches: the complex organic contaminants present in wastewater streams are transformed into simple, harmless gaseous or water-soluble compounds, together with residual sludge, instead of just being transferred into a different medium. Also, they generally require a smaller volume and footprint than the more conventional biological treatment systems with biomass removal, e.g., via sedimentation. The membrane also offers an elegant way to control the process effectively via independent adjustment of wastewater residence

time in the bioreactor and the product withdrawal rate through the membrane. Moreover, MBRs generally need less pretreatment steps and the membranes offer an effective barrier for microbes and other particles.

Wastewater treatment can be achieved via either aerobic or anaerobic conditions. As shown in Fig. 6, the two processes differ in the rate of sludge production, hydraulic residence time, biomass concentration, and the type of pollutants remaining to be treated via other processes. Lower organics removal rates, the potential for odors, and a higher start-up time are among the main characteristics of the anaerobic processes. On the other hand, they require less energy to operate. The majority of the industrial wastewater treatment applications are aerobic. Still, the type of micro-organisms used and the process parameters vary depending on the wastewater's origin (domestic or industrial). Air bubbling is applied to supply oxygen for the biomass growth and to create turbulent flow conditions near the membrane surface to minimize fouling, the main problem of MBRs. The membranes are mostly immersed in the reactor to save on module costs and to combine aeration with fouling reduction (Fig. 7). In some cases, however, the membrane can be present in a module on a sidestream. The possibility of increasing the tangential flow may alleviate the fouling problem but increases the costs and can cause cell lysis via the high mechanical shear.

Because common MBRs are only able to remove the water-soluble compounds, poorly water-soluble compounds can accumulate to reach toxic levels. Organophilic membranes can be used then to extract these compounds, such as in the extractive MBR where the organics are removed via a hydrophobic membrane to an aqueous part where they are biotransformed. High concentrations of accumulating inorganics, acids,

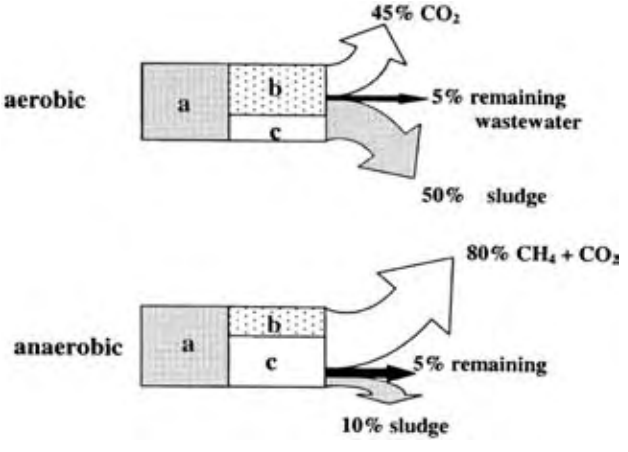

Fig. 6 Differences between aerobic and anaerobic biological wastewater treatment. a = wastewater; b = biomass content; c = hydraulic retention time. (From Ref.[9].)

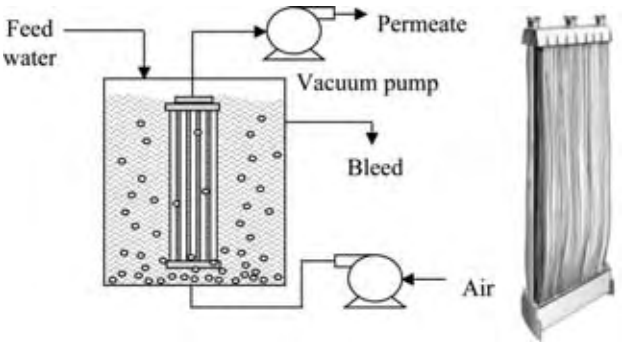

Fig. 7 Submerged membrane systems for wastewater treatment. *(View this art in color at www.dekker.com.)*

or biorefractory pollutants can prevent biological degradation.

Membrane bioreactors have finally also been applied to the treatment of gaseous phase wastes with a membrane used as a contactor, e.g., for the removal of organics (e.g., propene, chlorinated solvents, etc.) or inorganics (SO_2, NO_x, etc.). A biomass film is mostly grown on or within the membrane, or the bacteria can be homogeneously dispersed in the receiving liquid.

One of the most important processes in the production of biochemicals is the 40,000 tons/yr lactic acid production involving the *Lactobacillus* oxidation of lactose. The MBR productivity increased eightfold compared to a conventional batch reactor with a 19-fold increased biomass concentration. Even a 30-fold increased production of ethanol was found upon coupling the *Saccharomyces cerevisiae* fermentation to a membrane separation. Other successful industrial applications involve the pathogen-free production of growth hormones, the synthesis of homochiral cyanohydrins, the production of l-aspartic acid, phenylacetylcarbinol, vitamin B12, and the biotransformation of acrylonitrile to acrylamide.

In two-phase transformations, whole-cell MBRs use the membrane to separate the two different phases, thus avoiding phase mixing and emulsification. As a contactor, the membranes can also reduce mass transfer problems.

Perfusion MBRs have been introduced for the production of monoclonal antibodies. The mammalian cells that synthesize them are grown in the extracapillary space between the fibers in the module. Nutrients are supplied through the fibers, which also extract the metabolites continuously. The high cell concentrations between the fibers initiate high antibody harvests. These MBRs are also being investigated as an alternative concept for bioartificial organs such as liver and pancreas.

For the ABE (acetone–butanol–ethanol) fermentation, PV-coupled MRs have been described using a

variety of fermentation broths. The products formed inhibit the biocatalysis, making product removal from the fermentation broth via PV-coupled MRs an interesting option.

Enrichment of the impermeable components, i.e., salts and organic acids (mainly acetic and lactic acid) is an important challenge. The problem can be avoided by using a continuous ''bleed'' from the fermentor via an MF membrane. Another key challenge is membrane fouling. It can be minimized by selecting the right membrane material and conditions of operation, or by introducing an MF step before the PV unit to remove colloidal and macromolecular components. When the PV is applied only to the filtered cell-free broth, the PV efficiency can be increased by raising the temperature.

The technical challenges for MBRs are the high mechanical stress the biocatalysts experience at the elevated circulation rates required to maintain a good trans-membrane flux and biocatalyst deactivation because of limited mass transfer of nutrients or metabolites when immobilized in small pores or at high cell density. Another major problem is biofouling, caused by adsorption on the membrane of metabolites of coagulated proteins from lysed cells, and pore plugging owing to normal cell growth. Membrane cleaning can take place either by periodically shutting down the whole operation or continuously by employing two separate parallel units, one of which is in operation while cleaning the other. Membrane cleaning is obviously more difficult when whole-cell biocatalysts are immobilized in the small fibers. Immobilization of the biocatalysts in porous beads can facilitate this. Necessitating regular cleaning, the resistance to cleaning or sterilization cycles is a major issue in the selection of the membrane materials for MBRs.

CONCLUSIONS

In spite of many opportunities and lots of promises, multiyear large-scale industrial applications of MRs are still absent at high temperatures. The technical challenges to fit membranes leak-tight in high-temperature modules are substantial, and while membranes with extremely high hydrogen and oxygen selectivities are available already, their stability should be increased, and either their permeability should be increased or their operating temperature decreased.

Low and moderate temperature applications are more straightforward and small- to medium-scale niche applications are running already to produce fine chemicals. This is mainly the case in some specialized biotech applications where high-added-value products make the membrane process investments worthwhile. The largest current market is, however, in the treatment of low-added-value water, owing to the unique synergy between the biological treatment and the membrane process. The less severe requirements in terms of membrane housing and sealing, together with the possibility of using inexpensive, commercial polymeric membranes, have played a crucial role here, together with the fact that the MF and UF units that are coupled with the bioreactors are already proven and profitable technologies, well accepted by industry.

Polymer membranes have clearly matured much more than the metallic or ceramic membranes. For the former, fouling, long-term durability, module cost, and solvent resistance leave most room for further improvement. For the high-temperature applications with inorganic membranes, the membrane cost, the limited commercial availability, the low permeability, the module construction, and the operating costs probably remain the main factors hindering significant progress in, for instance, the petrochemical industry, where classical processes are mature and highly optimized, and where low returns on investments do not leave much room for implementing new technologies.

Mesoporous Silica Films

Brian W. Eggiman
Hugh W. Hillhouse
Purdue University, West Lafayette, Indiana, U.S.A.

INTRODUCTION

Mesoporous materials are defined by IUPAC as porous materials having a pore diameter between 2 and 50 nm. In 1992, researchers at Mobil developed a technique[1] that relies on the self-assembly of surfactants to create mesoporous silica (MCM-41 and MCM-48) with well-defined pore diameter and pore geometry. Since then great interest has been generated by the possible applications of these materials. The powder form of MCM-41 has become commercially available, and doped or modified versions of the material are being employed as a catalyst in processes at ExxonMobil and Sumitomo Chemical. Techniques to synthesize thin films of these materials have been developed and applications are just now being commercialized. Air Products and Chemicals has recently developed a spin-on mesoporous thin film called MesoELK©, which is being marketed as a low-*k* dielectric thin film for the electronics industry. The potential applications of these films extend beyond low-*k* dielectrics to membrane separations, catalytic supports, and other novel optical, magnetic, and electronic applications. However, the commercialization of many of these ideas as well as the development of new applications is hindered by the nontrivial processing steps involved to reproducibly synthesize these films. Thus, this entry focuses on this issue by reviewing and discussing the steps required to reliably and reproducibly synthesize and process surfactant templated mesoporous silica thin films with controlled nanoscale architecture.

GENERAL METHODS FOR SYNTHESIS OF MESOPOROUS THIN FILMS

The synthesis of mesoporous silica films typically begins with the preparation of precursor solutions. These solutions contain a silica source (typically an alkoxide, although chloride and colloidal precursors can be used), a surfactant molecule used to template the mesostructure, an acid or base catalyst, and solvents. The nanoscale structure is then formed by a cooperative self-assembly of monomeric or partially condensed silica species and surfactant molecules into a liquid crystalline-like mesostructure, as shown in Fig. 1. After the deposition, postsynthesis treatments may be used to further condense the silica into a network and enhance the structural stability of the film. The surfactant template is then removed, leaving empty pores and thus creating an ordered mesoporous thin film where the pore system mimics the liquid crystalline order generated by the surfactant.

There has been extensive research on the synthesis of mesoporous silica thin films since the first reports in 1996.[2] However, most research has focused on two general synthesis techniques: evaporation induced self-assembly and spontaneous film growth from solution.

Evaporation Induced Self-Assembly (EISA) Method of Film Growth

In this technique, the self-assembly is driven by the evaporation of volatile solvents from a thin liquid coating of the precursor solution. As evaporation proceeds, the silica and surfactant species become more concentrated and begin to self-assemble into a nanostructured inorganic–organic hybrid structure. The self-assembly may occur over composition regions quite different from a solution of surfactant alone and may depend very sensitively on the state of the silica source, interfacial interactions, and environmental conditions. Upon self-assembly, both hydrophilic and hydrophobic domains are created with the silica segregating into the hydrophilic regions. Depending on the precursor solution, the silica may be monomeric, oligomeric, or form a condensed interconnected network. If the silica is sufficiently condensed, the template may be removed by calcination, extraction, or other techniques, creating a mesoporous silica thin film.

Both spin coating and dip coating have been used to create a uniform thin liquid coating of the precursor solution. In spin coating, a thin liquid film is formed on a suitable substrate by first dispensing a small amount of the liquid on the substrate followed by spinning (typically less than 6000 rpm). Alternately, the coating solution can be added dropwise to the already spinning substrate (Fig. 2). The solution then covers the substrate and spins off until interfacial and viscous

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120019073

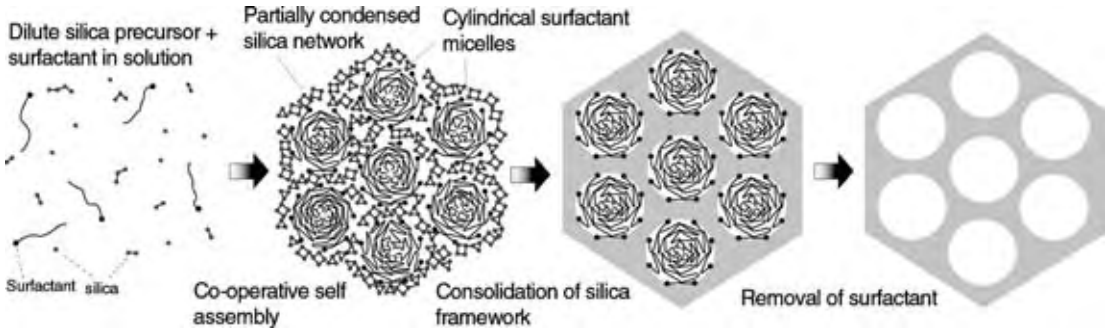

Fig. 1 A schematic for the formation of mesoporosity in a silica film shown for 2-D hexagonal (*P6mm*) phase. *(View this art in color at www.dekker.com.)*

effects balance the centrifugal forces, whereupon a thin liquid film remains.

For dip coating, a suitable substrate is immersed in the coating solution and withdrawn at a controlled rate, usually around 1 mm/sec.[3] During the withdrawal, the liquid film drains until interfacial, viscous, inertial, and disjoining effects balance gravitational forces. As the solvent in the coating solution evaporates and the solution becomes concentrated, nanostructured aggregates first assemble at the substrate–solution and air–solution interfaces and then grow into the liquid film.[4,5] After the solvent evaporates, the self-assembled thin film may be poorly condensed, and thus changes in environmental conditions (humidity, temperature, etc.) may alter the topology of the self-assembly (Fig. 3).

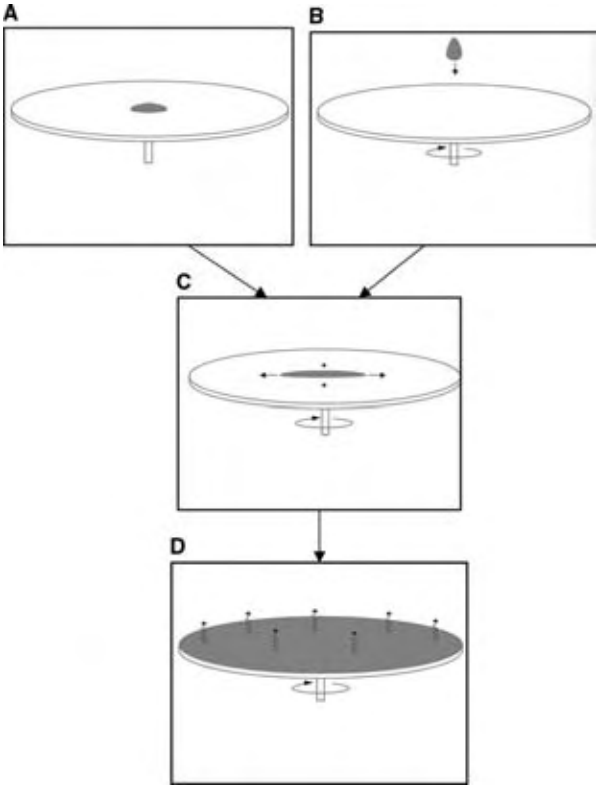

Fig. 2 A schematic for spin coating thin films. The coating solution is either (A) dripped on the substrate while it is at rest; or (B) dripped on while the substrate is spinning; (C) spin-off stage, forming a thin liquid coating on the substrate; (D) solvent evaporation results in self-assembly and thin film formation.

Spontaneous Growth from Solution

In this technique, favorable substrate–solution or air–solution interfacial interactions are used to drive the self-assembly and formation of a thin film of the mesostructured material. The precursor solutions used

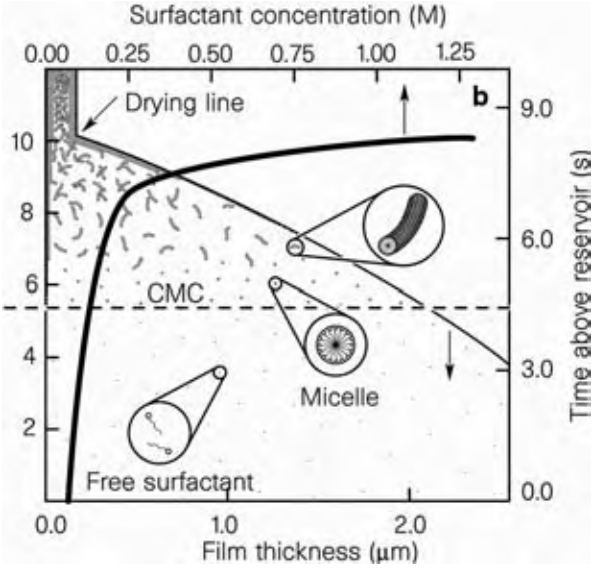

Fig. 3 Mechanism for the synthesis of a hexagonal silica thin film by dip coating. This is zoomed in at the substrate–bulk solution interface. The dotted line indicates the second critical micelle concentration, above which the micelles form cylindrical micellar rods. These rods then begin to assemble at the air–liquid interface and the liquid–substrate interface. (From Ref.[5].)

are typically (though not necessarily) more concentrated than those used for EISA but less concentrated than those used to form mesoporous powders. The key is to adjust the substrate and solution conditions to favor heterogeneous nucleation and growth. The first report of this method of synthesis of films on a substrate was from Yang et al.[2]. In this study, the surfactant and silica precursor heterogeneously nucleated a mesostructured phase on mica in acidic solution. Other reports have generalized the synthesis to include glass, graphite, mica,[7] and polyamide films.[8] In addition, with this technique, directional orientation can be imparted to the mesostructured film by the application of external fields[9] or epitaxial growth.[10]

There have been several other thin film synthesis techniques, such as the use of pulsed laser deposition.[11] However, the promising processing techniques for the economic mass production of mesoporous silica thin films are all based on EISA. Synthesis times can be as short as a few minutes and the processing equipment is readily available. Thus the remainder of this entry focuses on EISA techniques.

PROCESSING MESOPOROUS SILICA THIN FILMS BY SPIN AND DIP COATING

Chemistry and Reaction Mechanisms

The chemistry involved in the formation of mesoporous silica thin films is qualitatively well understood. However, specific reaction mechanisms of the individual steps are still debated. In addition, owing to the complexity of the sol–gel reaction pathways and cooperative self-assembly, full kinetic models have not been developed. From the time of mixing, hydrolysis reactions, condensation reactions, protonation and deprotonation, dynamic exchange with solution nucleophiles, complexation with solution ions and surfactants, and self-assembly, all occur in parallel and are discussed here. Although the sol–gel reactions involved may be acid or base catalyzed, mesoporous silica film formation is carried out under acidic conditions, as silica species are metastable and the relative rates of hydrolysis and condensation reactions lead to interconnected structures as opposed to the stable sols produced at higher pH. Silicon alkoxides are the primary silica source (tetramethyl orthosilicate, tetraethyl orthosilicate, tetrapropyl orthosilicate, etc.) and are abbreviated TMOS, TEOS, and TPOS, respectively. Starting from the alkoxide, $Si(OR)_4$, in ROH and H_2O solution, some of the general reactions are:

$$\equiv Si\text{–}OR + H_2O \underset{\text{esterification}}{\overset{\text{hydrolysis}}{\rightleftharpoons}} \equiv Si\text{–}OH + ROH$$

$$\equiv Si\text{–}OR + HO\text{–}Si\equiv \underset{\text{alcoholysis}}{\overset{\text{alcohol condensation}}{\rightleftharpoons}} \equiv Si\text{–}O\text{–}Si\equiv + ROH$$

$$\equiv Si\text{–}OH + HO\text{–}Si\equiv \underset{\text{hydrolysis}}{\overset{\text{watercondensation}}{\rightleftharpoons}} \equiv Si\text{–}O\text{–}Si\equiv + H_2O$$

$$\equiv Si\text{–}OH + H^+(aq) \underset{\text{deprotonation}}{\overset{\text{protonation}}{\rightleftharpoons}} \equiv Si\text{–}OH_2^+ \quad (\text{for pH} \leq 2)$$

Typically, condensation begins before hydrolysis is complete, and the reactions result in silica species of the form $Si(OR)_x(OH)_y(OH_2^+)_z$ where $x + y + z = 4$, in addition to further condensed oligomers. The isoelectric point of silica occurs at a pH of ~2, and thus below this pH some silica species will protonate to form stable cationic species. For the pH range of 0–2, for solutions prepared from only the alkoxide, HCl, alcohol, and water, the average z is less than 1. It is believed that both the hydrolysis and condensation reactions proceed via nucleophilic substitution (S_N2) reactions involving pentacoordinated reaction intermediates. This mechanism is commensurate with steric and inductive effects observed experimentally in silica solutions. Larger alkoxide groups result in steric hindrances of the pentacoordinated intermediate and increasing hydrolysis rates in the series TMOS > TEOS > TPOS. In addition, it is proposed that the first step in the condensation reactions is protonation of a Si–OH group, and it is observed experimentally that the condensation rate is proportional to the H^+ concentration.[12]

After hydrolysis begins, the neutral, charged, or partially condensed silica species may begin to associate and form complexes with counterions and surfactant molecules in solution. However, these associations evolve in time as the hydrolysis and condensation reactions proceed. Controlling this ''aging'' time is the key to reproducibly synthesize some mesophase structures (as discussed later). After forming a thin liquid coating, the ethanol and water begin to evaporate from the liquid film. The concentration of the solution increases, causing the silica complexes to cooperatively self-assemble with the surfactant into lyotropic liquid crystalline arrays.

Self-Assembly of Surfactant and Silica Species

The geometry of the assembled aggregates and the topology of the resulting mesophase depend strongly on the properties of the surfactant, the silica species, and solution conditions. Many of these aspects may

be understood qualitatively by considering a molecular packing parameter (sometimes referred to as the critical packing parameter, CPP) based on space filling arguments:

$$\text{CPP} = \frac{v}{al}$$

where v is the volume of the hydrophobic chain of the surfactant, a the effective cross-sectional area that one head group of the surfactant occupies on the micelle surface, and l the critical length of the tail. The volume may be estimated from the density of a liquid of pure hydrophobic chains, and the critical length will be less than the extended end-to-end tail length. The key parameter is a, which may be very sensitive to environmental or solution phase conditions. For example, adding a salt to solution will decrease the effective area of a charged head group by screening the repulsive electrostatic interactions from neighboring head groups. The CPP can be used to predict the geometry of the aggregate that is geometrically favored to form in solution, as shown in Fig. 4. For instance, a CPP below one-third will result in spherical micelles that may pack in a cubic structure. A CPP between one-third and one-half will result in cylindrical geometries that may assemble into a hexagonal array, and a CPP around 1 will yield phases with a low net curvature, such as lamellar phase or cubic bicontinuous phases.[13]

Self-assembly using cationic quaternary ammonium surfactants

The most prevalent cationic surfactant used for mesoporous thin film synthesis is cetyltrimethylammonium bromide (CTAB). It is a large head group cationic surfactant and has been shown to produce 3-D cubic ($Pm3n$), 3-D hexagonal ($P6_3/mmc$), and 2-D hexagonal mesostructures ($p6m$).[14] The resulting pore size of the mesoporous film may be tailored by using different alkyl tail lengths or adding swelling agents such as trimethyl benzene. The head group area may be controlled by adjusting salt concentrations or using larger alkyl groups on the ammonium head group. In addition, gemini surfactants (which are two covalently linked cationic quaternary ammonium surfactants) may be used to further tailor the geometry.[15] Also, it is important to note that the choice of surfactant counter anion and acid can significantly affect the self-assembly and are seen to follow the Hofmeister series.[16] These anions can affect the water structure in the solution, and structural differences between CTAB and cetyltrimethylammonium chloride (CTAC) are commonly observed.

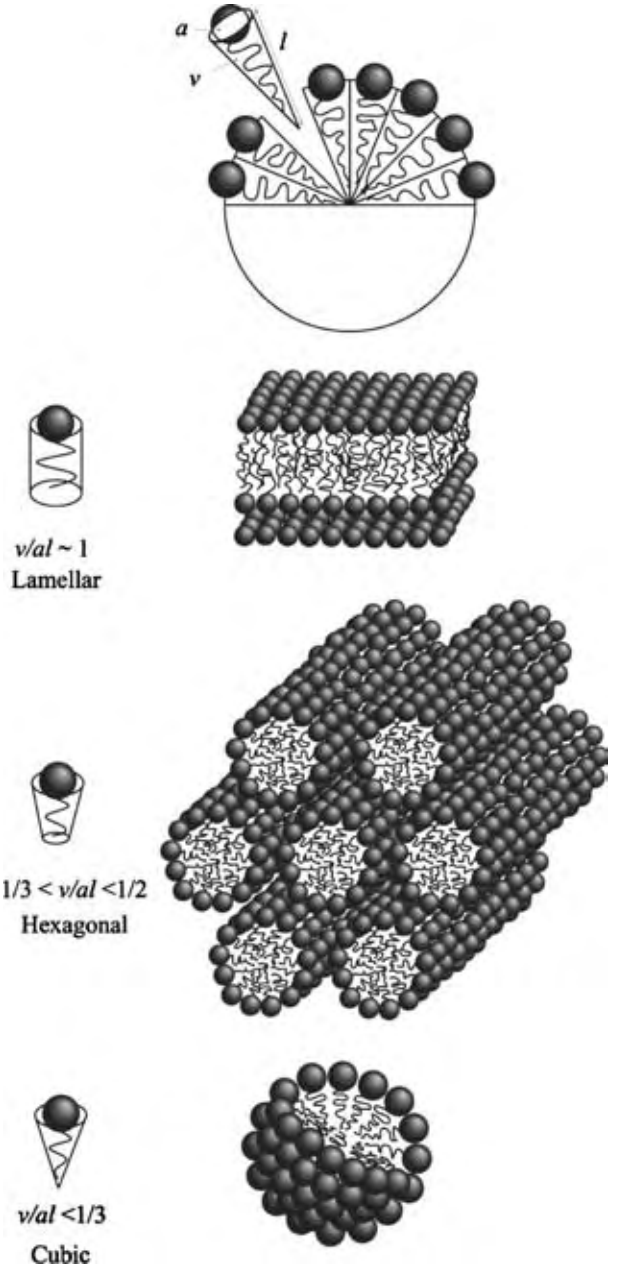

Fig. 4 Critical packing parameters and characteristic structure typical to mesoporous silica films. The top shows a cross-section of a micelle, displaying the parameters used to calculate the CPP. The spherical head group for the surfactant represents the effective cross-sectional area that the head group occupies. *(View this art in color at www.dekker.com.)*

Self-assembly using nonionic polymeric surfactants

Some of the most widely used surfactant templates are nonionic amphiphilic triblock copolymers composed of poly(ethylene oxide)–poly(propylene oxide)–poly (ethylene oxide) blocks.[17] These templates are nontoxic,

biodegradable, and commercially available. The two most prevalent block lengths used for templating mesoporous silica are Pluronic P123 ($EO_{20}PO_{70}EO_{20}$) and Pluronic F127 ($EO_{106}PO_{70}EO_{106}$) available from BASF. The ternary phase behavior of these amphiphiles with water and ethanol has been extensively studied by Holmqvist et al.[18,19] The external poly-(ethylene oxide) (PEO) blocks are the more hydrophilic portions and the internal poly-(propylene oxide) (PPO) blocks are more hydrophobic. The micelle is constructed with a hydrophobic PPO core surrounded by the hydrophilic PEO blocks. It is intuitive that the lengths of the blocks in the surfactant will have direct effects on the mesostructure of the film. The length of the PEO block mainly determines the phase mesostructure and wall thickness of the film. Typically, shorter PEO blocks (less than 10) will result in lamellar structures, medium length chains (between 17 and 37) favor two-dimensional hexagonal *p6mm* structures, and longer chains (in hundreds) favor cubic structures.[20] As the core of the micelle is constructed by the PPO block, the length of this block directly affects the pore size of the resulting mesoporous silica. The pore size can be tailored by varying the length and the hydrophobicity of this block, and these surfactants produce some of the largest pore diameters, as evident by the reported pore sizes of 120 Å for a cubic powder templated with a poly-(ethylene oxide)$_{39}$–poly-(butylene oxide)$_{47}$–poly-(ethylene oxide)$_{39}$ surfactant,[21] and 85 Å for a cubic film templated with F127. These diameters are much larger than those produced by low molecular weight alkyl(ethylene oxide) nonionic surfactants like CTAB, which has had a pore size of 34 Å reported for a cubic film.[17] In addition, these polymeric surfactants tend to produce mesoporous structures with significant microporosity between the mesopores.

While a surfactant can be chosen that preferentially forms one phase or another, any individual surfactant can form many different mesostructures. A recent study examined the effect of P123 concentration on the resulting mesophase.[3] Using a parameter Φ, defined as

$$\Phi = \frac{V_{pol}}{V_{pol} + V_{inorg}}$$

where V_{pol} is the volume of surfactant present in solution and V_{inorg} is the volume of nonvolatile components, they were able to predict what mesostructure would be produced at a certain surfactant concentration. It was found that for values of Φ between 30 and 36, a cubic structure was formed; for values between 40 and 55, a hexagonal phase is formed; and for larger values, 63–75, a lamellar phase is obtained. These data are consistent with the trends determined by the critical packing parameter. A low Φ indicates less volume of surfactant in solution than that of silica and hence fewer molecules of surfactant. This will increase the curvature of the micelles because of an increase of the effective area of one head group, and if the CPP is less than one-third, a cubic structure will form, which is what is observed for the low values of Φ.

Preparation of Dip and Spin Coating Solutions

Typically, silica precursor solutions and surfactant solutions are prepared separately where the alkoxide precursors in the silica solution are allowed to hydrolyze for some period before mixing with a surfactant solution to form the coating solution. Likewise, the surfactant solution is allowed to equilibrate before the mixing.

Preparation and prehydrolysis of the silica precursor solution

The silica precursor solution is typically prepared from a silicon alkoxide, water, and hydrochloric acid. The silica precursor solution is maintained at a pH of around 2, which coincides with the isoelectric point of silica. This is done to allow the hydrolysis of the silica while sustaining a low condensation rate. The first step in the acid catalyzed condensation is protonation of a Si–OH group, thus lower concentrations of the H^+ lower the overall condensation rate. A typical silica precursor preparation involves mixing 10.4 g of TEOS with 5.4 g water, 0.00197 g HCl, and 12 g of ethanol with stirring at room temperature for 20 min.[3] Once mixed, the reaction begins and solution age can greatly affect the self-assembly in the next stage. However, solutions may be prehydrolyzed and then chilled to retard the evolution of silica oligomers in solution.

Preparation and equilibration of the surfactant solution

A solution containing the surfactant and a portion of the solvent is often prepared separately from the silica solution and allowed to equilibrate. The larger molecular weight triblock copolymers may take some time to dissolve and should be allowed to equilibrate in solution to standardize the preparation of the coating solution. As there are no reactions taking place in these solutions, they may be stored and kept after preparation. A typical solution consists of 1.7 g Pluronic P123 ($EO_{20}PO_{70}EO_{20}$) and 8 g of ethanol.[3]

Preparation and aging of the coating solution

The coating solution refers to the final solution that is used for dipping or spinning and is prepared by mixing the silica solution and the surfactant solution. To control the self-assembly during solvent evaporation, the coating solutions are typically aged to allow the silica species and association complexes to evolve. The aging of the coating solution may differ widely depending on the components of the solution and the phase desired. It has been shown that for Pluronic P123 templates, a short coating solution aging time (10 min) is required to obtain a cubic mesostructure, while longer aging times (180 min) are required for hexagonal mesostructures. Also, trends show that lower temperatures, 5–15°C, favor a cubic mesostructure, while ambient temperatures are suitable for hexagonal films.[3] Keeping with our earlier example, the final composition of a typical coating solution would be 10.4 g TEOS, 5.4 g water, 0.00197 g HCL, 20 g ethanol, and 1.7 g Pluronic P123.

There are also many alternate routes to prepare the coating solution, and some syntheses involve no prehydrolysis of the silicon alkoxides.[22]

Coating Process and Self-Assembly of Mesostructured Films

A prerequisite for dip coating and spin coating is that the coating solution must wet the substrate. This is a necessary but not a sufficient criterion, as ultimately the disjoining pressure and liquid–solid interfacial energy must be able to resist droplet formation on the substrate. This is a function of the chemical interactions between the coating solution and the substrate in addition to surface roughness. Most research has employed borosilicate glass slides as substrates because of the low contact angle with water and low cost. Specific interactions with the substrate can be very important and may dramatically affect the self-assembly process.

In spin coating, after the initial stages where excess fluid spins off the substrate, viscous forces and interfacial interactions balance centrifugal forces, and a thin liquid film remains for the EISA. Thus, for a given spinning rate, higher concentrations of the surfactant and silica precursor will result in thicker films because of viscous effects, while faster spinning rates result in thinner films. Details of the fluid mechanics have been discussed by Bornside et al.[23] and in subsequent articles. In contrast, in dip coating, faster substrate withdrawal rates result in thicker coatings as more fluid is entrained on the substrate.[14] The final mesoporous film thickness is tunable, but typically preparations yield films around 200 nm thickness. In both techniques, x-ray diffraction data have shown decreased order in thicker films.

As the assembly of the mesostructure is driven by solvent evaporation and the ultimate equilibrium between the film and the vapor phase, external parameters such as relative humidity and the concentration of solvent in the vapor phase affect the formation of the mesostructured film. Recently, the effect of relative humidity on mesostructure has been studied.[6] Keeping the coating solution constant, films were dipped at three different relative humidities: 20%, 40%, and 70%. It was resolved that above 40% relative humidity, two regimes of solvent evaporation occur. During withdrawal, ethanol evaporates quickly, normally less than 20 sec, followed by the slower evaporation of water, which can take up to 1 min with a relative humidity of 70%. It was also determined that humidity can create a phase transformation within the films. If the relative humidity was too low, RH = 20%, the rate of water loss from the film occurred too quickly, which did not allow enough time for the CTAB to self-assemble, resulting in disordered films with no nanostructure. A relative humidity of 40% resulted in a film with *p6m* hexagonal structure, whereas at RH = 70%, a cubic *Pm3n* structure was preferentially formed. It was determined that the water content in the film at the high relative humidity caused an increase in the affective area of the head group of the surfactant, *a*, which promoted a cubic structure over the hexagonal structure that was formed at RH = 40%.

Postsynthesis Treatments of Mesostructured Films

Films are typically allowed to dry immediately after deposition to drive the silica condensation reaction toward completion. However, the film may not be fully condensed and stable after drying, and postsynthesis treatments are often employed to improve film stability, reduce shrinkage upon template removal, and drive the condensation reaction toward completion.

Drying and thermal treatment

After the film has been synthesized, the substrate and the film are normally allowed to dry for several hours. The details surrounding the drying of the film vary greatly depending on the coating solution and the desired film properties. However, it is important to note that immediately after dip or spin coating, the silica may be poorly condensed and capable of significant structural changes in response to the environment. Recently, this effect was dramatically demonstrated by Cagnol et al.[6] After coating, the mesophase structure was repeatedly modulated by varying the humidity.

When a film that was deposited at a relative humidity of 40% was exposed to an environment with a relative humidity of 85% 10 min after deposition, a phase change from 2-D hexagonal to cubic was observed. Other relative humidity changes led to a disordered to ordered transition in the film.

Thermal postsynthesis treatments have also been studied over a range of temperatures. These treatments are normally carried out well below the temperature required to remove the template and strive to strengthen the silica network while the template is still in place. In one report, the samples were treated at increasing temperatures, and it was shown that between the temperatures of 150°C and 175°C the order of the mesostructure increased.[24]

Chemical treatments

After drying, the films may be subjected to a variety of chemical postsynthesis treatments to increase the stability of the mesostructure. In one report, the as-deposited film was exposed to tetraethyl orthosilicate (TEOS) vapor in a closed container for 3 hr at 135°C.[22] This treatment, which was first carried out on hexagonal silica thin films templated with CTAB, adds silica to the structure, increases the density of the silica walls, and significantly improves the thermal stability of the films. Template removal of these treated materials yielded films with little to no peak shift in x-ray diffraction patterns and significantly reduced cracking. Ammonia atmospheres have also been reported to base catalyze the condensation of the silica and increase the thermal stability.[25] In the base treatment, the thin film was exposed to a saturated ammonia environment for 45 min. It was reported that upon template removal, the d spacing of the (200) plane shrunk by 15%. However, a prolonged exposure to ammonia creates cracks and delamination on the films. Hydrothermal treatments have also been reported to enhance the stability of the film. Heating in deionized water at 80°C overnight was reported to improve the polymerization of the silica and thermal stability of the film.[17]

Template Removal to Yield Mesoporous Films

Once the film is stable, the surfactant template must be removed to create the mesoporous film from the nonporous mesostructured film. However, upon removal of the template, films may contract and crack, and therefore care must be taken during removal to yield continuous and well-ordered films.

Calcination

Calcination of silica thin films involves heating the film to between 350°C and 500°C in the presence of oxygen to remove the templating surfactant. At these temperatures, the surfactants decompose and react with oxygen to form gaseous organic products (CO_2, H_2O, etc.), which diffuse out of the film. The temperature profile usually consists of a temperature ramp of 1°C/min to the desired calcination temperature, a holding period between 4 and 8 hr, and a decrease back to room temperature at a rate of 1°C/min. The calcination process and its effects on the film structure were studied in detail by Kleitz et al.[26]. They found significantly different decomposition pathways for different surfactants as characterized by in situ x-ray diffraction, thermogravimetric analysis, and mass spectrometry. For example, when a hexagonal film synthesized with the triblock copolymer Pluronic P123 was examined during calcination, one main step for mass loss was found. This loss occurred below 280°C and was accounted for by decomposition of the organic surfactant into smaller fragments with m/z ratios of 42, 58, and 74, which correspond to C_3H_6, C_3H_6O, and $C_3H_6O_2$, respectively. These components were removed over a relatively small range of temperatures, between 150 and 200°C. Between 200°C and 400°C, species were fully oxidized to carbon dioxide and water. Alternately, for a cubic mesostructured film templated by CTAB, between 150 and 250°C, the head group of CTAB surfactant was removed by way of Hofmann degradation in which a β-elimination reaction results in the loss of a β-proton and the cleavage of the trimethylamine head group from the alkyl chain. What is left in the pore is a mixture of different hydrocarbon species, which leave as C_2H_2, C_3H_6, C_4H_7, C_5H_9, CO_2, and water between 250°C and 350°C.

Solvent extraction

Solvent extraction is the process where the as-synthesized thin film containing the template is exposed to heated solvent to remove the template from the pores. The technique can involve maintaining the thin film in the solvent with stirring and heating, either in a closed container or in a reflux apparatus. One report indicates that the surfactant was removed by hot ethanol for 5 hr by soxhlet extraction.[25]

Ozone treatment

Surfactant removal in ozone has been reported in two different forms: one in which ozone was produced by UV treatment under ambient conditions[27] and the other in which ozone was bubbled through a

water solution that contained the bulk (powder) mesostructured silica.[28] In the UV treatment, bulk powder MCM-41 that was templated by CTAB was placed for 24 hr under a UV lamp, which produced wavelengths (254 and 180 nm) known to produce ozone from ambient oxygen. It was theorized that water and carbon dioxide were the major products of the reaction, which were eliminated from the pores by diffusion. Diffuse-reflectance infrared Fourier transform (DRIFT) spectra and nitrogen sorption isotherms were utilized to verify that the template was removed. In the second type of ozone treatment, the surfactant, CTAB, was removed from the powder MCM-41 by bubbling ozone for 30 min through a water solution, which contained the bulk mesostructured sample. This ozone treatment is advantageous when compared with the UV treatment because of the ability to control the amount of ozone that interacts with the surfactant and the amount of time that is required for the removal, 30 min for the bubbling compared with 24 hr for the UV treatment.

CHARACTERIZATION TECHNIQUES

To determine the success of synthesis efforts and to provide feedback on quality control, the mesoporous silica films are characterized by several techniques. The ability to determine the continuity and quality of the films must be quick and accurate. Owing to this fact, x-ray diffraction has proven the easiest way to resolve the film structure. However, phase identification by x-ray diffraction alone is not always conclusive (e.g., when only one peak is observed). Other techniques must be employed to fully determine the phase of the mesostructure.

X-Ray Diffraction (XRD)

X-ray diffraction is the most prevalent characterization technique to determine the phase of a film. Bragg diffraction is the result of the constructive interference of scattered x-rays that are scattered from regularly spaced variations in the electron density. The spacing of these variations is determined via Bragg's law:

$$d_{hkl} = \frac{\lambda}{2\sin\theta}$$

where λ is the wavelength of the incident radiation (typically 1.54 Å, for laboratory x-ray sources using Cu Kα radiation), d_{hkl} the periodic spacing indexed by the ($h\,k\,l$) Miller plane, and θ angle of incidence. Bragg's law is basically a scalar version of the von Laue equations. It encodes a spacing criterion necessary to observe a diffraction peak. However, there is an additional criterion for reflection geometry diffractometers that these variations be perpendicular to the plane of the film. Regular spacings along any other direction will not result in observed diffraction peaks. Details of the XRD pattern interpretation from mesoporous thin films are discussed by Hillhouse et al.[29]. The mesophase may then be identified from the peak positions. For the example of a lamellar phase thin film, where the sheets are parallel to the substrate, the observed peaks will be (1 0 0), (2 0 0), (3 0 0), and so on. These peaks will be equally spaced and diminishing in intensity. This diffraction pattern is also to be expected from an oriented 2-D hexagonal phase (with the 1 0 0 parallel to the substrate). However, upon removal of the template from the mesostructured silica in the lamellar phase, the film loses all structure and no x-ray pattern is expected. The hexagonal phase, on the other hand, will retain the diffraction peaks from (1 0 0) and, depending on the degree of orientation, the (2 0 0) and (3 0 0) peaks. The presence of these peaks after template is typically reported as evidence that a hexagonal structure was obtained, as shown in Fig. 5. However, many cubic phase films may show only one peak in the XRD pattern, and thus 2-D XRD, TEM, or polarized optical microscopy should be used to verify the mesophase structure.

Transmission Electron Microscopy (TEM)

Transmission electron microscopy is utilized regularly to characterize silica thin films. Although TEM is a more labor-intensive characterization technique than x-ray diffraction, it has several key advantages. High resolution transmission electron microscopy images from multiple orientations allow the mesostructure of a film to be determined conclusively. Pore size, wall thickness, orientation relative to the substrate, and long range order of the film can also be quickly determined. As the spacings in the mesostructure are much larger than that for traditional crystals (2–20 nm as compared with only a few Å), microscopes of moderate resolution may be used. Typically, clear images may be obtained on 100 keV microscopes. Sample preparation for TEM can be tedious and difficult. However, for mesophase identification, the film can be simply scraped off the substrate, dispersed in a solvent (ethanol), and coated onto TEM grids. Examples of TEM images can be seen in Figs. 6C–6F. These give clear insight into the structure of the films produced, as seen in Fig. 6D, where the hexagonal packing of the pores in a 2-D hexagonal film is apparent, and in Fig. 6E, where the 90° orientation of the pores with respect to each other elicits a cubic mesostructure.

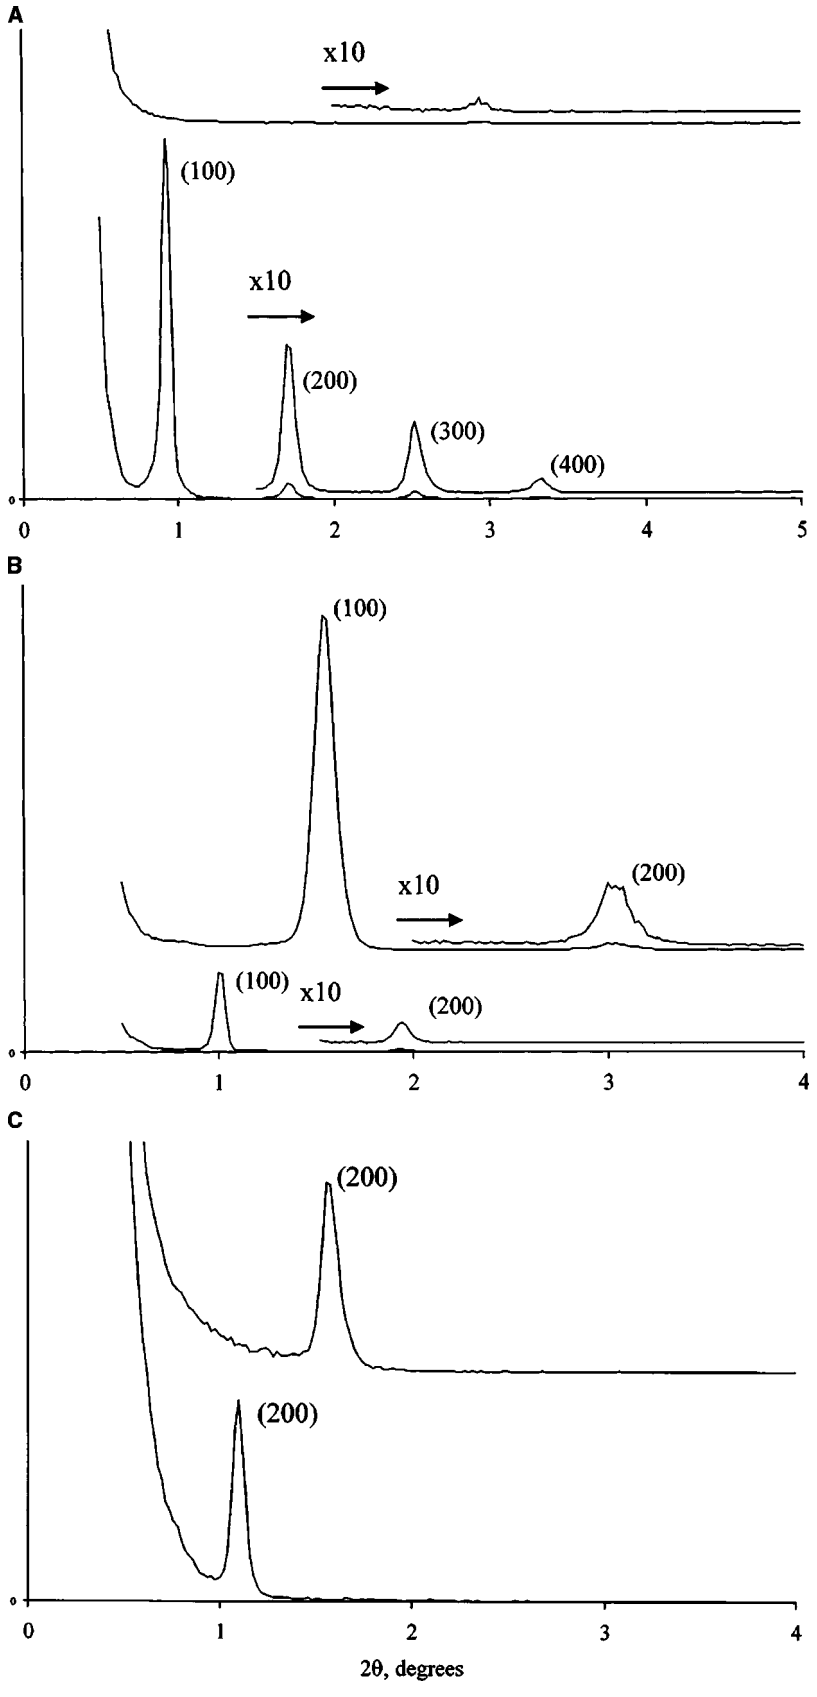

Fig. 5 X-ray diffraction patterns for silica films: (A) lamellar phase, (B) hexagonal, and (C) cubic. For each set of patterns, the bottom is as-synthesized, and the top is calcined. (From Ref.[3].)

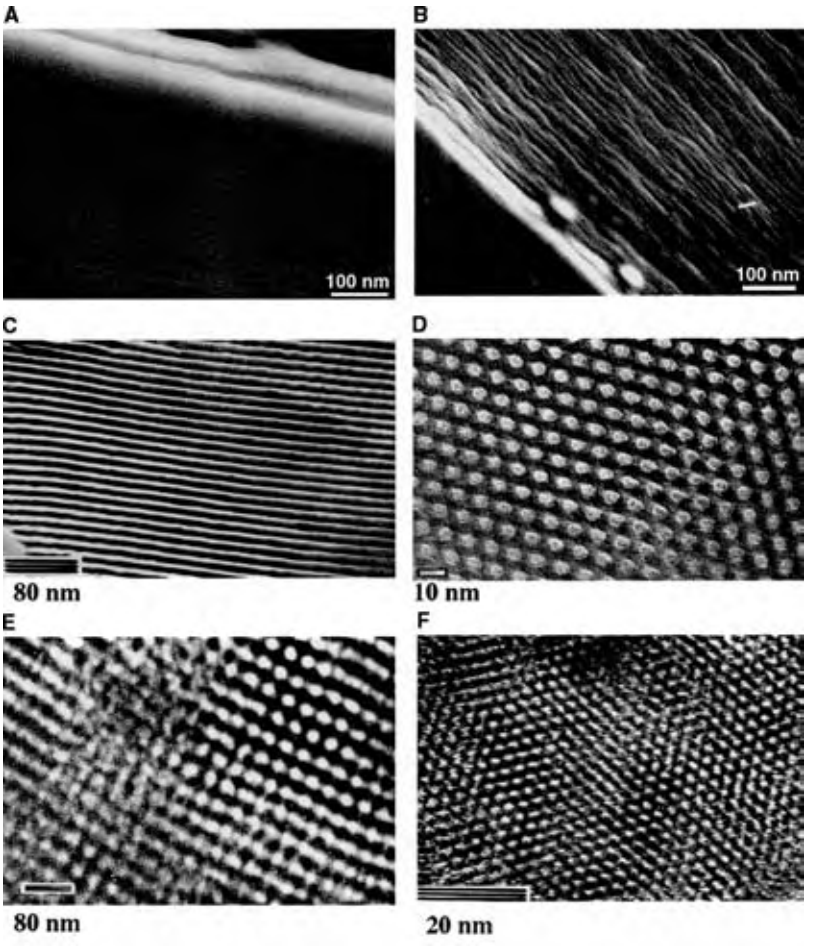

Fig. 6 (A,B) SEM images of an as-deposited and calcined hexagonal silica film, respectively, templated by Pluronic P123. (C) TEM image of the hexagonal film along the (1 1 0) zone axis. (D) TEM image of the hexagonal film along the (1 0 0) zone axis. (E,F) TEM images of a cubic silica film templated by Pluronic F127 along the (E) (1 1 0) zone axis and (F) (1 0 0) zone axis. (From Ref.[17].) *(View this art in color at www.dekker.com.)*

Scanning Electron Microscopy (SEM)

Typically, SEM is used to determine the continuity and the thickness of the film. Large-scale cracks and defects of the film can be determined by top view SEM images, and film thickness is easily obtained from cross-sections. It has been used extensively with powdered samples of mesoporous silica to determine morphology and thus assist in phase determination. However, thin films produced by dip and spin coating typically have a scarcity of features that may be resolved in SEM. This can be seen in Figs. 6A and 6B, SEM images of a mesoporous films templated with P123.

Other Characterization Techniques

There are other techniques that can be used to characterize the thin film. For powdered materials, nitrogen adsorption–desorption isotherms are typically used to determine the pore volume and surface area. However, this technique is rather difficult for films, as the physical amount of sample produced in one synthesis is not enough to perform an analysis. Attenuated total reflectance-infrared spectroscopy (ATR-IR) may be used to determine the chemical bonding characteristics of a thin film. For example, the extent of condensation of silica can be determined by monitoring the characteristic frequency of Si–OH.

CONCLUSIONS

Interest in the synthesis and processing of mesoporous silica materials has grown extensively since their discovery in 1992, and the exciting potential that these films hold in low-k dielectrics, sensors, nanowire fabrication, catalysis, membrane separations, and many other applications will continue to fuel academic and industrial interest in these films. While there are many new synthesis routes for processing mesoporous silica thin films, spin coating and dip coating remain the most facile methods available. These methods deliver high quality reproducible films that can be used for any of the variety of applications.

Metallocene Catalysts for Olefin Polymerization

T. C. Chung
Department of Materials Science and Engineering, The Pennsylvania State University, University Park, Pennsylvania, U.S.A.

INTRODUCTION

Metallocene is a class of organometallic compounds that contains a transition metal sandwiched by one or two cyclopentadienyl ligands. Metallocene catalysts used in α-olefin polymerization are usually prepared by the combination of a metallocene (catalyst) from a group 4 metal (titanium, zirconium, and hafnium) and a cocatalyst to form an active metal cation. This cation contains both M-C species and an empty d-orbital suitable for α-olefin coordination/insertion reaction. The cocatalysts can be divided into two categories, including organoaluminum compounds (alkylaluminums and alkylaluminoxanes) and anionic counterions (borates or fluorinated borates), which form a weak coordination with the cationic active site. One unique feature of metallocene catalysts is the well-defined active site with a tunable ligand structure for manipulating olefin polymerization, and the resulting polymer structures. Although metallocene catalyst are soluble in common hydrocarbon solvents (used in α-olefin polymerization), the commercial catalysts are usually immobilized on supports for controlling polymer morphology and for reducing the requirement of a large excess of cocatalyst.

BACKGROUND INFORMATION

As early as the 1950s, the metallocene/alkylaluminum system was reported for mediating ethylene polymerization.[1–3] However, the polymer obtained was of low molecular weight and had extremely low catalytic activity, compared with those prepared by a heterogenous Ziegler–Natta catalyst system ($TiCl_4/AlEt_3$), discovered a few years earlier. Despite the ill-defined active sites, most of the research activities had focused on Ziegler–Natta catalysts and the resulting polyolefins in the following two decades. This includes polyethylene (PE), polypropylene (PP), poly(4-methyl-1-pentene), ethylene–propylene–elastomer, and ethylene–propylene–diene rubber. The commercial importance of polyolefin products and the furious competition among the major producers together led to technological advancement in developing Ziegler–Natta catalysts with superior activity and stereospecificity, and also to the development of economically viable production processes and products.

On the other hand, the research activity in a homogenous metallocene catalyst system was relatively dormant until the discovery of methylaluminoxane (MAO) cocatalyst by Sinn and Kaminsky in the late 1970s.[4] The combination of metallocene, such as Cp_2ZrCl_2, and MAO produces high-molecular weight PE with unprecedented catalytic activity (10^6 g PE/g Zr.hr.bar) that is much higher than that of the commercially used Ziegler–Natta catalysts. This historic discovery opened up another golden age in polyolefin research with intense competition across the world both in industrial and in academic laboratories.

In 1984, Ewen made the first stereospecific bridged metallocene catalyst (*rac*-ethylidenebis(indenyl)titanium dichloride/MAO) that produced isotactic PP (i-PP).[5] He also discovered *ansa*-ziroconium metallocene ($Me_2C(Cp\text{-}9\text{-}Flu)ZrCl_2$) for the production of highly syndiotactic polypropylene (s-PP) a couple of years later.[6] Around the same time, Kaminsky synthesized highly i-PP using a chiral *ansa*-zirconocene/MAO catalyst.[7] In the late 1980s, Dow discovered constrained geometry metallocene catalysts, which are titanium-based catalysts with monocyclopentadienyl and a donor ligand stabilizing the metal center. The resulting open active site allows the incorporation of higher α-olefins with comparative rates similar to that of ethylene. This brings in the significant advantage of metallocene catalysis to obtain polyolefin copolymers with a broad range of compositions and narrow composition and molecular weight distributions, which cannot be realized by heterogenous Ziegler–Natta catalysts. Since then, worldwide industrial and academic research in metallocene catalysis for olefin polymerization has been rapidly accelerating, and this advanced technology has been brought to commercial use.

METALLOCENE CATALYSTS AND POLYMERIZATION

Metallocene catalysts can be classified into several categories based on ligand symmetrical structures. This includes C_2, C_{2v}, C_s, C_1, oscillating structures, and bridged half-metallocenes. The main features of these

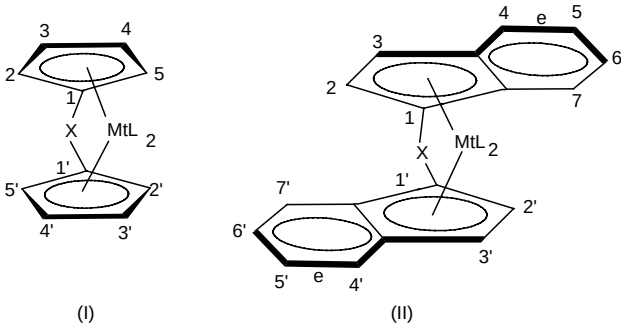

Scheme 1

catalysts and polymerization mechanisms, as well as their applications in olefin polymerization, will be discussed below.

C_2-Symmetric Metallocenes

Chiral C_2-symmetric bridged metallocenes are the most successful highly enantioselective polymerization catalysts. The catalysts produce PPs with microstructures ranging from almost atactic to almost perfectly isotactic, and often contain a small amount of isolated regio-irregularities. The basic structures of these catalysts are shown in Scheme 1.

The bridge (X), such as $-Me_2Si-$, $-Me_2C-$, or $-CH_2-CH_2-$ connecting two cyclopentadienyl rings, prevents their rotation and locks them in a chiral configuration. In type (I), highly enantioselective catalysts can be obtained when preferably bulky substituents are present at position 3,3′ or 4,4′. In type (II), the role of such substituents is played by the phenyl of the 1-indenyl moieties and additional substitution. Particularly, position 4,4′ is highly beneficial. In both cases, ancillary substituents at position 2,2′ result in producing higher molecular weight polymers because of the reduction in β-H elimination of the propagating chain end.[8]

The stereoselectivity of catalysts during the α-olefin polymerization is well understood.[9] Scheme 2 shows the model for an active species representative of type (II), i.e., *rac*-$Me_2C(1\text{-Ind})_2ZrCl_2$. The catalytic complex is pseudotetrahedral and cationic, with an *iso*-butyl group simulating the growing polymer chain and a propylene molecule at the remaining coordination site. The aromatic ligand is in the (*R*,*R*) configuration. The growing polymer chain must adopt a conformation that minimizes the steric interaction with one of the two phenyl rings of the bis-indenyl moiety. The first C–C bond has to be bent to one side. This favors the 1,2-insertion of propylene with the enantioface that brings the methyl substituent *anti* to that C–C bond [*re*-face for the (*R*,*R*)-catalytic complex]. As a result, 2,1-insertion is always difficult owing to direct steric interactions of the CH_3 group with the aromatic rings. At the completion of each insertion step, the growing chain will always reside at the coordination site previously occupied by the monomer (chain-migratory insertion mechanism). However, this orderly coordination/insertion process may not always be the case, depending on the reaction condition (catalyst, temperature, etc.). There are some stereoerrors generated during the chain propagation. Generally, the C_2 symmetry ensures the equivalence of the two active sites; chain propagation is expected to be predominantly isotactic and site-controlled with occasional $\cdots$mmmmrrmmmm$\cdots$ stereodefects.

Table 1 shows the data of liquid propylene polymerization in the presence of some representative C_2-symmetric metallocene catalysts.[9] The flexibility of the bridge between two indenyl rings plays an important role in the microstructure and properties of the resulting polymer. Stereoselectivity and molecular weight increase in the order $Me_2C < Et < Me_2Si$. The introduction of an alkyl substituent of the 2 position in the *ansa*-bisindenyl zirconium complexes increases both the stereoregularity and the molecular weight of the produced PP. Combining substitutions in the 2- and 4- positions leads to some of the most successful isospecific zirconocene catalysts, which provide incredible catalyst activity, isotacticity, and molecular weight. These catalysts have also been successfully supported on a carrier, retaining their high activity at much lower Al/Zr ratios, and have met the requirements for industrial scale production of i-PP. In general, increasing temperature to a certain extent results in the decrease of stereoselectivity and molecular weight of the products, especially using *ansa*-metallocenes that contain flexible ethylene or silane bridge.

In general, C_2-symmetric metallocenes are not exceedingly regioselective in propylene polymerization.
